2026 Genetic Testing Policies

MVP Health Care® Policy and Procedure Guidelines

Policies effective January 1, 2026

Table of Contents

1. Chromosomal Microarray and Low-pass Whole Genome Sequencing
2. Esophageal Pathology Testing
3. Fibromyalgia Testing
4. Gene Expression Profiling and Protein Biomarkers for Prostate Cancer
5. General Genetic Testing, Germline Disorders
6. General Genetic Testing, Somatic Disorders
7. Genetic Markers for Assessing Risk of Cardiovascular Disease
8. Genetic Testing and Genetic Expression Profiling in Patients with Uveal
9. Genetic Testing For Alpha- and Beta- Thalassemia
10. Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate Cancers
11. Genetic Testing for CHARGE Syndrome
12. Genetic Testing for Connective Tissue Disorders
13. Genetic Testing for Cystic Fibrosis
14. Genetic Testing for Diagnosis of Inherited Peripheral Neuropathies
15. Genetic Testing for Duchenne, Becker, Facioscapulohumeral, and Limb-Girdle Muscular Dystrophies
16. Genetic Testing for Epilepsy
17. Genetic Testing for Familial Alzheimer Disease
18. Genetic Testing for Familial Hypercholesterolemia
19. Genetic Testing for Fanconi Anemia
20. Genetic Testing for FMR1 Mutations
21. Genetic Testing for Germline Mutations of the RET Proto-Oncogene
22. Genetic Testing for Hereditary Hearing Loss
23. Genetic Testing for Hereditary Hemochromatosis
24. Genetic Testing for Hereditary Pancreatitis
25. Genetic Testing for Inherited Cardiomyopathies and Channelopathies
26. Genetic Testing for Lactase Insufficiency
27. Genetic Testing for Li-Fraumeni Syndrome
28. Genetic Testing for Lipoprotein(a) Variant(s) as a Decision Aid for Aspirin Treatment and/or CVD Risk Assessment
29. Genetic Testing for Neurodegenerative Disorders
30. Genetic Testing for Neurofibromatosis and Related Disorders
31. Genetic Testing for Ophthalmologic Conditions
32. Genetic Testing for Polyposis Syndromes
33. Genetic Testing for PTEN Hamartoma Tumor Syndrome
34. Genetic Testing for Rett Syndrome
35. Genetic Testing of CADASIL Syndrome
36. Genetic Testing of Mitochondrial Disorders
37. Genomic Testing for Hematopoietic Neoplasms
38. Liquid Biopsy
39. Lynch Syndrome
40. Microsatellite Instability and Tumor Mutational Burden Testing
41. Minimal Residual Disease (MRD)

42. Molecular Analysis for Gliomas
43. Molecular Diagnostics for Breast Cancer Prognosis
44. Molecular Markers in Fine Needle Aspirates of the Thyroid
45. Molecular Profiling for Cancers of Unknown Primary Origin
46. Molecular Testing for Cutaneous Melanoma
47. Molecular Testing of Pulmonary Specimens
48. Mutation Analysis in Myeloproliferative Neoplasms
49. Pancreatic Cancer Risk Testing Using Pancreatic Cyst Fluid
50. Pharmacogenetic Testing
51. Precision Genetic Test Management Reimbursement Policy
52. Pre-Implantation Genetic Testing
53. Prenatal Screening (Genetic)
54. Prenatal Screening for Fetal Aneuploidy
55. Proteogenomic Testing of Individuals with Cancer
56. Red Blood Cell Molecular Testing
57. Testing for Alpha-1 Antitrypsin Deficiency
58. Testing for Colorectal Cancer Management
59. Testing for Targeted Therapy of Non-Small-Cell Lung Cancer
60. Testing of Homocysteine Metabolism-Related Conditions
61. Transplant Rejection Testing
62. Use of Common Genetic Variants (single nucleotide polymorphisms) to Predict Risk of Non-Familial Breast Cancer
63. Venous and Arterial Thrombosis Risk Testing
64. Whole Genome and Whole Exome Sequencing

Chromosomal Microarray and Low-pass Whole Genome Sequencing

Policy Number: AHS – M2033 – Chromosomal Microarray and Low-pass Whole Genome Sequencing	Prior Policy Name and Number, as applicable: AHS – M2033 – Chromosomal Microarray
Initial Policy Effective Date: 01/01/2026

I. Policy Description

Chromosomal microarray (CMA) testing refers to the use of comparative genomic hybridization (CGH) arrays to detect small (10 to 100kb) duplications or deletions of chromosomal DNA (copy number variants or CNVs), similarity in single nucleotide sequences (homozygosity), and triploidy when chromosomal abnormality is suspected based on clinical presentation (Schrijver & Zehnder, 2024). Genetic counseling is strongly recommended for individuals being considered for chromosomal microarray testing. Low-pass whole genome sequencing (low-pass WGS) is a method of WGS that is less expensive and has lower coverage than standard WGS. Low-pass WGS maintains a high accuracy for detecting single nucleotide sequences by using imputation algorithms (Gencove, 2023).

For guidance on whole exome sequencing, please see AHS-M2032-Whole Genome and Whole Exome Sequencing.

II. Related Policies

Policy Number	Policy Title
AHS-G2055	Prenatal Screening for Fetal Aneuploidy
AHS-M2032	Whole Genome and Whole Exome Sequencing
AHS-M2075	Genetic Testing for Epilepsy
AHS-M2176	Testing for Autism Spectrum Disorder and Developmental Delay
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) To evaluate any second-trimester or later pregnancy loss **or** the second consecutive first-trimester pregnancy loss, chromosomal microarray (CMA) testing **or** low-pass whole genome sequencing (low-pass WGS) of the products of conception (e.g., fetal tissue and/or the fetus) **MEETS COVERAGE CRITERIA**.

2) Prenatal CMA testing **or** low-pass WGS **MEETS COVERAGE CRITERIA** when **any** of the following conditions are met:
   a) When diagnostic testing for fetal aneuploidy is needed for pregnant individuals undergoing invasive prenatal testing (i.e., amniocentesis, chorionic villus sampling, or fetal tissue sampling).
   b) When non- invasive prenatal screening (NIPS) results require confirmation.
   c) As a follow-up test for any smaller copy-number changes that were reported as positive by NIPS.
   d) When ultrasound examination reveals one or more structural abnormalities.
   e) When, regardless of gestational age, fetal growth restriction is detected and a fetal malformation or polyhydramnios (or both) are also present.
   f) When unexplained isolated fetal growth restriction is diagnosed at <32 weeks of gestation.
   g) When there is intrauterine fetal demise or stillbirth in the third trimester and CMA is indicated to determine the potential cause.
   h) When the fetus is at high risk for a chromosome abnormality detectable by CMA, based on family history.

3) Evaluation with CMA testing **or** low-pass WGS **MEETS COVERAGE CRITERIA** for **any** of the following situations:

a) For individuals with multiple congenital anomalies that are not specific to a well-delineated genetic condition and cannot be identified based on clinical evaluation alone.

b) For individuals with non-syndromic developmental delay/intellectual delay.

c) For individuals with autism spectrum disorder.

d) For individuals with a suspected inherited seizure disorder.

e) When sex determination by NIPS is discordant with physical examination or clinical findings are suggestive of a disorder of sexual differentiation.

f) For individuals with proportionate short stature with other physical or structure defects.

4) When performed in parallel with fetal diagnostic testing, maternal cell contamination (MCC) analysis **MEETS COVERAGE CRITERIA**.

5) For central nervous system (CNS) tumors and pediatric solid and soft tissue tumors, CMA testing **MEETS COVERAGE CRITERIA.**

6) When a chromosomal trisomy is suspected, postnatal CMA testing **DOES NOT MEET COVERAGE CRITERIA**.

7) Co-testing CMA and low-pass WGS **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

8) For all other situations not described above, CMA testing **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table Of Terminology

Term	Definition
AAN	American Academy of Neurology
AAP	American Academy of Paediatrics
ACMG	American College of Medical Genetics and Genomics
ACOG	American College of Obstetricians and Gynaecologists
AMP	Association For Molecular Pathology
ASD	Autism Spectrum Disorder
ASRM	American Society for Reproductive Medicine

CCMG	Canadian College of Medical Geneticists
CGH	Comparative genomic hybridization
CLIA	Clinical Laboratory Improvement Amendments
CM	Chromosomal mosaicism
CMA	Chromosomal microarray analysis
CMS	Centers for Medicare and Medicaid
cnLOH	Copy-neutral loss of heterozygosity
CNS	Central nervous system
CNVs	Copy number variants
CSCA	Chromosomal abnormalities
CVS	Chorionic villi sampling
DD	Developmental delay
DD/ID	Developmental disability/Intellectual disability
ES	Endocrine Society
FGR	Fetal growth restriction
GDD/ID	Global developmental delay
ID	Intellectual disability
ISCA	International standard cytogenetic array
ISPD	International Society for Prenatal Diagnosis
ISS	Idiopathic short stature
IUGR	Intrauterine growth restriction
LDTs	Laboratory developed Tests
LOH	Loss/Absence of Heterozygosity
LP-GS	Low-pass genome sequencing
MCC	Maternal cell contamination
NIHF	Non-immune hydrops fetalis
NIPS	Non- invasive prenatal screening
POC	Products of conception
PQF	Perinatal Quality Foundation
QF-PCR	Quantitative fluorescent polymerase chain reaction
RAD	Restriction-site associated DNA sequencing
SMFM	Society for Maternal-Fetal Medicine
SNP	Single nucleotide polymorphism
SOGC	Society of Obstetricians and Gynaecologists of Canada
STR	Short tandem repeat
UPD	Uniparental isodisomy
VOUS/VUS	Variant of unknown significance
VPS	Variant of possible significance

WES	Whole exome sequencing
WGS	Whole genome sequencing

V. Scientific Background

Chromosomal abnormalities are associated with a variety of disorders including developmental delay (DD), intellectual disability (ID), and congenital anomalies (Miller et al., 2010), as well as pregnancy loss (Reddy, Page, Saade, et al., 2012).

Chromosomal microarray (CMA) testing to detect copy number variations (CNVs), homozygosity, and triploidy has replaced karyotyping as the first-tier diagnostic tool for many cases where chromosomal abnormality is suspected (Miller et al., 2010; Pivalizza & Lalani, 2024; Schrijver & Zehnder, 2024). CMA is significantly more sensitive (10 to 100 kb) than traditional karyotyping (5 to 10 Mb); additionally, CMA does not require cell culture, which reduces the turnaround time for results (Miller, 2022), and provides an alternative to karyotyping when dividing cells are not available for analysis. This technique may be used for several different purposes, such as identifying a cause of pregnancy loss or identifying other aneuploid conditions, such as Down Syndrome (ACOG, 2016; Reddy, Page, & Saade, 2012). **"**Emerging studies suggest that low-pass genome sequencing (GS) provides additional diagnostic yield of clinically significant copy-number variants (CNVs) compared with chromosomal microarray analysis (CMA). However, a prospective back-to-back comparison evaluating accuracy, efficacy, and incremental yield of low-pass GS compared with CMA is warranted" (Wang et al., 2020).

Chromosomal microarray (CMA) uses comparative genomic hybridization (CGH) to compare the DNA of a patient with a normal control using standard sets of DNA probes immobilized on a glass slide or glass beads (Aradhya & Cherry, 2007). CGH arrays have been designed to cover the entire genome, for targeted analysis of known microdeletion/microduplication syndromes, and for known loci of inherited mutations (Schrijver & Zehnder, 2024). Array sensitivity varies based on the size and type of probes used. Oligonucleotide probes (~60 base pairs) or single nucleotide polymorphism (SNP) probes (32-40 base pairs) are most common. Oligonucleotide probes can be used to cover the entire genome at an average resolution of about 35 kb. Current arrays generally use a combination of copy number probes (oligonucleotide) to detect copy gains and losses and single nucleotide polymorphism (SNP) probes to detect similarity in single nucleotide sequences (homozygosity). The combination of probes detect runs of homozygosity between the maternal and paternal copy of each chromosome, enabling diagnosis of triploidy, uniparental disomy, and consanguinity as well as improving the detection of low levels of mosaicism (Miller, 2022).

Chromosomal microarray (CMA), as all genetic tests, can have variable clinical sensitivity due to the numerous types of genetic abnormalities that can impact gene expression. Some genetic conditions are caused by a change in copy number and/or a sequence change in the gene that is undetectable by CMA. If a genetic condition in which a subset of cases are caused by sequence changes, then other testing should be considered either in place of, or in addition to, CMA (Miller, 2022).

Low-pass WGS is a less expensive but lower coverage method of standard WGS. Low-pass WGS typically has less than 1x coverage, while standard WGS has a depth of 30x to 50x (Illumina, 2024). Alternatively, compared to traditional low-cost microarrays, low-pass WGS results have over ten times the amount of information. Low-pass WGS maintains accuracy with reduced coverage by using imputation algorithms, a statistical analysis method that assigns values to missing data based on known information. With imputation algorithms, the low-pass WGS method uses known genetic variants within a representative population to genotype an individual without measurements from every locus (Gencove, 2023).

CMA and Seizures

A seizure occurs due to erroneous electrical activity in the brain and may strike for many reasons including a brain injury or infection, abnormal sodium or glucose levels in the blood, congenital brain defects, epilepsy, and electric shock.

Epilepsy is a neurological disorder associated with abnormal electrical brain activity. CMA is often the first genetic tool used to obtain more information about a patient's epilepsy (Poduri et al., 2014) and has a diagnostic yield of approximately 8% with several studies reporting higher values (Dubbs, 2022). Testing a specific gene may be appropriate in some epileptic cases as more than 80 genes have been associated with epilepsy and hundreds more associated with disorders that are accompanied by seizures (Dubbs, 2022). However, if results are negative, CMA or gene testing should commence as this is likely more appropriate than testing several more genes individually (Mefford, 2015). If CMA testing is negative, gene panel and exome testing are appropriate.

Olson et al. (2014) have found that in many patients, CNVs identified through CMA were able to explain an epileptic phenotype. The authors concluded that "Because the diagnostic yield of CMA for epilepsy patients is similar to the yield in autism spectrum disorders and in prenatal diagnosis, for which published guidelines recommend testing with CMA, we recommend the implementation of CMA in the evaluation of unexplained epilepsy" (Olson et al., 2014).

CMA and Short Stature

Short stature is a general term used to describe individuals whose height is two standard deviations or more below the mean compared to peers of the same age and racial-ethnic group (Richmond & Rogol, 2024). The most common causes of short stature are genetic and delayed growth; these are considered normal or nonpathologic variants of growth (Richmond & Rogol, 2024).

Intrauterine growth restriction (IUGR) is a condition which describes when an unborn baby is growing abnormally slow in the womb; this could be due to either genetic or environmental factors and may cause significant morbidity and mortality in infants (Mandy, 2024). CMA has been used for diagnostic purposes in fetuses due to IUGR (Daum et al., 2019).

Idiopathic short stature (ISS) describes individuals whose height falls below two standard deviations of the mean for age, but no metabolic, endocrine, or other diagnosis has been identified to cause the height disorder (Richmond & Rogol, 2024). Regarding the genetic evaluation of short stature, some researchers suggest that for patients with ISS, patients born small for gestational age, or patients with growth hormone deficiency, "Targeted evaluation of a single gene or panels of genes is recommended... For those patients who do not fit into a distinct subgroup or for whom initial genetic testing is inconclusive, we recommend consideration of genome-wide evaluation through exome sequencing and chromosomal microarray to detect both sequence variants and CNVs" (Dauber et al., 2014). A significant association has been identified between CNVs and short stature (Yu et al., 2015), and many report that CMA is a promising tool to identify pathogenic CNVs in patients with ISS (Richmond & Rogol, 2024).

Proprietary Testing

The only FDA-approved commercial CMA test is CytoScan® by Affymetrix. This test helps identify the underlying genetic causes of developmental delay, intellectual disability, congenital anomalies, or dysmorphic features in children. CytoScan® detects chromosomal copy number variants (CNV) in genomic DNA from peripheral whole blood (Affymetrix, 2013).

Several other commercial CMA tests are available including the GenomeDx CMA by GeneDx. The GenomeDx is able to confirm clinical diagnoses, differentiate between de novo and familial cases, and assist with prenatal diagnoses in at-risk pregnancies (GeneDx, 2024). This test has a three-week turnaround time and may utilize both blood (preferred) and buccal swabs (cheek swabs) as the tested specimen. The GenomeDx is a whole-genome CMA, containing 118,000 oligonucleotide probes that detect CNVs (GeneDx, 2024).

Quest Diagnostics has developed the ClariSure® Postnatal CMA Test; the ClariSure® consists of over 2.6 million probes that detect 1,900,000 CNVs and 750,000 SNPs (Quest, 2024). With a 10- to 15-day turnaround time, this test can help to determine the genetic cause of developmental delay or mental retardation. Blood is the preferred specimen for this test, but saliva may also be used.

LabCorp has developed Reveal®, an SNP microarray aimed for pediatric purposes. This test uses a blood or salivary sample to detect chromosomal abnormalities that may be associated with congenital anomalies or developmental delay (LabCorp, 2023). Results are provided in 14-17 days.

The FirstStep^{DX} PLUS®, developed by Lineagen (2024), is a CMA test that uses a buccal sample to identify developmental disabilities. Lineagen claims that cheek swabs are a more effective way to ensure accurate CMA results than blood-based samples, and that "mosaicism is better diagnosed through DNA collected by cheek swab than by blood draw" (Lineagen, 2024).

Invitae released a Pregnancy Loss Chromosomal Microarray Analysis test which analyzes products of conception tissue to determine whether a chromosomal abnormality caused a miscarriage, intrauterine fetal demise, or a stillbirth. The average turnaround time is 10-12 days. This test can detect whole and segmental aneuploidies, submicroscopic gains and losses that cannot be detected using karyotype, size and gene content of copy number variations, regions of homozygosity, uniparental isodisomy, and triploidy and complete molar pregnancies (Invitae, 2024).

CentoArrayCyto® is a CMA test released by Centogene which detects known structural aberrations such as CNVs, chromosomal imbalances, regions exhibiting loss/absence of heterozygosity (LOH), uniparental isodisomy (UPD), and mosaicism. The test has a turnaround time of 15 days. CentoArrayCyto® can be used as a first-step analysis for detection of intellectual disability and multiple malformation, in conjunction with whole exome sequencing to complement large CNVs, for deletion/duplication analysis of extremely large genes, and for prenatal testing to help determine a cause of ultrasound-detected abnormalities (CentoGene, 2024).

Analytical Validity

Although chromosomal microarray testing can vary widely in technology, resolution, and the likelihood of producing results of unknown significance, studies have demonstrated that CMA provides chromosomal evaluation at a much higher resolution than karyotyping (Miller et al., 2010; Schrijver & Zehnder, 2024). Miller et al. (2010) noted that most clinical CMA platforms available in 2010 could detect copy number changes at a resolution of 400 kb; this was considered at least a "10-fold"

improvement over G-banded karyotyping.

In a retrospective study, Zhu et al. (2021) compared the utility of non-invasive prenatal screening (NIPS) with chromosomal microarray analysis (CMA) for the detection of chromosomal abnormalities in high-risk pregnancies. Of the 774 high risk pregnancies, 550 (71.1%) had a positive NIPS result, while 308 (39.8%) had a positive CMA result. The rate of full or partial concordance was 82.2% between NIPS and CMA. CNV's were more often detected by CMA, with an incidence of 7.9% by CMA and 3.1% by NIPS. In addition, a genetic aberration was detected by CMA in 1 in 17 high risk pregnancies that had a negative NIPS result. Overall, the authors conclude that "CMA should be offered instead of expanded NIPS for high-risk pregnancies" (Zhu et al., 2021).

Chaubey et al. (2020) compared the diagnostic utility of low-pass genome sequencing (LP-GS) to chromosomal microarrays (CMAs) in its ability to detect copy number variants (CNVs). 409 DNA samples were studied for CNV accuracy, precision, specificity, and sensitivity using both techniques. The LP-GS test accurately detected 40 positive control samples with clinically relevant CNVs, absence of heterozygosity, deletions and duplications, and translocations and accurately reported 38 control samples without any clinically significant CNVs. In addition, 331 clinical specimens were tested for developmental delay, autism, intellectual disability, congenital anomalies, and dysmorphic features. Of the 331 cases, pathogenic CNVs were detected in 57 cases relating to microdeletion/microduplication syndromes, intragenic deletions and intragenic duplications, uniparental isodisomy, triploidy, and whole chromosome aneuploidies. The other cases were classified as variants of unknown significance or did not have a reportable CNV finding. The authors conclude that "LP-GS was able to reliably detect absence of heterozygosity, microdeletion/microduplication syndromes, and intragenic CNVs with higher coverage and resolution over the genome" (Chaubey et al., 2020). The authors suggest that this study could be used by professional societies to recommend replacing CMAs with LP-GS.

Mazzonetto et al. (2024) preformed a study evaluating the performance of low-pass whole genome sequencing (LP-WGS) to detect copy number variants (CNVs) in clinical cytogenetics. The DNA samples selected for this study were obtained from 44 unrelated individuals previously referred to molecular investigation in clinical cytogenetics. The patients were investigated by CMA (either array-CGH or SNP-array), currently considered the gold standard diagnostic test for CNV analysis DNA panel, with 12 prenatal and 32 postnatal samples, comprising a total of 55 genomic imbalances. The CNVs were chosen to represent a wide range of clinically relevant CNVs detected by CMA in diagnostic routine, being the vast majority of them associated with intellectual disability or recognizable syndromes. The selected CNVs contained at least one coding sequence. They were mapped to a variety of

chromosomes ranging in copy number state from zero to 3/4, and ranging in genomic size from 75 kb to 90.3 Mb, including aneuploidies and two mosaic cases. Particularly, for methodology evaluation and quality control metrics, we used DNA extracted from several types of biological samples. The data shows "the potential use of LP-WGS to detect CNVs in clinical diagnosis and confirm the method as an alternative for chromosome imbalances detection" (Mazzonetto et al., 2024).

Clinical Utility and Validity

A review of 33 studies, comparing traditional karyotyping to CMA, has shown that CMA increases the detection rate for chromosomal abnormalities in individuals with DD/ID (developmental disability/intellectual disability) or autism spectrum disorder (ASD). CMA detected pathogenic genomic imbalances with an average diagnostic yield of 12.2% across all studies in this patient population, which is about 10% more than karyotyping alone (Miller et al., 2010).

Hillman et al. (2013) performed both a meta-analysis and cohort study evaluating CMA's detection rate of chromosomal abnormalities. The authors investigated 243 pregnant individuals who had both a CMA and karyotype performed, and the meta-analysis included 25 primary studies. Overall, CMA was found to detect 4.1% more abnormalities compared to karyotyping in the cohort study and 10% more in the meta-analysis (Hillman et al., 2013).

Reddy, Page, Saade, et al. (2012) compared the detection rates of microarray and traditional karyotyping. A total of 532 stillbirths were examined. The authors found that microarrays provided more results than karyotyping (87.4% compared to 70.5%) and identified more genetic abnormalities (8.3% vs 5.8%). Microarray analysis also found more genetic abnormalities among 443 antepartum stillbirths (8.8% vs 6.5%) and among 67 stillbirths with congenital abnormalities (29.9% vs 19.4%). Overall, microarray analysis provided a relative increase in the diagnosis of genetic abnormalities of 41.9% in all stillbirths, 34.5% in antepartum stillbirths, and 53.8% in stillbirths with anomalies compared to karyotyping (Reddy, Page, Saade, et al., 2012).

Coulter et al. (2011) assessed impact of CMA results on clinical decision making. A total of 1792 patients were examined, and 235 of them had either an "abnormal" result (n = 131) or a "variant of possible significance" (VPS) (n = 104). Clinical action was recommended for 54% of the patients in the "abnormal" cohort and 34% of the patients in the VPS cohort (Coulter et al., 2011).

Brady et al. (2013) performed a prospective study of fetuses with abnormalities detected on ultrasound. A total of 383 prenatal samples were examined. Causal imbalances were found in 37 samples, submicroscopic CNVs were found in 10 of the

37 samples, and arrays added "valuable information" over conventional karyotyping in 15 of 37 samples. The authors concluded that there was added value of chromosomal microarrays for prenatal diagnosis in the presence of ultrasound anomalies (Brady et al., 2013).

Borrell et al. (2017) performed a meta-analysis of literature to estimate the incremental yield of CMA over karyotyping in fetal growth restriction (FGR). The authors identified 10 studies and found a 4% incremental yield of CMA over karyotyping in "nonmalformed growth-restricted fetuses" and a 10% incremental yield in FGR when associated with fetal malformations (Borrell et al., 2017).

Robson et al. (2017) compared karyotyping and CMA in fetuses with ultrasound anomalies. Out of 629 cases with structural anomalies, CMA detected copy number variants (CNVs) and more pathogenic CNVs than karyotyping. CMA was also found to have a turnaround time of five days quicker than karyotyping. Finally, CMA was found to be £113 more expensive per patient than karyotyping. The authors conclude, "CMA is a robust, acceptable and probably cost-effective method to detect more clinically significant chromosomal imbalances in the anomalous fetus. The results suggest that CMA should replace karyotyping in these care pathways" (Robson et al., 2017).

Li et al. (2018) performed a study investigating the cost effectiveness of karyotyping, CMA, and NGS in genetic diagnosis of unexplained global developmental delay. The authors found that: "CMA testing results in more genetic diagnoses at an incremental cost of US $2692 per additional diagnosis compared with karyotyping, which has an average cost per diagnosis of US $11,033" (Li et al., 2018). The authors also found that performing both tests sequentially result in the same number of diagnoses but costs less when CMA testing is done first and karyotyping second. The authors also analyzed the cost-effectiveness of a variant of unknown significance. When CMA testing yields a variant of unknown significance, additional genetic diagnoses can be obtained "at an incremental cost of US $4220 by CMA testing of both parents, and when parents are not available or the patient had a normal CMA result, targeted NGS of the patient can add diagnoses at a further incremental cost of US $12,295." The authors concluded that "These results provide a cost effectiveness rationale for the use of CMA as the first-tier test for the genetic diagnosis of unexplained GDD/ID [global developmental delay/intellectual disability] and further indicate that testing of both parents may be cost effective when a variant of unknown significance is detected in the patient" (Li et al., 2018).

Hydrops fetalis occurs when fluid accumulates in fetal serous cavities and soft tissues; nonimmune hydrops fetalis (NIHF) develops when red cell alloimmunization does not cause the hydrops fetalis case in question. A retrospective study of all prenatally

diagnosed NIHF cases identified at the University of California, San Francisco from 2008 to 2018 was performed. A total of 131 cases were identified. The researchers found that "In 43/44 cases with a CMA performed, results were categorized as normal or likely benign. One case was found on CMA to have a large pathogenic duplication" (Mardy et al., 2020). This shows that CMA is not an effective diagnostic tool for NIHF.

Another study aimed to assess the diagnostic capabilities of CMA among pregnancies terminated due to fetal malformations identified with ultrasounds. CMA was performed on 71 pregnancies using fetal DNA or placental DNA. The authors noted that "Findings were abnormal in 17 cases (23.9%), of which 13 were detectable by karyotype. The incremental yield of CMA was 4/71 (5.6%); 1/32 (3.1%) for cases with an isolated anomaly and 3/39 (7.7%) for cases with nonisolated anomalies" (Pasternak et al., 2020). CMA identified more chromosomal abnormalities than karyotype and did not require dividing cells, making it a more practical option after termination.

Rodriguez-Revenga et al. (2020) studied the diagnostic yield of CMA in prenatal diagnosis. 2905 prenatal samples with a normal rapid aneuploidy detection test were referred for CMA testing. The study revealed pathogenic CNVs associated with syndromic disorders in 4.8% of the 2905 cases, adding a 2.8% diagnostic value of CMA over karyotyping. This study shows that "CMA increases 2-fold the diagnostic yield achieved by conventional karyotyping." Therefore, "chromosome microarray analysis should be offered to all invasive prenatal diagnostic testing following a normal rapid aneuploidy test result" (Rodriguez-Revenga et al., 2020).

Bajaj Lall et al. (2021) evaluated the diagnostic yield and clinical utility of CMA by comparing it to karyotyping results. CMA and karyotyping were performed on consecutive referrals of 370 prenatal samples of amniotic fluid (n = 274) and chorionic villi (n = 96) from Indian pregnant individuals with high maternal age (n = 23), biochemical screen positive (n = 61), previous child abnormal (n = 59), abnormal fetal ultrasound (n = 205) and heterozygous parents (n = 22). The overall diagnostic yield of abnormal results was higher via CMA than by karyotyping (9.18% vs. 5.40%, respectively). As such, the authors argue that "CMA must be used as the first tier test in all cases with abnormal fetal ultrasound and if cost is not an issue, it can be offered to all pregnant [individuals] undergoing the invasive test, as the test results are faster and the diagnostic yield is higher by CMA than by karyotyping even in other groups" (Bajaj Lall et al., 2021).

In cases of isolated fetal growth restriction, the clinical utility of chromosomal microarray analysis has yet to be evaluated fully, leading Monier et al. (2021) to evaluate the use of chromosomal microarray analysis as compared to karyotyping in these situations. Both karyotyping and chromosomal microarray analysis were

performed in 146 fetuses, and the researchers found that the detection rate of genetic abnormalities by CMA was 7.5%, with an incremental yield of 3.6% as compared to karyotyping. Moreover, CMA was able to identify a variant of unknown significance in three fetuses boasting normal karyotypes. Consequently, the level of granularity of CMA in "these results support the use of chromosomal microarray analysis in addition to karyotype for isolated fetal growth restriction" (Monier et al., 2021).

Zhang et al. (2021) investigated the incidence and clinical significance of chromosomal mosaicism (CM) in a single-center retrospective study of invasive prenatal diagnosis of CM. From a sample of 5758 G-band karyotyping results and 6066 CMA results, the authors deduced that their findings "demonstrate that increased risk in genetic counselling is due to discordant CM from different specimens or testing methods" and so "It is highly recommended to use more comprehensive assays such as a combination of CMA, FISH [fluorescence in situ hybridization analysis] and karyotyping to detect mosaicism in AF [amniotic fluid] and CB [cord blood] before any irreversible decision is made in regard to the pregnancy (Zhang et al., 2021).

Chau et al. (2020) conducted a retrospective back-to-back comparison study of "low-pass GS versus routine CMA for 532 prenatal, miscarriage, and postnatal cases, the overall diagnostic yield was 22.4% (119/532) for CMA and 23.1% (123/532) for low-pass GS. Thus, the overall relative improvement of the diagnostic yield by low-pass GS versus CMA was ~ 3.4% (4/119). Identification of cryptic and clinically significant CNVs among prenatal, miscarriage, and postnatal cases demonstrated that CNV detection at higher resolutions is warranted for clinical diagnosis regardless of referral indications. Overall, [the] study supports low-pass GS as the first-tier genetic test for molecular cytogenetic testing" (Chau et al., 2020).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG)

In the Clinical Practice Resource for Array-based technology and recommendations for utilization in medical genetics practice for detection of chromosomal abnormalities, the ACMG recommends CMA testing "as a first-line test in the initial postnatal evaluation of individuals with the following (Manning & Hudgins, 2010):

A. "Multiple anomalies not specific to a well-delineated genetic syndrome."
B. "Apparently nonsyndromic DD/ID."
C. "Autism spectrum disorders."

The ACMG also recommends "further determination of the use of CMA testing for the evaluation of the child with growth retardation, speech delay, and other less well-

studied indications…, particularly by prospective studies and after- market analysis." Additionally, ACMG recommends "appropriate follow-up … in cases of chromosome imbalance identified by CMA, to include cytogenetic/FISH studies of the patient, parental evaluation, and clinical genetic evaluation and counseling"(Manning & Hudgins, 2010). These statements were reaffirmed in 2020 by the ACMG Board of Directors.

An update from ACMG states that a stepwise or tiered approach to the clinical genetic diagnostic evaluation of autism spectrum disorder is recommended, with the recommendation being for first tier to include fragile X syndrome and chromosomal microarray analysis (CMA).

In 2016 the ACMG published guidelines on the use of noninvasive prenatal screening for the diagnosis of fetal aneuploidy which recommends (Gregg et al., 2016):

- "Informing all pregnant [individuals] that NIPS is the most sensitive screening option for traditionally screened aneuploidies (i.e., Patau, Edwards, and Down syndromes)."
- "Allowing patients to select diagnostic or screening approaches for the detection of fetal aneuploidy and/or genomic changes that are consistent with their personal goals and preferences."
- "Offering diagnostic testing (CVS or amniocentesis) with CMA when NIPS identifies a CNV"
- "Offering diagnostic testing with CMA when a no-call result is obtained after NIPS due to possible UPD or parental consanguinity" (Gregg et al., 2016).

In 2017 the ACMG published a laboratory practice resource outlining an algorithm for diagnostic cytogenetic testing following positive noninvasive prenatal screening results which recommends (Cherry et al., 2017):

- "CMA testing on either CVS or amniotic fluid may be used as confirmatory diagnostic testing in cases with positive NIPS results, or as reflex testing in cases with initial normal results from chromosome analysis."
- CMA is recommended as follow-up testing for any smaller copy-number changes that are reported as positive by NIPS.
- They also suggest that when "prenatal diagnostic testing may not be performed due to loss of the pregnancy before testing is possible. In such instances, testing of the products of conception and/or the fetus by either chromosome analysis or CMA should be considered on a case-by-case basis."
- In newborns for whom the screen is suggestive of aneuploidy, but further testing is declined a genetics consultation with physical examination is sufficient for

neonates, however, "if the neonate has an abnormal physical examination that is not suggestive of the trisomy in question, CMA is recommended."

- CMA is also recommended when the sex determination by NIPS is discordant with physical examination, or clinical findings suggestive of a disorder of sexual differentiation.

In 2009, the ACMG published guidelines on the genetic evaluation of short stature. These guidelines provide recommendations for genes associated with short stature and intrauterine growth restriction (IUGR) and state that high resolution chromosome analysis and/or array CGH can be used to evaluate IUGR (Seaver & Irons, 2009).

In 2018, the ACMG published a clinical practice report on genetic testing after CMA for the diagnosis of neurodevelopmental disability and congenital anomalies. These guidelines state that "Chromosomal microarray (CMA) is recommended as the first tier test in evaluation of individuals with neurodevelopmental disability and congenital anomalies. CMA may not detect balanced cytogenomic abnormalities or uniparental disomy (UPD), and deletion/duplications and regions of homozygosity may require additional testing to clarify the mechanism and inform accurate counseling" (Waggoner et al., 2018).

In 2020, the ACMG published guidelines on the use of fetal exome sequencing in prenatal diagnosis. These guidelines recommend that "Exome sequencing may be considered for a fetus with ultrasound anomalies when standard CMA and karyotype analysis have failed to yield a definitive diagnosis. If a specific diagnosis is suspected, molecular testing for the suggested disorder (with single-gene test or gene panel) should be the initial test" (Monaghan et al., 2020).

The *ACMG Technical Standards for Clinical Genetics Laboratories (2021 Revision)* state, "the contamination of both direct and cultured cells from AF and CVS with maternal cells is well documented and therefore represents a potential source of error in prenatal diagnosis. Prenatal samples should be examined in parallel with a maternal sample to rule out error due to maternal cell contamination (MCC). Laboratories should understand how their testing methods are affected by the presence and the amount of MCC. For example, prenatal detection of a deletion using PCR, as is the case in testing for DMD and SMA, is expected to be more sensitive to maternal contamination, since a normal maternal allele could mask the deletion. A prenatal test using an allele-specific PCR reaction to detect a paternal RhD gene in the fetus of a RhD-negative mother is much less sensitive to maternal contamination" (ACMG, 2021).

American Academy of Pediatrics (AAP)

The 2014 AAP guidance for the comprehensive evaluation of children with intellectual disability or global developmental delays noted that "chromosome microarray is designated as a first-line test and replaces the standard karyotype and fluorescent in situ hybridization subtelomere tests for the child with intellectual disability of unknown etiology" (Moeschler & Shevell, 2014). It further added that "CMA is now the standard for diagnosis of patients with GDD/ID, as well as other conditions, such as autism spectrum disorders or multiple congenital anomalies."

Another clinical report published by the AAP on the identification of infants and young children with developmental disorders states that "The child with suspected global developmental delay or intellectual disability should have laboratory testing done, including chromosomal microarray and fragile X testing" (Lipkin & Macias, 2020). Further, the authors also note that "The initial genetic workup of the child with suspected ASD is evolving; current recommendations also include chromosomal microarray and fragile X testing" (Lipkin & Macias, 2020).

The AAP has an epilepsy webpage overview and on the genetic testing for epilepsy page states that "The genetic tests most utilized in the evaluation of children with epilepsy include chromosomal microarray (CMA), epilepsy gene panels, and whole-exome sequencing (WES). Each test has its own specific benefits and limitations, and the utility of different tests may vary for a given individual. Decisions regarding testing need to consider the clinical indication including associated symptoms, turn-around time, insurance coverage, and cost" (Dubbs, 2022).AAP published guidelines on the evaluation of children with autism spectrum disorder. According to the guidelines, CMA is recommended if the etiology for developmental disability is not known. Since Fragile X Syndrome increases the risk for autism spectrum disorder, DNA testing for Fragile X should be recommended in all children with ASD, especially for boys and children with a family history of intellectual disability. "The cytosine-guanine-guanine trinucleotide repeat expansion that is responsible for fragile X syndrome is not detected on CMA and must be ordered as a separate test. When the history and physical examination, CMA, and fragile X analysis do not identify an etiology, the next step at this time in the etiologic evaluation for [autism spectrum disorder] is whole-exome sequencing (WES)." AAP does not recommend the use of commercially marketed tests as they do not provide a molecular etiologic diagnosis (Hyman et al., 2020).

American Academy of Neurology (AAN)

The AAN published coverage policies for chromosomal microarray analysis for intellectual disabilities in 2015 (Satya-Murti, 2015). The policy document notes the

criteria do not represent a binding standard of care and that the criteria are proposed as clinical contexts that readily support the use of microarray testing. The authors note that chromosomal microarray analysis is reasonable and medically necessary for diagnosing a genetic abnormality when all of the following conditions are met (Satya-Murti, 2015):

- "In children with developmental delay/intellectual disability (DD/ID) or an autism spectrum disorder (ASD) according to accepted Diagnostic and Statistical Manual of Mental Disorders-IV criteria;

  AND
- If warranted by the clinical situation, biochemical testing for metabolic diseases has been performed and is negative;
- Targeted genetic testing, (for example: *FMR1* gene analysis for Fragile X), if or when indicated by the clinical and family history, is negative;
- The results for the testing have the potential to impact the clinical management of the patient;
- Face-to-face genetic counseling with an appropriately trained and experienced healthcare professional has been provided to the patient (or legal guardian(s) if a minor child). Patient or legal guardians have given their consent for testing. Cognitively competent adolescent patients have given their assent for testing as well."

The document notes the presence of major and minor congenital malformations and dysmorphic features should be considered evidence that microarray testing will be more likely to yield a diagnosis. However, dysmorphic and syndromic features are not required for testing (Satya-Murti, 2015).

American College of Obstetricians and Gynecologists (ACOG) and Society for Maternal-Fetal Medicine (SMFM)

Originally published 2013 reaffirmed in 2020, the ACOG and SMFM issued joint guidelines recommending the following use of CMA for prenatal diagnosis:

- "Most genetic changes identified by chromosomal microarray analysis that typically are not identified on standard karyotype are not associated with increasing maternal age; therefore, the use of this test can be considered for all women, regardless of age, who undergo prenatal diagnostic testing.
- Prenatal chromosomal microarray analysis is recommended for a patient with a fetus with one or more major structural abnormalities identified on ultrasonographic examination and who is undergoing invasive prenatal diagnosis. This test typically can replace the need for fetal karyotype.

- In a patient with a structurally normal fetus who is undergoing invasive prenatal diagnostic testing, either fetal karyotyping or a chromosomal microarray analysis can be performed.
- Chromosomal microarray analysis of fetal tissue (i.e., amniotic fluid, placenta, or products of conception) is recommended in the evaluation of intrauterine fetal death or stillbirth when further cytogenetic analysis is desired because of the test's increased likelihood of obtaining results and improved detection of causative abnormalities.
- Comprehensive patient pretest and posttest genetic counseling from an obstetrician–gynecologist or other health care provider with genetics expertise regarding the benefits, limitations, and results of chromosomal microarray analysis is essential. Chromosomal microarray analysis should not be ordered without informed consent, which should include discussion of the potential to identify findings of uncertain significance, nonpaternity, consanguinity, and adult-onset disease.
- The routine use of whole-genome or whole-exome sequencing for prenatal diagnosis is not recommended outside of the context of clinical trials until sufficient peer-reviewed data and validation studies are published."

ACOG and SMFM do not recommend use of CMA for evaluation of first- and second-trimester pregnancy loss due to limited clinical utility information. Additionally, they recommend pre- and post-test genetic counseling "from qualified personnel such as a genetic counselor or geneticist regarding the benefits" (ACOG, 2016). This position was reaffirmed in 2023.

A 2018 study of these guidelines analyzed 3223 prenatal samples undergoing CMA. Cases were categorized into 2 groups: those that met ACOG guidelines for CMA versus those that met ACOG guidelines for either CMA or karyotype. They found that "in patients who could have elected either CMA or karyotype, 2.5% had clinically significant chromosomal abnormalities (CSCA) that would have been missed if the patient had elected to pursue karyotype" (Hay et al., 2018).

American Society for Reproductive Medicine (ASRM)

In 2012, ASRM published a committee opinion on evaluation and treatment of recurrent pregnancy loss with clinical practice recommendations. ASRM recommended to proceed with the evaluation of recurrent pregnancy loss after two consecutive clinical pregnancy losses. This definition of recurrent pregnancy loss was reaffirmed in 2013. The recommended assessment of recurrent pregnancy loss included screening for genetic, hormonal and metabolic factors in addition to other factors. They have

stated that "karyotypic analysis of products of conception may be useful in the setting of ongoing therapy for recurrent pregnancy loss" (ASRM, 2012).

In 2020, the Practice Committee and Genetic Counseling Professional Group (GCPG) of the ASRM published their opinion on the clinical management of mosaic results from preimplantation genetic testing for aneuploidy (PGT-A) of blastocysts. Defining prenatal diagnostic testing as including chorionic villus sampling or amniocentesis, the group recommends the following:

- "Prenatal genetic counseling is strongly recommended for any pregnancy resulting from the transfer of embryos with mosaic results and should include a discussion of the risks, benefits, and limitations of CVS and amniocentesis. If prenatal diagnostic testing is performed, additional analyses beyond routine karyotyping should be considered depending on the specific PGT-A result. At the discretion of the ordering provider, these may include:
  - Chromosomal microarray, if a partial chromosome aneuploidy is involved.
  - Uniparental disomy studies (UPD), depending on the chromosome involved.
  - Additional cell counts, in an effort to identify lower-level mosaicism.
- Postnatal evaluation by peripheral blood karyotype and/or microarray should be considered, particularly if prenatal diagnostic testing is declined. Referral to a pediatric specialist in genetics is recommended in the event of an abnormal physical or developmental phenotype" (ASRM, 2020).

Society of Obstetricians and Gynaecologists of Canada (SOGC)- Canadian College of Medical Geneticists (CCMG) Joint Technical Update

The 2018 joint guideline Armour et al. (2018) supersedes the 2011 iteration.

- "Offer of chromosomal microarray analysis (in addition to any other relevant diagnostic testing) is recommended in cases with multiple fetal anomalies identified by a comprehensive obstetric ultrasound (II-1A). Other diagnostic testing may include specific single gene, multigene panels or other genetic tests if the pattern of anomalies suggests a specific genetic condition not identified by array."
- "Single structural defects in association with other abnormal ultrasound findings (e.g., intrauterine growth restriction (IUGR), oligohydramnios) should not be considered isolated, and thus array should be offered if RAD is normal."
- "In cases with a single fetal anomaly, prenatal CMA should be considered for those malformations associated with a high frequency of abnormal results. Its use in cases where the diagnostic yield is lower may be considered, if resources are available."
- "In fetuses with a nuchal translucency ≥3.5 mm, prenatal CMA should be offered."

For "analysis of fetal loss prior to 20 weeks gestation":

- "In cases of congenital anomalies and/or IUGR, in any fetal loss prior to 20 weeks gestation, if QF-PCR methodologies and/or other directed diagnostic inquiries do not provide a diagnosis and further cytogenetic analysis is intended, it is recommended that karyotype be replaced with chromosomal microarray analysis."

For fetal deaths ≥20 weeks gestation:

- "Aneuploidy is the most common abnormal chromosomal finding in stillbirths. If RAD and/or other directed diagnostic inquiries are uninformative, it is recommended that in cases complicated by congenital anomalies and/or IUGR, karyotype be replaced with CMA when further cytogenetic analysis is desired."
- "In stillbirths without structural fetal anomalies, CMA may be considered in the context of local resource availability and site-based postmortem protocol (whether complete, limited or external only)" (Armour et al., 2018).

Association for Molecular Pathology (AMP)

The MCC [maternal cell contamination] Guidelines Working Group of the AMP Clinical Practice Committee issued laboratory guidelines for detecting MCC in 2011. They state, "To determine the pure fetal origin of all prenatal specimens undergoing genetic analysis, it is recommended that MCC analysis be performed in parallel with diagnostic testing, regardless of the genetic disorder or its mode of inheritance" (Nagan et al., 2011).

The Association for Molecular Pathology Training and Education Committee published a series of quick reference cards called Molecular-in-My-Pocket™ for trainees and anyone looking to quickly reference molecular diagnostics information.

In their oncology subdivision, the AMP summarize assays and techniques for molecular biomarkers for various cancers. Below are summaries of their syntheses.

When testing for primary and recurrent tumors for the *KIT* biomarker in cutaneous melanoma, "NGS, pyrosequencing, Sanger sequencing, PCR-based assays, microarray" are applicable for therapeutic indications.

When testing for primary and recurrent tumors for 1p/19q co-deletion in tumors of the central nervous system, "FISH, array, NGS" are approved for diagnosis and prognosis. Moreover, when testing for EGFR amplification, gain of chromosome 7, and loss of chromosome 10, "FISH, array, NGS" are applicable for diagnosis.

Similarly, in their pediatric molecular pathology section, the AMP summarizes assays and techniques for pediatric brain tumors. The following table, adapted from the oncology Molecular-in-my-Pocket™ card, lists the assays and techniques mentioning CMA and their corresponding tumor types (AMP, 2023):

Tumor type	Gene/Biomarker	Significance	Primary assays
Low grade gliomas	*FGFR* mutation, fusion	Diagnosis	NGS (DNA), CMA
	NF1 loss or inactivating mutation, loss of heterozygosity	Diagnosis, familial cancer if germline	NGS (DNA), CMA
	MYB fusion, amplification	Diagnosis, prognosis	NGS (DNA), CMA
	MYBL1 fusion, amplification	Diagnosis, prognosis	NGS (DNA), CMA
High grade gliomas, IDH wildtype	*EGFR* amplification	Prognosis	NGS (DNA), CMA, FISH
	CDKN2A/B homozygous deletion	Prognosis	CMA, NGS (DNA)
	TP53 loss-of-function (LOF) and gain-of-function mutations, loss, LOH	Prognosis	NGS (DNA), CMA
	NF1 loss or inactivating mutation, loss of heterozygosity	Prognosis	NGS(DNA), CMA
	PDGFRA amplification	Prognosis	CMA, NGS (DNA)
	RB1 loss or inactivating mutation, loss of heterozygosity	Prognosis	NGS (DNA), CMA
	MDM4 amplification	Prognosis	NGS (DNA), CMA, FISH
	MET amplification, fusion, mutation	Prognosis	NGS (DNA), CMA, FISH
	Gain of chromosome 7	Prognosis	CMA
	10q loss	Prognosis	CMA
Oligodendroglioma	1p/10q codeletion	Diagnosis	CMA, FISH
	1q gain	Prognosis	CMA, FISH

Medulloblastoma, SHH-activated	*PTCH1* inactivating mutation, loss of heterozygosity	Subtype-diagnosis, familial cancer risk if germline N	NGS (DNA), CMA
	SUFU inactivating mutation, loss of heterozygosity	Subtype-diagnosis, familial cancer risk if germline N	NGS (DNA), CMA
	TP53 loss-of-function (LOF) and gain-of-function mutations, loss, loss of heterozygosity, structural alterations (rare)	Prognosis	NGS (DNA), CMA
	10q loss or loss of heterozygosity	Diagnosis	CMA, FISH
	MYCN amplification	Diagnosis, prognosis	FISH, CMA, NGS (DNA)
Medulloblastoma, Group 3	Isochromosome 17q	Subtype-diagnosis	CMA, FISH
	MYC amplification, fusion (PVT1)	Prognosis	CMA, FISH
Medulloblastoma, Group 4	Isochromosome 17q	Subtype-diagnosis	CMA, FISH
	MYCN amplification	Diagnosis, prognosis	FISH, CMA, NGS
Meningioma	*NF2* loss-of-function (LOF) and gain-of-function mutations, loss, loss of heterozygosity	Diagnosis, familial cancer risk if germline	NGS, CMA, MLPA
Choroid plexus tumors	*TP53 l*oss-of-function (LOF) and gain-of-function mutations, loss, loss of heterozygosity, structural alterations (rare)	Diagnosis, familial cancer risk if germline	NGS, CMA, MLPA
ETMR	*C19MC* amplification and gain	Diagnosis, prognosis	CMA, FISH

Regarding pediatric solid tumors, the following table, adapted from the oncology Molecular-in-my-Pocket™ card (AMP, 2023), lists the assays and techniques mentioning CMA and their corresponding tumor types:

Tissue type	Tumor type	Gene/Biomarker	Significance	Primary assays
Kidney	Wilms Tumor	1q gain, 1p/16q loss of heterozygosity	Prognosis	CMA, NGS (DNA)
	Rhabdoid Tumor	*SMARCB1 (INI1), SMARCA4 (BRG1)* loss	Diagnosis	IHC, CMA, NGS, MLPA
Eye	Retinoblastoma	*RB1* inactivating mutation, loss, or loss of heterozygosity	Diagnosis, familial cancer risk if germline	Sanger sequencing, MLPA, CMA, NGS (DNA)
Adrenal	Neuroblastoma	1p/11q LOH loss	Prognosis	CMA, NGS
Multi-system	Gorlin	*SUFU*, *PTCH1* loss-of-function sequence variants, deletion/duplication	Diagnosis, familial cancer risk	Sequencing, CMA, MLPA

Regarding pediatric soft tissue tumors, the following table, adapted from the oncology Molecular-in-my-Pocket™ card (AMP, 2023), lists the assays and techniques mentioning CMA and their corresponding tumor types:

Tissue type	Tumor type	Gene/Biomarker	Significance	Primary assays
Miscellaneous	Chordoma (Poorly differentiated)	*SMARCB1 (INI1)* loss (sequence variant, partial deletion)	Diagnosis, prognosis	IHC, CMA, NGS, MLPA
	Rhabdoid (Extra-renal)	*SMARCB1 (INI1)* and *SMARCA4 (BRG1)*	Diagnosis	IHC, CMA, NGS, MLPA
	Epithelioid sarcoma	*SMARCB1 (INI1)* and *SMARCA4 (BRG1)*	Diagnosis, treatment	IHC, CMA, NGS, MLPA
Multi-system	Gorlin	*SUFU*, *PTCH1* loss-of-function sequence variants, deletion/duplication	Diagnosis, familial cancer risk	Sequencing, CMA, MLPA

Society for Maternal-Fetal Medicine (SMFM)

The SMFM recommends chromosomal microarray for evaluation of mild fetal ventriculomegaly and nonimmune hydrops fetalis (Fox et al., 2018; Norton et al., 2015).

SMFM released guidelines on the diagnosis and management of fetal growth restriction. The following recommendations were made:

- SMFM recommends that pregnant individuals "be offered fetal diagnostic testing, including chromosomal microarray analysis, when fetal growth restriction is detected and a fetal malformation, polyhydramnios, or both are also present regardless of gestational age."
- They also recommend that pregnant individuals "be offered prenatal diagnostic testing with chromosomal microarray analysis when unexplained isolated fetal growth restriction is diagnosed at <32 weeks of gestation" (Martins et al., 2020).

International Standard Cytogenomic Array (ISCA) Consortium

The ISCA (an international group of experts in the field) assembled to "address mutual concerns about standardization and collaboration for clinical CMA testing" (Miller et al., 2010). After much research, the ISCA has stated that "Our recommendation based on current evidence is to offer CMA as the first-tier genetic test, in place of G-banded karyotype, for patients with unexplained DD/ID, ASD, or MCA [multiple congenital anomalies]" (Miller et al., 2010).

International Society for Prenatal Diagnosis (ISPD), the Society for Maternal Fetal Medicine (SMFM), and the Perinatal Quality Foundation (PQF)

Joint guidelines on the use of genome-wide sequencing for fetal diagnosis were published by the ISPD, SMFM and PQF. However, these guidelines also mention CMA quite frequently because "The use of diagnostic sequencing is currently being introduced for evaluation of fetuses for whom standard diagnostic genetic testing, such as chromosomal microarray analysis (CMA), has already been performed and is uninformative or is offered concurrently according to accepted practice guidelines, or for whom expert genetic opinion determines that standard genetic testing is less optimal than sequencing for the presenting fetal phenotype" (ISPD, 2018).

Fetal sequencing is recommended in several scenarios, including the following which also mention CMA:

- "A current pregnancy with a fetus with a single major anomaly or with multiple organ system anomalies that are suggestive of a possible genetic etiology, but no genetic diagnosis was found after CMA; or in select situations with no CMA result,

following a multidisciplinary review and consensus, in which there is a fetus with a multiple anomaly 'pattern' that strongly suggests a single gene disorder.

- A personal (maternal or paternal) history of a prior undiagnosed fetus (or child) affected with a major single anomaly or multiple anomalies suggestive of a genetic etiology, and a recurrence of similar anomalies in the current pregnancy without a genetic diagnosis after karyotype or CMA
- In families with a history of recurrent stillbirths of unknown etiology after karyotype and/or CMA, where the fetus in the current pregnancy has a recurrent pattern of anomalies" (ISPD, 2018).

These recommendations show that CMA should be used as an initial strategy (before fetal sequencing) to determine the genetic causation during pregnancy of the aforementioned cases.

Autism Consortium Clinical Genetics/DNA Diagnostics Collaboration

These guidelines focus on clinical genetic testing for patients with autism spectrum disorders (ASDs). The authors note that "CMA had the highest detection rate among clinically available genetic tests for patients with ASD. Interpretation of microarray data is complicated by the presence of both novel and recurrent copy-number variants of unknown significance. Despite these limitations, CMA should be considered as part of the initial diagnostic evaluation of patients with ASD" (Shen et al., 2010). Further, the guidelines later state that "our results suggest that CMA with whole genome coverage should be adopted as a national standard of care for genetic testing among patients with ASDs" (Shen et al., 2010).

Endocrine Society (ES)

The Endocrine Society published guidelines on the diagnosis and treatment of children with idiopathic short stature (ISS) in 2008. These guidelines state that "In situations where a specific genetic diagnosis associated with short stature is expected (such as Noonan syndrome or GH insensitivity syndrome), the genes of interest should be examined" (Cohen et al., 2008). These guidelines do not mention CMA.

The National Fragile X Foundation

The National Fragile X Foundation's statement on genetic testing for Fragile X Syndrome and associated disorders includes within its recommendations the use of chromosomal microarray analysis and exome sequencing for the diagnosis of "the underlying cause of a child's developmental delays, autism, or intellectual disability". However, though the above are viable options for genetic testing in general, "Currently, Fragile X testing must be ordered as a separate test since expansions of the

FMR1 gene cannot be detected through microarray or exome sequencing", and as such a specific DNA test for Fragile X Syndrome via PCR and Southern Blot analysis will need to be used (National FragileX Foundation, 2024).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

In 2014 the FDA approved CytoScan® Dx Assay as a "qualitative assay intended for the postnatal detection of copy number variations (CNV) in genomic DNA obtained from peripheral whole blood in patients referred for chromosomal testing based on clinical presentation. CytoScan® Dx Assay is intended for the detection of CNVs associated with developmental delay, intellectual disability, congenital anomalies, or dysmorphic features" (FDA, 2014).

In 2017 the FDA approved GenetiSure Dx Postnatal Assay as a "qualitative assay intended for the postnatal detection of copy number variations (CNV) and copy-neutral loss of heterozygosity (cnLOH) in genomic DNA obtained from peripheral whole blood in patients referred for chromosomal testing based on clinical presentation. GenetiSure Dx Postnatal Assay is intended for the detection of CNVs and cnLOH associated with developmental delay, intellectual disability, congenital anomalies, or dysmorphic features" (FDA, 2017).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description

81228	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number variants, comparative genomic hybridization [CGH] microarray analysis
81229	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number and single nucleotide polymorphism (SNP) variants, comparative genomic hybridization (CGH) microarray analysis
81265	Comparative analysis using Short Tandem Repeat (STR) markers; patient and comparative specimen (eg, pre-transplant recipient and donor germline testing, post-transplant non-hematopoietic recipient germline [eg, buccal swab or other germline tissue sample] and donor testing, twin zygosity testing, or maternal cell contamination of fetal cells)
81349	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number and loss-of-heterozygosity variants, low-pass sequencing analysis
0252U	Fetal aneuploidy short tandem–repeat comparative analysis, fetal DNA from products of conception, reported as normal (euploidy), monosomy, trisomy, or partial deletion/duplications, mosaicism, and segmental aneuploidy Proprietary test: POC (Products of Conception) Lab/Manufacturer: Igenomix®
0469U	Rare diseases (constitutional/heritable disorders), whole genome sequence analysis for chromosomal abnormalities, copy number variants, duplications/deletions, inversions, unbalanced translocations, regions of homozygosity (ROH), inheritance pattern that indicate uniparental disomy (UPD), and aneuploidy, fetal sample (amniotic fluid, chorionic villus sample, or products of conception), identification and categorization of genetic variants, diagnostic report of fetal results based on phenotype with maternal sample and paternal sample, if performed, as comparators and/or maternal cell contamination Proprietary test: IriSightTM CNV Analysis Lab/Manufacturer: Variantyx Inc
S3870	Comparative genomic hybridization (CGH) microarray testing for developmental delay, autism spectrum disorder and/or intellectual disability

Esophageal Pathology Testing

Policy Number: AHS – M2171 – Esophageal Pathology Testing	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

The esophagus is a long tube that serves to connect the mouth to the stomach. Although the esophagus is primarily a connecting organ, it experiences significant chemical and mechanical trauma. The esophagus has mechanisms and structures to withstand this damage, but molecular injury is common (Zhang et al., 2020). Both serological and genetic markers have been suggested to identify, diagnose, or assess risk in the esophagus.

Eosinophilic esophagitis (EoE) is one such condition, as its nonspecific symptoms (pain, issues swallowing, vomiting, and so on) may be accompanied by inflammatory markers in the esophagus (Bonis & Gupta, 2023). Similarly, esophageal cancer is characterized by several nonspecific symptoms, while a predecessor condition, Barrett's esophagus (BE), may have no clinical symptoms at all (Saltzman & Gibson, 2023; Spechler, 2022).

For guidance concerning Tumor Mutational Burden Testing (TMB) and/or Microsatellite instability (MSI) analysis please refer to the AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing policy.

II. Related Policies

Policy Number	Policy Title
AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have been newly diagnosed with cancer of the esophagus or esophagogastric junction (EGJ), mismatch repair (MMR) analysis by immunohistochemistry (IHC) **MEETS COVERAGE CRITERIA**.

2) For individuals who have been diagnosed with locally advanced, recurrent, or metastatic cancer of the esophagus or EGJ and for whom PD-1 inhibitor treatment is being considered, tumor analysis of PD-L1 expression by IHC **MEETS COVERAGE CRITERIA**.

3) For individuals who have been diagnosed with inoperable locally advanced, recurrent, or metastatic adenocarcinoma of the esophagus or EGJ and for whom trastuzumab or an approved biologic or biosimilar drug to trastuzumab is being considered for first-line therapy, HER2 overexpression testing by IHC, fluorescence in situ hybridization (FISH), or other in situ hybridization (ISH) **MEETS COVERAGE CRITERIA**.

4) For individuals diagnosed with unresectable locally advanced, recurrent, or metastatic adenocarcinoma or squamous cell carcinoma of the esophagus or EGJ and for whom one of the following drugs is being considered as a second-line therapy, the corresponding gene testing **MEETS COVERAGE CRITERIA**:
   a) Larotrectinib or entrectinib: *NTRK* gene fusion.
   b) Selpercatinib: *RET* gene fusion.
   c) Dabrafenib or trametinib: *BRAF* V600E mutation.

5) The use of genetic testing (e.g., molecular panel tests, gene expression profiling) to diagnose or monitor an individual with eosinophilic esophagitis (EoE) or to assess the risk of an individual developing EoE **DOES NOT MEET COVERAGE CRITERIA**.

6) For the diagnosis and evaluation of Barrett's esophagus, low-grade esophageal dysplasia, or high-grade esophageal dysplasia, wide-area transepithelial sampling (WATS) **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

7) Assessing for risk of Barrett's esophagus and/or esophageal, including esophagogastric junction, cancer using a molecular classifier (e.g., BarreGEN test) **DOES NOT MEET COVERAGE CRITERIA**.

8) Epigenetic analysis for the likelihood for Barrett's esophagus, esophageal, or esophagogastric junction cancer (e.g., methylation analysis, EsoGuard) **DOES NOT MEET COVERAGE CRITERIA**.

9) To diagnose, assess, or monitor eosinophilic esophagitis (EoE), the Esophageal String Test **DOES NOT MEET COVERAGE CRITERIA**.

10) For esophageal and esophagogastric junction cancers, cell-free DNA/circulating tumor DNA (cfDNA/ctDNA) testing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For 5 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ACG	American College of Gastroenterology
AFS	American Foregut Society
AMACR	Alpha-methylacyl-CoA racemase
APC	*Adenomatous polyposis coli*
ARID1A	*AT-rich interactive domain-containing protein 1A*
ARID2	*AT-rich interactive domain 2*
ASGE	American Society for Gastrointestinal Endoscopy
BAT	Bethesda marker
BE	Barrett's esophagus
BLM	Bloom syndrome protein
BMJ	British Medical Journal
BS	Bloom syndrome
CAPN14	*Calpain 14*
CCL26	*C-C motif chemokine ligand 26*
CCNA1	*Cyclin A1*
cfDNA	Cell-free tumor DNA
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMM1	Familial cutaneous malignant melanoma-1
CMS	Centers For Medicare and Medicaid Services
COX2	*Cyclooxygenase 2*
CPS	Combined Positive Score
CSCO	Chinese Society of Clinical Oncology

CTCs	Circulating tumor cells
ctDNA	Circulating tumor DNA
DCC	*Deleted in colorectal carcinoma*
DNA	Deoxyribonucleic acid
DOCK2	*Dedicator of cytokinesis 2*
EAACI	European Academy of Allergy and Clinical Immunology
EAC	Esophageal adenocarcinoma
ED	Esophageal dysplasia
EDP	Eosinophilic esophagitis diagnostic panel
EGFR	*Epidermal growth factor receptor*
EGJ	Esophagogastric junction
ELISA	Enzyme-linked immunoassay
ELMO1	*Engulfment and cell motility protein 1*
EoE	Eosinophilic esophagitis
ESMO	European Society for Medical Oncology
ESPGHAN	European Society of Pediatric Gastroenterology, Hepatology And Nutrition
EST	Esophageal string test
EUREOS	European Society of Eosinophilic Oesophagitis
FA	Fanconi anemia
FANC	FA complementation group A
FB	Forceps biopsy
FBE	Familial Barrett's esophagus
FDA	Food and Drug Administration
FISH	Fluorescence in situ hybridization
GERD	Gastroesophageal reflux disease
HER2	*Human epidermal growth factor receptor 2*
HGD	High-grade dysplasia
HGD/EAC	High-grade dysplasia/esophageal adenocarcinoma
HIF1-ALPHA	Hypoxia-inducible factor 1-alpha
HoGG1	*8-oxoguanine DNA glycosylase*
ICER	Incremental cost-effectiveness ratio
IgE	Immunoglobulin E
IHC	Immunohistochemistry
IND	Indefinite for dysplasia
JSMO	Japanese Society of Medical Oncology
K20	Potassium oxide
KSMO	Korean Society of Medical Oncology

LDTs	Laboratory developed tests
LGD	Low-grade dysplasia
MBP-1	Major basic protein 1
MCC	*Colorectal mutant cancer protein*
ML	Mutational load
MMR	Mismatch repair
MSI	Microsatellite instability
MSI-H	High microsatellite instability
MXI1	*Max-interacting protein 1*
NBDE	Non-dysplastic intestinal metaplasia
NCCN	National Comprehensive Cancer Network
NDBE	Baseline nondysplastic BE
NF2	Neurofibromatosis type 2
NME1	Nucleoside Diphosphate Kinase 1
NNT	Number needed to test
NOTCH3	*Notch receptor 3*
NTRK	Neurotrophic tyrosine receptor kinase
PCR	Polymerase chain reaction
PD-1	Programmed death-1
PD-L1	Programmed death-ligand 1
PPK	Palmoplantar keratoderma
PRG2	*Proteoglycan 2, pro eosinophil major basic protein*
PSEN2	*Presenilin 2*
PTEN	*Phosphatase and TENsin homolog*
QALY	Quality-adjusted life-year
RB	*Retinoblastoma protein*
RHBDF2	*Rhomboid 5 homolog 2*
RNF43	*Ring finger protein 43*
SAGES	Society of American Gastrointestinal and Endoscopic Surgeons
SCCs	Squamous cell carcinomas
SMAD4	*SMA- and MAD-related protein 4*
SMARCA4	*Matrix associated, actin dependent regulator of chromatin, subfamily a*
SOC	Standard of care
SPG20	*Spastic paraplegia 20*
SSO	Sequence-specific oligonucleotide
STMN1	Stathmin 1
TAVAC	Technology And Value Assessment Committee
TFF1	*Trefoil factor 1*
TML	Tumor mutational load

TNFAIP8	*TNF alpha induced protein 8*
TOS	Thoracic outlet syndromes
TP53	*Tumor protein 53*
TPS	Tumor positive score
TRK	Tropomyosin receptor kinase
TSLP	*Thymic stromal lymphopoietin*
TVAC	Technology And Value Assessment Committee
UEG	United European Gastroenterology
VHL	Von hippel-lindau syndrome
VIM	Vimentin
WATS	Wide-Area Transepithelial Sampling
WATS3D	Wide-Area Transepithelial Sampling with Computer-Assisted 3-Dimensional Analysis

V. Scientific Background

The esophagus is a long tube that connects the mouth to the stomach. Its primary function is to transport food from the mouth to the stomach. However, this organ is often exposed to difficult conditions, from abrasive food to the acidic conditions of the stomach. Although mechanisms are in place to protect against injury (namely the tough squamous cells), it is common to see injury or disease in the esophagus (Zhang et al., 2020).

Many serological and genetic markers have been proposed as tools to assist in evaluation of esophageal pathology. Eosinophilic esophagitis (EoE), Barrett's esophagus (BE), and esophageal cancer are typically diagnosed with histological analysis from endoscopic biopsy (Bonis & Gupta, 2023; Saltzman & Gibson, 2023; Spechler, 2022), but biopsies frequently require careful consideration and resources to perform properly (NCCN, 2024). For these reasons, serum and genetic markers have been suggested as noninvasive markers for esophageal pathologies.

Eosinophilic Esophagitis (EoE)

Eosinophilic esophagitis (EoE) is marked by the presence of eosinophils in the esophagus. Eosinophils are typically associated with mitigating inflammation but are not normally found in the esophagus. EoE is represented by a broad set of clinical symptoms, such as difficulty swallowing, chest, or abdominal pain, and feeding dysfunction. Diagnosis is established through endoscopy with biopsies to confirm eosinophilia. The current diagnostic criteria set the cutoff for eosinophilia at ≥15 eosinophils per high power field, (60 eosinophils per mm^2) although this figure has been heavily discussed (Bonis & Gupta, 2023; Dellon et al., 2018).

Proprietary Testing- EoE

Laboratory tests have been suggested as a noninvasive adjunct for EoE. Serum IgE will be elevated in up to 60% of EoE patients, as allergy has a strong association with EoE. Many other markers, such as eotaxin-3, major basic protein-1, tryptase, chemokines, and serum eosinophil count, have all been suggested to assist in evaluation of EoE (Bonis & Gupta, 2023; Dellon et al., 2018). Immune system factors may also contribute to pathology. Since eosinophils are not normally found in the esophagus, their presence in the esophagus may suggest an underlying issue with the immune system. Various interleukins, mast cells, and T cells have all been proposed as contributing to pathogenesis, but the exact pathway and mechanisms are not completely understood (Rothenberg, 2023). Genetic features have also been used for EoE evaluation. Twin studies and family histories have indicated a role for genetics in EoE. Several genes have also been identified as potential risk factors, such as *CAPN14* (an interleukin-13 regulator), *TSLP* (a basophil regulator), and *CCL26* (promotes eosinophil movement into esophagus) (Sherrill & Rothenberg, 2014).

Wen et al. (2013) developed a diagnostic gene expression panel ("EDP") for EoE. The authors identified candidate genes using two cohorts of EoE and control patients, then validated these genes with a separate cohort of 194 patients (91 active EoE, 57 control, 34 ambiguous, 12 reflux). The panel was found to identify EoE patients at 96% sensitivity and 98% specificity. The authors also noted that the panel could separate patients in remission from unaffected patients (Wen et al., 2013).

Shoda et al. (2018) used an "EoE Diagnostic Panel" (EDP) to further classify EoE cases by histologic, endoscopic, and molecular features. The EDP consisted of 95 esophageal transcripts purported to identify EoE among both unaffected patients and patients with other conditions. 185 biopsies were studied. The authors identified three clear subtypes of EoE; subtype 1 with a normal-appearing esophagus and mild molecular changes, subtype 2 with an inflammatory and steroid-responsive phenotype, and subtype 3 with a "narrow-caliber" esophagus and severe molecular alterations. These findings were replicated in a 100-biopsy sample (Shoda et al., 2018).

Tests are commercially available for EoE. Noninvasive tests (as an alternative to endoscopy) have been recently popular. The Esophageal String Test (Testa et al.) is one such alternative. The patient swallows a gelatin-coated capsule with a string wrapped inside. Once the capsule is in the patient's stomach, the gelatin dissolves, allowing the capsule to pass through. The string itself is used to collect samples from the patient's esophagus and is easily removed from the patient. From there, the sample is analyzed for several biomarkers (major basic protein-1, eotaxins 2 and 3, and so on) to provide a

probability% (a trademarked "EoEscore") of esophageal inflammation (Ackerman et al., 2019; EnteroTrack, 2023).

Barrett's Esophagus (BE)

Barrett's esophagus (BE) is a condition in which the normal squamous tissue lining the esophagus is replaced by metaplastic columnar epithelium. This new epithelium contains gastric features and is typically caused by chronic gastroesophageal reflux disease (GERD). This condition predisposes to esophageal cancer. When noxious substances (gastric acid, bile, et al) are exposed to the squamous esophageal tissue, the damage is usually repaired through regeneration of these squamous cells. In BE cases, this damage is repaired not through creation of new squamous cells, but through metaplastic columnar cells. The exact reason for this is unknown. Although these metaplastic cells are more resistant to reflux-based damage than the normal squamous cells, these cells frequently show the oxidative DNA damage that is typical of cancer. Mutations in the p53 tumor suppressor gene appear to be the catalyst for cancers, as acquisition of this mutation in conjunction with the replication of the genome is conducive to carcinogenesis (Spechler, 2022).

Vollmer (2019) performed a review assessing incidence of adenocarcinoma detected during surveillance of BE. The author identified 55 studies encompassing 61371 total patients. Of the 61371 total patients, 1106 developed adenocarcinoma. Overall, the author found that the model created from the studies "predicted the per-person probability of developing cancer in five years of complete follow-up is approximately 0.0012." Variables affecting this probability included mean time of follow-up, definition of Barrett metaplasia, and fraction of patients followed up for at least five years (Vollmer, 2019).

Proprietary Testing- BE

Proprietary tests are commercially available for assessment of BE, usually to evaluate risk (BE progression to cancer, risk of BE itself, and such). For example, BarreGen, offered by Interpace Diagnostics, uses tumor mutational load (a measure intended to capture total genomic instability of a sample) to calculate risk of progression. Although many ways can estimate mutational load, BarreGen tests 10 key genomic loci which are as follows: "1p (*CMM1*, L-myc), 3p (*VHL*, *HoGG1*), 5q (*MCC*, *APC*), 9p (*CDKN2A*), 10q (*PTEN*, *MXI1*), 17p (*TP53*), 17q (*RNF43*, *NME1*), 18q (*SMAD4*, *DCC*), 21q (*TFF1*, *PSEN2*) and 22q (*NF2*)." These loci encompass integral tumor suppressors and are proposed to provide an accurate picture of genomic instability (Interpace, 2023; Trindade et al., 2019).

Another test, TissueCypher, also proposes to predict likelihood of progression from BE to esophageal cancer. The test measures nine protein biomarkers that represent morphological and cellular changes (p53, p16, AMACR, CD68, COX2, HER2, K20, HIF1-alpha, CD45RO). These biomarkers are quantified and converted to a risk score (1-10) and probability of progression (Castle Biosciences, 2023).

Esoguard, by Lucid Diagnostics, is an esophageal DNA test which analyzes 31 methylated biomarkers in the diagnosis of non-dysplastic Barrett's esophagus and adenocarcinoma. The assay uses next generation sequencing to examine individual DNA molecules for the presence or absence of cytosine methylation with a 90% specificity and 90% sensitivity (Lucid Diagnostics, 2024).

Finally, a proprietary imaging system, WATS3D, is commercially available. This imaging system samples from a wider area, as opposed to only taking focal samples in a traditional biopsy. This technology also provides a 3-dimensional image of the sampled area. This technology purports to provide more precise sampling than the traditional 4-quadrant biopsies, claiming an increased detection rate of BE and other dysplasias (Diagnostics, 2024).

Esophageal Cancer

Esophageal cancers are largely divided into two groups: squamous cell carcinomas (SCCs) and adenocarcinomas (EAC). SCCs usually begin in the middle of the esophagus, whereas EACs often originate near the gastroesophageal junction. Both share several risk factors, such as smoking. Due to the numerous environmental risk factors for both types of cancer, it is difficult to ascertain the true impact of genetic factors (Gibson, 2023). These cancers are primarily diagnosed through histologic examination, usually obtained through endoscopy (Saltzman & Gibson, 2023).

Advancements have been in the molecular characterization of both types of cancer. *TP53* mutations are the most common mutation seen in both types of cancer. Other frequently mutated genes in adenocarcinoma include *ELMO1* and *DOCK2* (enhance cell motility), *ARID1A*, *SMARCA4* and *ARID2* (chromatin remodelers), and *SPG20* (traffics growth factor receptors). BE, as the precursor to adenocarcinomas, includes certain similarities in genetic mutations but at a less severe rate. Further, the rate of overlap tended to increase with higher degree of dysplasia (Testa et al., 2017).

Squamous cell carcinoma mutations tend to be in genes associated with specific cellular pathways. Genes in ubiquitous pathways, such as *EGFR*, *NOTCH3*, and *RB*, are frequently mutated in SCC. The molecular profile of esophageal SCC tends to align more with other squamous cell cancers (such as head and neck cancers) rather than EAC (Testa et al., 2017). Numerous gene expression studies have been performed to

further classify molecular subtypes of esophageal cancer (Gonzaga et al., 2017; McLaren et al., 2017; Visser et al., 2017). Gene expression profiles may have utility in assessing response to treatment, prognosis, or risk assessment.

Historically, Carcinoembryonic Antigen (CEA) has been used as the serum cancer marker in the diagnosis of esophageal cancer, as CEA levels have been shown to be significantly higher in these patients. The sensitivity (8-70%), specificity (57-100%), and positive likelihood ratio (5.94) of CEA means that patients with EC have a 6-fold higher chance of having higher CEA levels. Other markers include squamous cell cancer antigen (SCC-Ag) and cytokeratin 21-1 fragment (CYFRA21-1). The sensitivity and specificity Cyfra21–1 ranged from 36% to 63% and from 89% to 100%, respectively, with patients having a 12-fold higher chance of having EC. The sensitivity and specificity of SCC-Ag ranged from 13% to 64% and from 91% to 100%, respectively, whereas its PLR was 7.66 (Visaggi et al., 2021).

Li et al. (2019) investigated potential biomarkers for lymph node metastasis for esophageal squamous cell carcinoma. Six studies encompassing 70 patients were included. The authors identified nine biomarkers and four cellular mechanisms that influence lymph node metastasis. From there, they identified three biomarkers with broader influence on prognosis of disease, *PTEN*, *STMN1*, and *TNFAIP8*. The authors suggested that those three biomarkers should be researched further (Li et al., 2019).

Plum et al. (2019) evaluated *HER2* overexpression's impact on prognosis of esophageal adenocarcinoma (EAC). 428 EAC patients that underwent a "transthoracic thoraco-abdominal esophagectomy" were included. The authors identified 44 patients with *HER2* positivity (IHC score 3+ or 2+ with gene amplification). This cohort was found to have a better overall survival (OS, 70.1 months vs 24.6 months), along with better histology, absence of lymphatic metastases, and lower tumor stages. The authors also noted a similarity in results to a large 2012 study (Plum et al., 2019).

Frankell et al. (2019) examined the molecular landscape of esophageal adenocarcinoma (EAC). The authors assessed 551 genomically characterized EACs. A total of 77 driver genes and "21 non-coding driver elements" were identified. The authors also found an average of 4.4 driver events per tumor. A three-way association was found, between hyper-mutation, *Wnt* signaling, and loss of immune signaling genes. Finally, the authors also identified "sensitizing events" (events causing a tumor to be more susceptible to a therapy) to CD4/6 inhibitors in over half of the EAC cases studied (Frankell et al., 2019).

Clinical Utility and Validity

Ackerman et al. (2019) evaluated the ability of the 1-hour Esophageal String Test (Testa et al.) to distinguish between active eosinophilic esophagitis (EoE), inactive eosinophilic esophagitis, and normal esophagi. A total of 134 patients (62 active EoE, 37 inactive EoE, 35 normal) were included. The authors found that eotaxin 3 measured from both EST samples and the control biopsy extracts to be the best marker for distinguishing active EoE from inactive EoE (by both sensitivity and specificity). Addition of major basic protein 1 (MBP-1) improved sensitivity by 0.039 (0.652 to 0.693) and specificity by 0.014 (0.261 to 0.275) across all patients (Ackerman et al., 2019).

Hao et al. (2019) performed a cost-effectiveness analysis of an "adenocarcinoma risk prediction multi-biomarker assay" (TissueCypher's Barrett's Esophagus Assay). A hypothetical cohort of 10000 patients with BE diagnoses (including non-dysplastic intestinal metaplasia [NBDE], indefinite for dysplasia [IND], and low-grade dysplasia [LGD]) was created. A Markov decision model was used to compare BE management costs between assay use and the standard of care (SOC). A surveillance interval of five years was used. Low-risk patients were found to have a 16.6% reduction in endoscopies. High-risk patients were found to have a 58.4% increase in endoscopic treatments (compared to the SOC arm), leading to a death total of 111 for the assay arm compared to 204 in the SOC arm (a 45.6% reduction). Overall, the authors calculated the incremental cost-effectiveness ratio (ICER) to be $52,483/quality-adjusted life-year (QALY), and they found that "the probability of the Assay being cost-effective compared to the SOC was 57.3% at the $100,000/QALY acceptability threshold" (Hao et al., 2019).

Eluri et al. (2018) aimed to validate a genomic panel intended to represent tumor mutational load (TML). Previously, the authors evaluated a panel of 10 genomic loci from which a TML score was calculated. This mean TML was found to be significantly higher in 23 BE patients that had progressed to high-grade dysplasia (HGD) or esophageal adenocarcinoma (EAC) as compared to 46 that had not progressed. The area under the curve in this prior study was found to be 0.95 at a mutational load (ML) cutoff of 1 (on a scale of 1-10). In the present study, 159 subjects were included. Cases had "baseline nondysplastic BE (NDBE) and developed HGD/EAC ≥ 2 years later." 58 subjects were progressors and 101 were nonprogressors. The authors identified no difference in mean ML in pre-progression tissue in both cohorts (ML = 0.73 ± 0.69 vs. ML = 0.74 ± 0.61). The area under the curve at the cutoff of ML 1 was only 0.50, and the authors concluded that the "utility of the ML to stratify BE patients for risk of progression was not confirmed in this study" (Eluri et al., 2018).

Trindade et al. (2019) evaluated tumor mutational load's (ML) ability to "risk-stratify those that may progress from non-dysplastic BE to dysplastic disease". 28 patients were included, and ML levels were compared between those that progressed to

dysplasia and those who had not. Eight total patients progressed to dysplasia (6 low-grade, 2 high-grade), and seven of these patients had "some level" of genomic stability detected (ML ≥.5 on a scale of 1 to 10). Ten of the 20 patients that did not progress to dysplasia had "no" ML level. The authors also noted that at an ML of ≥1.5, the risk of progression to high-grade dysplasia was 33%, with a sensitivity of 100% and specificity of 85%. The authors concluded "that ML may be able to risk-stratify progression to high-grade dysplasia in BE-IND. Larger studies are needed to confirm these findings" (Trindade et al., 2019).

Moinova et al. (2018) evaluated the ability of two DNA methylation signatures to detect BE. Methylation signatures of the *VIM* and *CCNA1* loci were evaluated in 173 patients with or without BE. *CCNA1* methylation was found to have an area under the curve of 0.95 for distinguishing BE-related dysplasia compared to normal esophagi. When the data for *VIM* methylation was added, the resulting sensitivity was 95%, and the resulting specificity was 91%. These findings were replicated in a validation cohort of 86 patients, with the combination of methylation markers detecting BE metaplasia at 90.3% sensitivity and 91.7% specificity (Moinova et al., 2018).

Critchley-Thorne et al. (2016) validated a pathology panel to predict progression of BE to esophageal cancer. The authors identified 15 potential biomarkers, which were evaluated in both training and validation sets. This "classifier" separated patients into three different risk classes: low, intermediate, and high in the training set of 183. The authors calculated the hazard ratio of intermediate to low risk at 4.19 and high to low at 14.73. In the validation set (n = 183), the concordance index (an estimation of area under the curve) of the 15-factor classifier was 0.772, the best of the amounts tested (3, 6, 9, 12, 15, 17). The authors also noted that this classifier provided independent prognostic information that were outperformed predictions based on other clinicopathological factors, such as segment length, age, and p53 overexpression (Critchley-Thorne et al., 2016).

Another multicenter study investigated the use of WATS^{3D} with either random or targeted FB in the detection of esophageal dysplasia (ED). A total of 12,899 patients were enrolled in the study, and WATS^{3D} detected an additional 213 cases of ED beyond the initial 88 cases identified by FB, representing an increase of 242%. Regarding screening for BE, WATS increased the overall detection by 153% (from 13.1% to 33% of the individuals enrolled). The authors noted that the order of testing (e.g., FB or WATS) did not impact the results. The authors conclude, "In this study, comprised of the largest series of patients evaluated with WATS, adjunctive use of the technique with targeted and random FB markedly improved the detection of both ED and BE. These results underscore the shortcomings of FB in detecting BE-associated neoplasia, which

can potentially impact the management and clinical outcomes of these patients" (Smith et al., 2019).

A study into the cost-effectiveness of WATS^{3D} testing as an adjunct to the standard-of-care forceps biopsy (FB) used a reference case of a 60-year-old individual with gastroesophageal reflux disease (GERD) to see the number of screens needed to avert one cancer and one cancer-related death as well as to calculate the quality-adjusted life years (QALYs) as measured in 2019 U.S. dollars. With this as a reference case, 320 – 337 individuals would need to be screened using WATS^{3D} to avert one cancer, and 328 – 367 individuals would be required to avert one death. The additional cost associated with WATS^{3D} was $1219, but an additional 0.017 QALYs were produced, resulting in an ICER of $71395/QALY. The authors concluded that screening for BE in certain GERD patients "is more cost-effective when WATS^{3D} is used adjunctively to the Seattle protocol than with the Seattle protocol alone" (Singer & Smith, 2020).

One study compared the use of the WATS^{3D} technology to standard forceps biopsy. A total of 117 individuals with a history of Barrett's esophagus with dysplasia had both techniques performed. For the biopsy, a four-quadrant biopsy quadrant protocol was performed every 1 – 2 cm. Evaluation of the biopsy and the WATS^{3D} technique was performed by separate pathologists, blinded to each other's results. Moreover, "Brush biopsy [WATS^{3D}] added an additional 16 position cases increasing the yield of dysplasia detection by 42% (95% CI: 20.7 – 72.7). The number needed to test (NNT) to detect one additional case of dysplasia was 9.4 (95% CI: 6.4 – 17.7)." The authors of the study noted that no statistical difference was evident between medical centers, the type of forceps used, or between sampling every 1 cm versus every 2 cm. They conclude, "These data suggest that computer-assisted brush biopsy is a useful adjunct to standard endoscopic surveillance regimens for the identification of dysplasia in Barrett's esophagus" (Anandasabapathy et al., 2011).

Another multicenter prospective trial of 4203 patients studied the use of WATS^{3D} as an adjunct to four-quadrant random forceps biopsy (FB) in detecting Barrett's esophagus (BE) and esophageal dysplasia (ED). FB alone detected 594 cases of BE, and the addition of WATS^{3D} detected an additional 493 cases, an increase of 83%. Likewise, WATS^{3D} detected an increase of 88.5% of low-grade dysplasia (LGD). The authors concluded that "Adjunctive use of WATS to FB significantly improves the detection of both BE and ED. Sampling effort, an inherent limitation associated with screening and surveillance, can be improved with WATS allowing better informed decisions to be made about the management and subsequent treatment of these patients" (Gross et al., 2018). These findings support the earlier study by Johanson and colleagues. In their study of 1266 patients being screened for BE and ED, they noted an overall increase of 39.8% in the detection of BE when WATS^{3D} (brush biopsy or BB) was used as an adjunct

to FB. They also report that the number of patients needed to test (NNT) to obtain a positive BE result was 8.7. Interestingly, specifically for patients with gastroesophageal reflux disease (GERD), the addition of WATS^{3D} resulted in an even higher increase in the detection of BE (by 70.5%) (Johanson et al., 2011).

Vennalaganti et al. (2018) published a randomized trial at 16 different medical centers (n = 160 patients) compared the order of testing (WATS^{3D} followed by biopsy sampling versus biopsy sampling followed by WATS^{3D}) to detect high-grade dysplasia/esophageal adenocarcinoma (HGD/EAC). The authors also stated secondary aims of determining the amount of additional time required for WATS^{3D} and the ability of each procedure to separately detect neoplasia. The order of the procedures was not statistically relevant. The use of WATS^{3D} as an adjunct to biopsy did result in a 14.4% absolute increase in the number of HGD/EAC cases detected. The authors noted that WATS^{3D}, on average, adds 4.5 minutes to the total procedure time. They conclude that "Results of this multicenter, prospective, randomized trial demonstrate that the use of WATS in a referral BE population increases the detection of HGD/EAC" (Vennalaganti et al., 2018).

Diehl et al. (2021) studied the impact of TissueCypher Barrett's esophagus (BE) assay on clinical decisions in the management of BE patients. TissueCypher was ordered for 60 patients with BE and the impact of the test was assessed. TissueCypher results impacted 55.0% of management decisions, resulting in either upstaging or downstaging of treatment. The authors note that "In 21.7% of patients, the test upstaged the management approach, resulting in endoscopic eradication therapy (Wechsler et al.) or shorter surveillance interval. The test downstaged the management approach in 33.4% of patients, leading to surveillance rather than EET. In the subset of patients whose management plan was changed, upstaging was associated with a high-risk TissueCypher result, and downstaging was associated with a low-risk result" (Diehl et al., 2021). The authors conclude that TissueCypher will help target EET for high risk patients and reduce unneeded procedures in low risk patients (Diehl et al., 2021).

Wechsler et al. (2021) studied the clinical utility of noninvasive biomarkers to identify EoE in children and predict esophageal eosinophilia. Blood/urine was collected from 183 children and several biomarkers were measured including Absolute eosinophil count (AEC), plasma eosinophil-derived neurotoxin (EDN), eosinophil cationic protein (ECP), major basic protein-1 (MBP-1), galectin-10 (CLC/GAL-10), Eotaxin-2 and Eotaxin-3, and urine osteopontin (OPN) and matrix metalloproteinase-9 (MMP-9). According to the results, all plasma and urine biomarkers were in increased in EoE. A panel that included all the other biomarkers was superior to measuring only AEC alone. AEC, CLC/GAL-10, ECP, and MBP-1 were significantly decreased in patients with esophageal eosinophil counts <15/hpf in response to treatment. AEC combined with MBP-1 best

predicted the esophageal eosinophil counts. The authors conclude that eosinophil-associated proteins along with AEC are superior to AEC alone in distinguishing EoE and predicting eosinophil counts (Wechsler et al., 2021).

VI. Guidelines and Recommendations

United European Gastroenterology (UEG), The European Society of Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN), the European Academy of Allergy and Clinical Immunology (EAACI), and the European Society of Eosinophilic Oesophagitis (EUREOS)

These joint guidelines were published by a task force of 21 physicians and researchers for eosinophilic esophagitis (EoE). In it, they note that noninvasive biomarkers (inflammatory factors, total IgE, chemokines, tryptase, et al) are "not accurate" to diagnose or monitor EoE. They remark that absolute serum eosinophil count fared best in correlating with severity of disease but had a diagnostic accuracy of 0.754. The guidelines state that histology is necessary for monitoring. The String Test was also mentioned as having good preliminary results but required further corroboration (Lucendo et al., 2017).

American Gastroenterological Association (AGA) and the Joint Task Force on Allergy-Immunology Practice Parameters (JTF) guideline

Regarding allergy-based testing for the purpose of identifying food triggers in patients with Eosinophilic Esophagitis, the AGA/JTF suggest an allergy-based elimination diet over no treatment. The task force notes that "due to the potential limited accuracy of currently available, allergy-based testing for the identification of specific food triggers, patients may prefer alternative medical or dietary therapies to an exclusively testing-based elimination. An important limitation of the studies available so far "involves the degree of inconsistency due to different testing techniques (e.g., skin-prick testing, serum-specific IgE testing, patch testing, or combinations of these) used in different studies." Additionally, a "sensitivity analysis failed to show any statistically significant difference between studies that used patch testing and those that did not" (Hirano et al., 2020).

Updated International Consensus Diagnostic Criteria for Eosinophilic Esophagitis: Proceedings of the AGREE Conference

These newly published international diagnostic criteria primarily include endoscopic findings. Although the guidelines emphasize ruling out other diagnoses (in which biomarkers may be useful), it does not mention any serum or genetic factors for EoE itself (Dellon et al., 2018).

National Comprehensive Cancer Network (NCCN)

The NCCN notes four syndromes that predispose to an increased risk for esophageal and esophagogastric junction (EGJ) cancers; tylosis with non-epidermolytic palmoplantar keratoderma (PPK) with esophageal cancer (including Howel-Evans syndrome), familial Barrett esophagus (FBE), Bloom Syndrome (BS, *BLM* gene*)*, and Fanconi Anemia (FA, *FANC A-E genes*). The *RHBDF2* gene has been associated with tylosis (with non-epidermolytic palmoplantar keratosis) for genetic risk assessment.

Though FBE may be associated with "one or more autosomally inherited dominant susceptibility alleles," no gene has been validated. With regards to next-generation sequencing, the NCCN concludes that "when limited tissue is available for testing, or the patient is unable to undergo a traditional biopsy, sequential testing of single biomarkers or use of limited molecular diagnostic panels may quickly exhaust the sample. In these scenarios, comprehensive genomic profiling via a validated NGS assay performed in a CLIA-approved laboratory may be used for the identification of *HER2* amplification, MSI [microsatellite instability], MMR deficiency, TMB, *NTRK* gene fusions, *RET* gene fusions, and *BRAF v600E* mutations. The use of IHC/ISH/targeted PCR should be considered first followed by NGS testing when appropriate"(NCCN, 2024).

Under microsatellite instability (MSI) and mismatch repair testing, the NCCN recommends "universal testing for MSI by polymerase chain reaction (PCR), NGS, or MMR by IHC should be performed for all newly diagnosed esophageal and EGJ cancers."

For squamous cell carcinoma, the NCCN recommends performing universal testing for microsatellite instability (MSI) by PCR/NGS or MMR by IHC in all newly diagnosed patients. It is also recommended that PD-L1 testing (if not done previously) if advanced/metastatic cancer is suspected. They also note that NGS may be considered via validated assay (NCCN, 2024).

Liquid biopsy aids in identifying genetic mutations in solid cancers by looking at circulating tumor DNA (ctDNA) in blood and can be used in those with advanced disease who cannot undergo clinical biopsies for disease surveillance and management. Detecting mutations in DNA from esophageal and EGJ carcinomas "can identify targetable alterations or the evolution of clones with altered treatment response profiles." The NCCN has also stated that "a negative result should be interpreted with caution, as this does not exclude the presence of tumor mutations or amplifications" (NCCN, 2024).

The NCCN notes that "testing for MSI by PCR/NGS or MMR [mismatch repair] by IHC should be considered on locally advanced, recurrent, or metastatic esophageal and EGJ

cancers in patients who are candidates for treatment with programmed cell death protein 1 (PD-1) inhibitors."

The NCCN also identifies several targeted therapeutic agents currently approved by the FDA: trastuzumab, pembrolizumab/nivolumab, and entrectinib/larotrectinib. Trastuzumab is based on *HER2* overexpression (NCCN notes that an approved biologic or biosimilar drug to trastuzumab is also appropriate for use) and pembrolizumab can also be added to the regimen for treating *HER2*, notwithstanding any contraindications.

Treatment with trastuzumab is based on testing for *HER2* expression. Treatment with pembrolizumab or nivolumab is based on "testing for MSI by PCR/NGS or MMR by IHC, PD-L1 expression by IHC, or high TMB by NGS." Select TRK inhibitors have also been FDA-approved for *NTRK* gene fusion-positive tumors. Additionally, selpercatinib can be used therapeutically for *RET* gene-related tumors and dabrafenib/trametinib for tumors with *BRAF V600E* mutations (NCCN, 2024).

Genetic biomarkers such as aneuploidy and loss of p53 heterozygosity have been proposed as useful for identifying increased risk of progression in BE patients, but the NCCN remarks that these biomarkers require "further prospective evaluation as predictors of risk for the development of HGD [high-grade dysplasia] and adenocarcinoma of the esophagus in patients with Barrett esophagus" (NCCN, 2024).

The NCCN notes that wide-area transepithelial sampling (WATS) has been used to detect esophageal carcinomas in BE patients. They state, "The use of wide-area transepithelial sampling with computer-assisted 3-dimensional analysis (WATS3D), a relatively new sampling technique combining an abrasive brush biopsy of the Barrett esophagus mucosa with computer-assisted pathology analysis to highlight abnormal cells, may help increase the detection of esophageal dysplasia in patients with Barrett esophagus." They go on to cite the 2017 study by Vennalaganti and colleagues that shows a 14.4% increase in the number of additional cases of HGD/esophageal adenocarcinoma captured by using WATS. However, the NCCN remarks that the "utility and accuracy of WATS for detecting HGD/adenocarcinoma in patients with Barrett esophagus needs to be evaluated in larger phase III randomized trials" (NCCN, 2024).

American Society for Gastrointestinal Endoscopy (ASGE)

The ASGE recommends the use of WATS3D as an adjunct to "Seattle protocol biopsy sampling" in patients with known or suspected BE (conditional recommendation, low quality of evidence). The society stated that they had downrated the certainty of the recommendation due to possible risk bios, insistency, and indirectness of the studies that were available at the time of publication since some of the studies had included

LGD (whereas others had not) and many of the studies had been sponsored by the test's manufacturer. The society also had noted that, as of the date of publication, no studies addressing the cost-effectiveness of WATS-3D had been published. (Qumseya et al., 2019) It should be noted that since the publication of these guidelines the 2020 cost-effectiveness study by Singer and Smith (2020) has been published.

Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) Technology and Value Assessment Committee (TAVAC)

The TAVAC of SAGES evaluated WATS^{3D} and published their findings and recommendations within the journal *Surgical Endoscopy* in 2020. They note that WATS^{3D} is not recommended "as a stand-alone substitute for cold forcep biopsies." Within their expert panel recommendation section:

- They state that no significant morbidity or mortality is associated with the testing.
- They also state that "WATS^{3D} increases diagnostic yield by 38 – 150% for Barrett's Esophagus, by 40 – 150% for Low Grade Dysplasia; and by 420% for High Grade Dysplasia; when compared to forceps biopsy alone."
- WATS^{3D} testing also "has very high inter-observer agreement for the pathological diagnosis of non-dysplastic and dysplastic Barrett's Esophagus."

Regarding value, "Increased detection of pre-malignant diseases of the esophagus by the adjunctive use of WATS^{3D} supports screening and surveillance by the adjunctive use of WATS^{3D} during upper endoscopy in appropriate patients" (Docimo et al., 2020).

American Foregut Society (AFS)

The AFS published a white paper reviewing WATS^{3D} in 2020. After reviewing the literature, they state, "The American Foregut Society (AFS) Board has concluded that there are sufficient data to support the routine use of WATS^{3D} technology in the diagnosis and ongoing evaluation of Barrett's esophagus" (AFS, 2021).

American College of Gastroenterology (ACG)

In 2022, the ACG updated the Barrett's Esophagus guideline and offered recommendations for the diagnosis, screening, surveillance, and endoscopic and medical therapy of BE. No recommendations were made regarding chemoprevention or use of "biomarkers" in routine practice due to "insufficient data."

Studies do suggest that "biomarkers may be better than routine histology alone" in helping to predict the progression of cancer. However, the ACG notes that no single prediction tool or panel to predict disease progression has been established as having

clear clinical utility. There have not been sufficient studies to evaluate the combination of clinical and biomarker variables.

The ACG could not recommend "routine use of p53 IHC or TissueCypher for risk stratification in patients with BE undergoing surveillance" due to unclear clinical validity (Shaheen et al., 2022).

However, the panel did not completely dissuade providers from the use of biomarkers under certain conditions since the predictive performance "has been shown to be better in some cases than the histologic diagnosis." In the future, and with more clinical studies, this may mean that biomarkers could have predictive value in a subset of patients with BE without dysplasia (Shaheen et al., 2022).

European Society for Medical Oncology (ESMO)

No form of molecular testing for diagnosis or risk assessment of esophageal cancer is mentioned in the ESMO 2022 guideline (Obermannová et al., 2022). The 2022 guideline does include a supplementary table listing biomarkers and molecular targets for precision medicines and corresponding scores for outcomes (ESMO, 2022):

Biomarker or genomic alteration	**Method of detection**	**Drug match**	**ESCAT score**
HER2	IHC for *HER2* protein expression or ISH for *HER2* gene amplification	Anti-*HER2* antibodies (e.g. trastuzumab)	I-A (alteration-drug match is associated with improved outcome with evidence from randomised clinical trials showing the alteration-drug match in a specific tumour type results in a clinically meaningful improvement of a survival end point)

PD-L1	Combined Positive Score (CPS) or Tumour Positive Score (TPS)	PD-1 inhibitors (e.g. pembrolizumab, nivolumab)	
MSI	High Microsatellite Instability (MSI-H)	PD-1 inhibitors (e.g. nivolumab, pembrolizumab)	I-C (alteration-drug match is associated with improved outcome with evidence from clinical trials across tumour types or basket clinical trials showing clinical benefit associated with the alteration-drug match, with similar benefit observed across tumour types)

(Obermannová et al., 2022)

Pan-Asian adapted ESMO Clinical Practice Guidelines: a JSMO-ESMO initiative endorsed by CSCO, KSMO, MOS, SSO and TOS

The only biomarker mentioned in these guidelines is *HER2*; intended "to select patients with metastatic esophageal adenocarcinoma for treatment with…trastuzumab." The guidelines go on to state that evidence for the role of other biomarkers or agents is "limited" (Muro et al., 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81194	NTRK (neurotrophic receptor tyrosine kinase 1, 2, and 3) (eg, solid tumors) translocation analysis
81301	Microsatellite instability analysis (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) of markers for mismatch repair deficiency (eg, BAT25, BAT26), includes comparison of neoplastic and normal tissue, if performed
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-**10** exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-**10** exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of **11**-**25** exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of **11**-**25** exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of **26**-**50** exons)
81479	Unlisted molecular pathology procedure
88104	Cytopathology, fluids, washings or brushings, except cervical or vaginal; smears with interpretation
88112	Cytopathology, selective cellular enhancement technique with interpretation (eg, liquid based slide preparation method), except cervical or vaginal
88160	Cytopathology, smears, any other source; screening and interpretation
88271	Molecular cytogenetics; DNA probe, each (eg, FISH)
88272	Molecular cytogenetics; chromosomal in situ hybridization, analyze 3-5 cells (eg, for derivatives and markers)
88273	Molecular cytogenetics; chromosomal in situ hybridization, analyze 10-30 cells (eg, for microdeletions)
88274	Molecular cytogenetics; interphase in situ hybridization, analyze 25-99 cells

CPT	CPT Description
88275	Molecular cytogenetics; interphase in situ hybridization, analyze 100-300 cells
88305	Level IV - Surgical pathology, gross and microscopic examination
88312	Special stain including interpretation and report; Group I for microorganisms (eg, acid fast, methenamine silver)
88341	Immunohistochemistry or immunocytochemistry, per specimen; each additional single antibody stain procedure (List separately in addition to code for primary procedure)
88342	Immunohistochemistry or immunocytochemistry, per specimen; initial single antibody stain procedure
88344	Immunohistochemistry or immunocytochemistry, per specimen; each multiplex antibody stain procedure
88360	Morphometric analysis, tumor immunohistochemistry (eg, Her-2/neu, estrogen receptor/progesterone receptor), quantitative or semiquantitative, per specimen, each single antibody stain procedure; manual
88361	Morphometric analysis, tumor immunohistochemistry (eg, Her-2/neu, estrogen receptor/progesterone receptor), quantitative or semiquantitative, per specimen, each single antibody stain procedure; using computer-assisted technology
88367	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; initial single probe stain procedure
88368	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; initial single probe stain procedure
88369	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; each additional single probe stain procedure (List separately in addition to code for primary procedure)
88373	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; each additional single probe stain procedure (List separately in addition to code for primary procedure)
88374	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; each multiplex probe stain procedure
88377	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; each multiplex probe stain procedure
0095U	Inflammation (eosinophilic esophagitis), ELISA analysis of eotaxin-3 (CCL26 [C-C motif chemokine ligand 26]) and major basic protein (PRG2

CPT	CPT Description
	[proteoglycan 2, pro eosinophil major basic protein]), specimen obtained by swallowed nylon string, algorithm reported as predictive probability index for active eosinophilic esophagitis Proprietary test: Esophageal String Test™ (EST) Lab/Manufacturer: Cambridge Biomedical, Inc.
0108U	Gastroenterology (Barrett's esophagus), whole slide–digital imaging, including morphometric analysis, computer-assisted quantitative immunolabeling of 9 protein biomarkers (p16, AMACR, p53, CD68, COX-2, CD45RO, HIF1a, HER-2, K20) and morphology, formalin-fixed paraffin-embedded tissue, algorithm reported as risk of progression to high-grade dysplasia or cancer Proprietary test: TissueCypher® Barrett's Esophagus Assay Lab/Manufacturer: Cernostics
0114U	Gastroenterology (Barrett's esophagus), VIM and CCNA1 methylation analysis, esophageal cells, algorithm reported as likelihood for Barrett's esophagus Proprietary test: EsoGuard™ Lab/Manufacturer: Lucid Diagnostics
0398U	Gastroenterology (Barrett esophagus), P16, RUNX3, HPP1, and FBN1 DNA methylation analysis using PCR, formalin-fixed paraffin-embedded (FFPE) tissue, algorithm reported as risk score for progression to high-grade dysplasia or cancer Proprietary test: ESOPREDICT® Barrett's Esophagus Risk Classifier Assay Lab/Manufacturer: Capsulomics, Inc d/b/a Previse

X. Revision History

Revision Date	Summary of Changes

Fibromyalgia Testing

Policy Number: AHS –M2177 – Fibromyalgia Testing	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Fibromyalgia is a chronic diffuse pain condition and the most common cause of chronic widespread musculoskeletal pain (Goldenberg, 2023a). It is also known by "diffuse myofascial pain syndrome," "fibromyalgia-fibromyositis syndrome," or "fibromyalgia syndrome" (Ada, 2022). FM has The etiology and pathophysiology of FM is generally unknown, but it can be found with "fatigue, cognitive disturbance psychiatric symptoms, and multiple somatic symptoms;" however, presentation may vary from patient to patient (Goldenberg, 2023a; Kimura & Walco, 2023). Controversy has arisen regarding the disease origin, as it has been considered to be psychogenic or psychosomatic, but recent research indicates it as a disorder of pain regulation, a form of "central sensitization" (Goldenberg, 2023a).

Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS-G2155	General Inflammation Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

1) For the diagnosis of fibromyalgia or chronic pain syndromes, the following tests **DO NOT MEET COVERAGE CRITERIA**:
   a) Genetic testing (e.g., mutation analysis, copy number variants, epigenetic analysis, mRNA expression, miRNA expression).
   b) Biomarker panel testing with proprietary algorithms and/or index scores (e.g., FM/a®, NutrEval FMV®).

IV. Table of Terminology

Term	Definition
5HT	Serotonin
5-HT2A	Serotonin 2A
A1AT	Alpha-1 antitrypsin
AAPT	American Pain Society Pain Taxonomy
ACE I/D	*Angiotensin-converting enzyme I/D polymorphism*
ACR	American College of Rheumatology
ACTTION	Analgesic, Anesthetic, and Addiction Clinical Trial Translations Innovations Opportunities and Networks
ADRA1A	*Adrenoreceptor alpha 1A gene*
ADRB2	*Adrenoreceptor beta 2 gene*
ADRB3	*Adrenoreceptor beta 3 gene*
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
ANS	Autonomic nervous system
APS	American Pain Society
BDNF	*Brain derived neurotrophic factor gene*
CB-1	Cannabinoid receptor type 1
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers for Medicare and Medicaid Services
CNR1	*Cannabinoid receptor 1 gene*
CNS	Central nervous system
CNV	Copy number variant
COMT	*Catecholamine o-methyl transferase gene*
CRA	Canadian Rheumatology Association
CRP	C-reactive protein
CSF	Cerebrospinal fluid

CWP	Chronic widespread pain
DNA	Deoxyribonucleic acid
DRD3	*Dopamine receptor D3 gene*
EDN1	*Endothelin 1 gene*
ESR	Erythrocyte sedimentation rate
FDA	Food and Drug Administration
FIQ	Fibromyalgia-Impact Questionnaire
FM	Fibromyalgia
GABRB3	*Gamma-aminobutyric acid receptor subunit beta-3 gene*
GBP1	*Guanylate binding protein 1 gene*
GCH1	*Guanosine triphosphate (GTP) cyclohydrolase 1 gene*
GERD	Gastroesophageal reflux disease
GRIA4	*Glutamate ionotropic receptor AMPA type subunit 4 gene*
HLA-DRB1	*Human leukocyte antigen DR beta 1 gene*
HTR2A	*5-Hydroxytryptamine Receptor 2A gene*
HTR3A	*5-Hydroxytryptamine Receptor 3A gene*
HTR3B	*5-Hydroxytryptamine Receptor 3B gene*
IBS	Irritable bowel syndrome
IFN-γ	Interferon-γ
IGHV1OR21-1	Immunoglobulin domain-containing like protein
IGLV3-25	Immunoglobulin lambda variable 3-25
IL-10	Interleukin-10
IL1RAP	Interleukin-1 receptor accessor protein
IL-4	*Interleukin-4 gene*
IL-5	Interleukin-5
IL-6	Interleukin-6
IL-8	Interleukin-8
LDTs	Laboratory-developed tests
MAOA	*Monoamine oxidase A gene*
MAPK	Mitogen-activated protein kinase
MCP-1	Monocyte chemoattractant protein-1
MEFV	*Mediterranean fever gene*
METTL18	Methyltransferase-like 18
MIP-1β	Macrophage inflammatory protein-1β
MSP	Multisite pain
MTHFR	*Methylenetetrahydrofolate reductase gene*
MYT1L	*Myelin transcription factor 1 like gene*
NA	Noradrenaline

NRXN3	*Neurexin 3 gene*
OPRM1	*Opioid receptor mu 1 gene*
PBMC	Plasma and peripheral blood mononuclear cells
PHA	Phytohemagglutinin
PMA	Phorbol-12-myristate-13-acetate
RA	Rheumatoid arthritis
RGS4	*Regulator of G protein signaling 4 gene*
SCL-90	Symptom Checklist-90 for Psychopathological Disorders
SCN9A	Sodium voltage-gated channel alpha subunit 9 gene
SLC64A4	*Solute carrier family 64 member 4 gene*
SERPINA1	*Serpin family A member 1 gene*
SLE	Systemic lupus erythematosus
SNPs	Single nucleotide polymorphisms
SS	Sjögren syndrome
TAAR1	*Trace amine-associated receptor 1 gene*
TACR1	*Tachykinin receptor 1 gene*
TMD	Temporomandibular joint disorder
TPC	Tender point count
TPQ	Tridimensional Personality Questionnaire
TRPV2	*Transient receptor potential vanilloid channel 2 gene*
TRPV3	*Transient receptor potential vanilloid channel 3 gene*
TSH	Thyroid stimulating hormone
TSPO	*Translocator protein gene*
WPI	Widespread pain index

V. Scientific Background

Fibromyalgia (FM) is a condition characterized by chronic and diffuse non-inflammatory musculoskeletal pain. FM is often accompanied by fatigue, cognitive disturbances (“fibro fog”), psychiatric symptoms, and multiple other nonspecific somatic symptoms (Galvez-Sánchez & Reyes Del Paso, 2020; Goldenberg, 2023a). Aside from the secondary symptoms, patients may at times experience abdominal and chest wall pain, irritable bowel syndrome (IBS), gastroesophageal reflux disease (GERD), and symptoms of autonomic nervous system (ANS) dysfunction. Despite this, FM is generally of unknown etiology and pathophysiology. However, FM should be considered as a diagnosis in patients experiencing idiopathic chronic pain for at least three months and is solely confirmed by a clinical, symptom-based assessment (D'Agnelli et al., 2019). What adds to the controversial and mysterious nature of the condition is that it depends on subjective symptoms. On a normal physical examination, patients often appear well and do not show abnormalities other than

"widespread soft tissue tenderness" with normal laboratory and radiologic studies, making it a common but elusive diagnosis. However, a history of other medical conditions that cause musculoskeletal pain can coexist with or mimic FM like rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), and thyroid disease. Medical history can support a FM diagnosis (Goldenberg, 2023a). FM is more commonly diagnosed in women than men. The prevalence of FM in the United States and other countries is about two to three percent and incidence tends to increase with age (Bhargava & Hurley, 2020). FM can also be diagnosed in adolescents in the form of juvenile primary fibromyalgia, and it is confirmed mostly symptomatically but based on slightly different diagnostic criteria for research and epidemiological purposes (Kimura & Walco, 2023).

Fibromyalgia is categorized as a "disorder of pain regulation," under "central sensitization" (Goldenberg, 2023b). This finding is supported by biochemical abnormalities that are oftentimes present in FM patients: low concentrations of metabolites of serotonin (5HT) and noradrenaline (NA), and high concentrations of substance P and nerve growth factors (Julien et al., 2005). Patients are more sensitive to central nervous system inputs of pain, and those with FM at times can experience symptoms like those suffering from other central pain disorders, like migraines, IBS, and temporomandibular joint disorder (TMD) (Goldenberg, 2023b). Reduced 5HT and NA may actually account for the widespread pain symptoms by contributing to the dysfunction of endogenous systems that inhibit pain sensation (Julien et al., 2005).

Contrary to the established findings published about FM, recent research has demonstrated that there is a possible genetic basis to the disease progression; up to 50% of disease risk can be attributed to candidate genes (D'Agnelli et al., 2019). There also appears to be a strong familial predisposition to FM, although it is suspected to have a more polygenic mode of inheritance (Arnold et al., 2019; Buskila et al., 2007). However, there is no singular definitive gene that directly causes FM; several genes under consideration include *SLC64A4, TRPV2, MYT1L,* and *NRXN3* (D'Agnelli et al., 2019). Single nucleotide polymorphisms (SNPs) in the *SLC64A4* gene, which encodes a sodium-dependent serotonin transporter, has been associated with both FM and TMD. *SLC64A4* mutations that cause increased serotonin reuptake have been associated with high levels of depression and psychological disorders, as well as "SCL-90 [Symptom Checklist-90 for psychopathological disorders] scores for somatic awareness and anger, TPQ [tridimensional personality questionnaire] harm avoidance trait, increased salivary cortisol level, [and] increased leukocyte count" (D'Agnelli et al., 2019; Diatchenko et al., 2013). *TRPV2* (transient receptor potential vanilloid channel 2) gene is needed for not only cell cycle progression, growth, and differentiation of hematopoietic stem cells and innate immunity, but also the pain threshold due to its presence in the mechanoresponsive and thermo-responsive neurons in the dorsal root

and trigeminal ganglia (D'Agnelli et al., 2019; Mickle et al., 2015; Santoni et al., 2013). Genetic correlations in FM between mutations in *SLC6A4* and *TRPV2*, which encodes a calcium-permeable channel that is heat-activated and modulates many cellular functions, are further supported by linkage analysis done with FM to the chromosome 17p11.2-q11.2 region, which happens to house the two genes (Arnold et al., 2013; Kojima & Nagasawa, 2014).

Docampo et al. (2014) discovered that the rs11127292 polymorphism in the *MYT1L* (myelin transcription factor 1 like) gene, which is critical in the process of neuronal differentiation and has historically been associated with neuropsychiatric disorders, and an intronic CNV (copy number variant) in the *NRXN3* (neurexin 3) gene, which is involved in signal transmission by promoting synapse stability and function, affect the central nervous system (CNS) aspect of FM as well (Docampo et al., 2014).

Studies have also examined the differences in other allelic frequencies and influence of genetics on the sequelae of FM progression. Smith et al. (2012) identified significant variations in allelic frequency of *GABRB3* (rs4906902), *TAAR1* (rs8192619), and *GBP1* (rs7911) between FM patients and controls. *TAAR1* was demonstrated to alter dopamine bioavailability and function, which may cause the increased pain sensitivity seen in FM. *RGS4*, *CNR1*, and *GRIA*4 were implicated in other cohorts from the study by Smith et al. (2012), and are genes primarily involved in mechanisms of analgesia and central sensitivity as well. *RGS4*, which is expressed in the CNS regions like the dorsal horn of the spinal cord and the locus coeruleus, influences opioid receptor function when overexpressed. *CNR1*, which encodes the CB-1 cannabinoid receptor, has been indirectly utilized in FM treatment by the cannabinoid receptor agonist nabilone. Low *CNR1* expression and thus low CB-1 receptor activity may pose as a strong candidate for future testing, as several FM patients have increased circulating anandamide, an endocannabinoid, which has been hypothesized to underlie the pain in conditions like FM. Alterations to the *GRIA4* gene affect AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors, which play roles in the pain and comorbidities associated with FM (Smith et al., 2012).

Another gene commonly associated with FM is the *COMT* (catecholamine o-methyl transferase) gene. Though not directly affecting disease presentation, the *V158M* variant may contribute to subsequent depression, anxiety, and disability in many FM females (D'Agnelli et al., 2019). Mutations in the *COMT* gene are more closely linked to "pain catastrophizing, increased pain level during elevated pain attention, thermal and pressure sensitivity, psychological distress, increase number of tender points in TPC [tender point count], pain and positive affect interaction, and FIQ [fibromyalgia-impact questionnaire]-defined pain, fatigue, sleep, disturbance, morning stiffness, and disability" (Diatchenko et al., 2013). Similarly, mutations in the *HTR2A* (5-

hydroxytryptamine receptor 2A) gene, which encodes for its receptor, 5-HT2A, contributed to lower levels of total 5-HT in serum and CSF of FM patients (Park & Lee, 2017). The phenotype in FM more closely relates to psychological facets of FM – including reduced perception of environmental quality, "increased SCL-90-R total score and subscales scores for somatic awareness, anxiety, psychosis, obsessive-compulsive behavior, hostility, global severity index, interpersonal sensitivity, phobic anxiety, [and] depression" (Diatchenko et al., 2013).

Research has also demonstrated the role of epigenetics in FM phenotype and progression. Ciampi de Andrade et al. (2017) investigated DNA methylation states in samples obtained from FM cases and healthy controls, and found that the majority (1042 genes, 65%) of the differently methylated genes between the two were mostly hypomethylated. These genes were involved in "transduction and calcium signaling, MAPK signaling pathway, regulation of actin cytoskeleton endocytosis, and neuroactive ligand-receptor interaction pathways," and the sites that were identified were involved in DNA repair, immune system response and regulation, and membrane transport (D'Agnelli et al., 2019). Additionally, circulating miRNAs obtained from cerebrospinal fluid (CSF) and serum samples were found to be associated with many of the clinical symptoms of FM, including pain and fatigue, alterations in energy metabolism and growth, alterations in pain threshold, and sleep disturbance (Bjersing et al., 2015; Bjersing et al., 2013).

Proprietary Testing

The gradually progressing genetic and epigenetic findings for FM make biomarker testing attractive to researchers and physicians to solidify an alternative nonclinical diagnosis for this debilitating disease. The FM/a® Test takes advantage of the understanding of the immunological biomarkers and genetic components of FM to develop a blood test for diagnosis (FM/a, 2020). Biomarkers assayed through this test were based on a study on levels of cytokines interferon-γ (IFN-γ), interleukin-5 (IL-5), IL-6, IL-8, IL-10, macrophage inflammatory protein-1β (MIP-1β) , monocyte chemoattractant protein-1 (MCP-1), and MIP1-α obtained from samples of plasma and peripheral blood mononuclear cells (PBMC) with/without mitogenic activator treatment (Behm et al., 2012). Results identified that there was no statistically significant difference in these cytokines between FM samples and controls. However, when phytohemagglutinin (PHA), which induces PBMC proliferation and cytokine secretion, phorbol-12-myristate-13-acetate (PMA), and ionomycin, which "stimulate PBMCs and activate extracellular expressions of cytokines," were cultured with the blood samples, the concentrations of most cytokines in FM samples compared to normal samples were statistically significant, except for IL-5. This immunoassay indicated a connection to the coexisting diagnoses of FM with mental depression and

chronic pain, as both these populations tend to experience high pro-inflammatory cytokine levels as well (Behm et al., 2012).

Results supporting the FM/a® Test were further elucidated by Wallace et al. (2015), who looked into the cytokine and chemokine profiles in FM, rheumatoid arthritis, and systemic lupus erythematosus. Using the Luminex multiplex immunoassay bead array technology with mitogenic stimulation of PBMCs, cytokine concentrations for IL-6, IL-8, MIP-a, and MIP-b were recorded. Measures of analytical validity were done using a cytokine/chemokine composite test score. This measurement with all the cytokines/chemokines altogether was considered to have a sensitivity of 93%, a specificity of 89.4%, positive predictive value of 92%, and negative predictive value of 91% for the diagnosis of FM (Wallace et al., 2015).

Other researchers have opted for a proteomics approach to identify individuals with FM. Among females with FMS, Han et al. (2020) discovered dysregulated proteins and mechanisms associated with an FM diagnosis. They propose a panel of methyltransferase-like 18 (METTL18), immunoglobulin lambda variable 3-25 (IGLV3-25), interleukin-1 receptor accessor protein (IL1RAP), and putative V-set and immunoglobulin domain-containing like protein (IGHV1OR21-1) to differentiate FM from healthy controls. This conclusion was drawn from using a decision tree model that yielded an accuracy of 0.97. Collectively, they offered 100% detection sensitivity in their training cohort, and a specificity of 88% (Han et al., 2020).

Genova Diagnostics has also released the NutrEval FMV® Profile, which is a "blood and urine profile that evaluates over 125 biomarkers and assesses the body's functional need for 40 antioxidants, vitamins, minerals, essential fatty acids, amino acids, digestive support, and other select nutrients." NutrEval® aims to provide insight into conditions such as depression, anxiety, certain inflammatory conditions, and chronic pain syndromes (Genova, 2024). While there are no peer-reviewed studies published to confirm either the analytical or clinical utility of this particular proprietary test, researchers have delved into the biomarkers that comprise this assay. The aforementioned research on *COMT* proves relevant in the genomics component of this test. The clinical utility for the NutrEval® Profile is particularly pertinent to the chronic pain aspect. In patients with chronic pain, it was found that quinolinic acid, pyroglutamic acid (indicator of glutathione depletion), xanthurenic acid (indicator of vitamin B6 insufficiency), 3-hydroxyropyl mercapturic acid (acrolein metabolite), and methylmalonic acid (indicator of vitamin B12 deficiency) were all elevated to a certain degree among patients experiencing chronic pain. Seventy-seven percent of patients with chronic pain all had at least one abnormal biomarker (Gunn et al., 2020). This demonstrates that understanding the role of nutrition metabolism is necessary for

delineating the underlying processes of FM, a chronic pain condition, but additional research is needed.

Clinical Utility and Validity

Currently, most, if not all, of the FM diagnoses are solely clinical. Judgment is made subjectively and dependent on guidelines to conclude if subjective symptoms translate to FM. The sensitivity and specificity of utilizing the 2016 ACR guidelines, when compared to the 1990 criteria in a referral care setting, are 71% and 60%, respectively, with a positive predictive value of 85% and a negative predictive value of 39% (Ahmed et al., 2019). These statistical measures evidently prove that there need be more sensitive and specific measures beyond clinical symptoms for diagnosis of FM.

The clinical utility of an FM diagnosis extends beyond genetic testing and biomarkers; FM is also found concurrently among those with primary immunodeficiency and autoimmune diseases, such as RA, SLE, and Sjögren Syndrome (SS) (Han et al., 2020; Wilke, 1999). Confirming an FM diagnosis could aid in explicating the additional complications found in RA and SLE, such as "alternating constipation and diarrhea, urinary frequency, diffuse paresthesias, and cognitive difficulties." The converse also holds true – diagnoses of SS could prompt possible FM diagnoses as well, as seen in the cases of seeing sicca symptoms and tender point count of six (though not necessary with 2016 ACR guidelines) (Wilke, 1999).

Janssen et al. (2021) conducted a review that identified the polymorphisms related to FM and the respective clinical characteristics. From 27 articles, they found the relevant genes to be *MTHFR, RGS4, MYT1L, TACR1, SCN9A, DRD3, ADRB2, IL-4, HLA-DRB1, EDN1, CNR1, TAAR1, OPRM1, ADRA1A, ADRB3, BDNF, GRIA4, HTR3A, HTR3B, HTR2A, SERPINA 1 or A1AT, NRXN3, GCH1, MEFV, TRPV3, SLC6A4, ACE I/D, TSPO, COMT,* and *MAOA*. Additionally, "73.33% of the genes related to FM were also associated with some psychological disorders, such as anxiety, depression, schizophrenia, and obsessive and compulsive disorder, and 40.00% with pain sensitivity and/or migraine, besides other disorders associated (drug addiction, autoimmune disorders, circulatory problems, and metabolic alterations)." Of note, *SLC6A4, HTR3A, HTR3B,* and *HTRA* genes were associated with serotonergic regulation, chronic pain conditions, and anxiogenic situations; *COMT* was related to FM risk and increase in pain severity, increased likelihood of psychological disorders like "depression, anxiety and schizophrenia, alcoholism, opioid addiction, and eating disorders; *BDNF* was associated with hyperalgesia in FM; and *TACR1* was related to dementia and fatigue. As for treating FM, Janssen et al. (2021)also found that *TAAR1, RGS4, CNR1, GRIA4* may be considered as targets. These collective findings continue to demonstrate the

comorbidities associated with FM, and how understanding the genetic bases may aid in preventing and treating additional sequelae (Janssen et al., 2021).

Kendler et al. (2022) studied the familial genetic risk for functional somatic disorders including internalizing disorders, chronic fatigue syndrome, IBS, and FM. The study included 5,829,186 individuals in Sweden. The authors used a novel method that assessed aggregated risk in first to fifth degree relatives and adjusted for cohabitation. "Patients with FM carry substantial genetic risks not only for FM, but also for pain syndromes and internalizing, autoimmune and sleep disorders." Overall, patients with FM had a unique family risk genetic score with elevated genetic risk across other disorders; the was a similar but less marked pattern of genetic risks in patients of other functional somatic disorders. The authors suggest that the genetic risk score for FM differentiated it from classic autoimmune disorder and internalizing disorder (Kendler et al., 2022).

VI. Guidelines and Recommendations

American Pain Society

The Analgesic, Anesthetic, and Addiction Clinical Trial Translations Innovations Opportunities and Networks (ACTTION) partnership with the Food and Drug Administration (FDA) and APS created the ACTTION-APS Pain Taxonomy (AAPT) to help standardize clinically useful and consistent diagnoses of chronic pain disorders. First and foremost, all patients must have chronic pain to be diagnosed with FM. The working group members raised a concern of defining FM-pain as by the 1990 ACR criteria (CWP – chronic widespread pain) or the ACR 2010/2016 criteria of multisite pain (MSP), which were distinguished in count (MSP) versus anatomical distribution (CWP) of pain.

To facilitate identifying FM in clinical practice and in research, the AAPT core diagnostic criteria for FM are as follows:

1. "MSP defined as 6 or more pain sites from a total of 9 possible sites [head; left arm; right arm; chest; abdomen; upper back and spine; lower back and spine, including buttocks; left leg; and right leg]
2. Moderate to severe sleep problems OR fatigue
3. MSP plus fatigue or sleep problems must have been present for at least 3 months" (Arnold et al., 2019).

This guideline did not mention genetic testing for FM (Arnold et al., 2019).

American College of Rheumatology (ACR)

In 2016, the ACR published revisions to their 2010/2011 guidelines on preliminary diagnostic criteria for fibromyalgia and measurements of symptom severity. To satisfy a diagnosis of fibromyalgia, a patient must have:

1. "Widespread pain index (WPI) ≥ 7 and symptom severity (SS) scale score ≥ 5 or WPI 4-6 and SS scale score ≥ 9.
2. Generalized pain, defined as pain in at least 4 or 5 regions, must be present. Jaw, chest, and abdominal pain are not included in generalized pain definition.
3. Symptoms have been present at a similar level for at least 3 months.
4. A diagnosis of fibromyalgia is valid irrespective of other diagnoses. A diagnosis of fibromyalgia does not exclude the presence of other clinically important illnesses."

The table below obtained from the ACR's publication regarding ascertainment of WPI and SS is shown.

Ascertainment

(1) WPI: note the number of areas in which the patient has had pain over the last week. In how many areas has the patient had pain? Score will be between 0 and 19

Left upper region (Region 1)	*Right upper region (Region 2)*	*Axial region (Region 5)*
Jaw, left[a]	Jaw, right[a]	Neck
Shoulder girdle, left	Shoulder girdle, right	Upper back
Upper arm, left	Upper arm, right	Lower back
Lower arm, left	Lower arm, right	Chest[a]
		Abdomen[a]
Left lower region (region 3)	*Right lower region (Region 4)*	
Hip (buttock, trochanter), left	Hip (buttock, trochanter), right	
Upper leg, left	Upper leg, right	
Lower leg, left	Lower leg, right	

(2) Symptom severity scale (SSS) score

Fatigue
Waking unrefreshed
Cognitive symptoms

For the each of the 3 symptoms above, indicate the level of severity over the past week using the following scale:

0 = No problem
1 = Slight or mild problems, generally mild or intermittent
2 = Moderate, considerable problems, often present and/or at a moderate level
3 = Severe: pervasive, continuous, life-disturbing problems

The symptom severity scale (SSS) score: is the sum of the severity scores of the 3 symptoms (fatigue, waking unrefreshed, and cognitive symptoms) (0–9) plus the sum (0–3) of the number of the following symptoms the patient has been bothered by that occurred during the previous 6 months:

(1) Headaches (0–1)
(2) Pain or cramps in lower abdomen (0–1)
(3) And depression (0–1)

The final symptom severity score is between 0 and 12

The fibromyalgia severity (FS) scale is the sum of the WPI and SSS

The FS scale is also known as the polysymptomatic distress (PSD) scale.

[a] Not included in generalized pain definition.

Several cases previously deemed positive by the 2010/2011 criteria would be considered negative by the 2016 modified criteria, indicating a lower specificity. The current criteria also state patients can experience pain in 4-5 regions (four quadrants and axial), termed "generalized pain," to distinguish from the 1990 guideline's "widespread pain" definition. The 2016 ACR guidelines also now recognize spatial distribution of painful sites (Arnold et al., 2019). It lastly modifies the language from the 2010 guidelines that discuss other disorders serving as the etiology of experienced pain, and assumes the 1990 ACR guideline criterion of possible comorbidities with fibromyalgia (#4) (Wolfe et al., 2016).

After conducting an in-depth review of existing guidelines and literature, Heymann et al. (2017) published recommendations based on the 2010 ACR guidelines, and endorse using the 2010 ACR criteria for diagnosis of FM. They stated:

1. "The presence of widespread pain is essential for the diagnosis of patients with suspected FM.
2. Tender points may be useful in the diagnosis of fibromyalgia when evaluated in combination with other functional disorders covered in the 2010 [ACR] criteria. The tender point count may be correlated with the intensity of some symptoms, particularly emotional stress.
3. Sleep disorders and changes in cognition and fatigue should be considered in the diagnosis of FM. They should also be considered in the assessment of severity of patients with FM.

We suggest the systematic measurement of mood disorders using validated instruments suitable to the healthcare level in which they are administered because they are highly important when assessing the severity of patients with FM" (Heymann et al., 2017).

These guidelines did not mention genetic testing for FM.

Canadian Rheumatology Association (CRA)

The CRA released recommendations to the "identification, evaluation, and management" of those with FM after conducting a needs assessment. In relation to diagnosis of FM, the CRA recommends:

- "Fibromyalgia, a condition that can wax and wane over time, should be diagnosed in an individual with diffuse body pain that has been present for at least 3 months, and who may also have symptoms of fatigue, sleep disturbance, cognitive changes, mood disorder, and other somatic symptoms to variable degree, and when symptoms cannot be explained by some other illness [Level 5, Grade D].
- All patients with a symptom complaint suggesting a diagnosis of fibromyalgia should undergo a physical examination which should be within normal limits except for tenderness on pressure of soft tissues (ie. hyperalgesia which is increased pain following a painful stimulus) [Level 4, Grade D].
- Fibromyalgia should be diagnosed as a clinical construct, without any confirmatory laboratory test, and with testing limited to simple blood testing including a full blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), creatine kinase, and thyroid stimulating hormone (TSH). Any additional laboratory or radiographic testing should depend on the clinical

evaluation in an individual patient that may suggest some other medical condition [Level 5, Grade D]" (Fitzcharles et al., 2012).

This guideline did not mention genetic testing for FM (Fitzcharles et al., 2012).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
81599	Unlisted multianalyte assay with algorithmic analysis
84999	Unlisted chemistry procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Gene Expression Profiling and Protein Biomarkers for Prostate Cancer

Policy Number: AHS – M2166 – Gene Expression Profiling and Protein Biomarkers for Prostate Cancer	Prior Policy Name and Number, as applicable: AHS – M2166 – Gene Expression Profiling and Protein Biomarkers for Prostate Cancer Management
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Prostate cancer is characterized by malignancy which originates in the small walnut-shaped gland that produces the seminal fluid in individuals who have a prostate. Heterogeneous in both molecular alterations and progression, clinical course ranges from a microscopic tumor that never becomes clinically significant to aggressive disease that can cause metastases, morbidity, and death (Benedettini et al., 2008; Taplin & Smith, 2024).

Gene expression assays quantify specific mRNAs being transcribed to assess the genes that are active in a particular cell or tissue. Analyses of gene expression can be clinically useful for disease classification, diagnosis, prognosis, and tailoring treatment to underlying genetic determinants of pharmacologic response (Steiling & Christenson, 2023). Protein expression-based assays measure the expression of the translation end-product(s) to assess cell-cycle progression. Similar to gene expression assays, protein biomarker-based assays can be clinically useful for disease classification and possible surveillance (Blume-Jensen et al., 2015; Ross et al., 2022).

II. Related Policies

Policy Number	Policy Title
AHS-G2007	Prostate Biopsy Specimen Analysis
AHS-G2008	Prostate Specific Antigen (PSA) Testing
AHS-G2054	Liquid Biopsy

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with low-risk or favorable intermediate-risk disease, as defined by the NCCN (see Note 1), the one-time use of Prolaris®, Oncotype DX Genomic Prostate Score®, **or** Decipher® tumor-based assays to guide the management of prostate cancer **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:
   a) When pathological examination showed localized adenocarcinoma of the prostate with no clinical evidence of metastasis or lymph node involvement;
   b) When the individual has no significant co-morbidities, including advanced age, to suggest they have an estimated life expectancy of less than 10 years.

2) For individuals with unfavorable intermediate-risk and high-risk disease, as defined by the NCCN (see Note 1), the one-time use of Prolaris® **or** Decipher® tumor-based assays to guide the management of prostate cancer **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:
   a) When pathological examination showed localized adenocarcinoma of the prostate with no clinical evidence of metastasis or lymph node involvement;
   b) When the individual has no significant co-morbidities, including advanced age, to suggest they have an estimated life expectancy of less than 10 years.

3) For individuals for whom there is a potential need for a prostate biopsy, the one-time use of the ExoDx Prostate (IntelliScore) (EPI) biomarker test (either once prior to initial biopsy or once prior to repeat biopsy) **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:
   a) The individual has confirmed (see Note 2), moderately elevated PSA levels:
      i) For individuals ages 50 – 75 years, PSA levels between 3 – 10 ng/mL
      ii) For individuals over the age of 75, PSA levels between 4 – 10 ng/mL
   b) The individual has none of the following conditions for which a prostate biopsy is already indicated:
      i) DRE suspicious for cancer.
      ii) Persistently elevated PSA.

iii) Positive multiparametric MRI, if performed.

iv) Known to have a high-penetrance prostate cancer risk gene(s) per NCCN guidelines (see Note 3).

c) The individual has no other relative contraindication for prostate biopsy, including **any** of the following:

i) A less than 10-year life expectancy.

ii) Benign disease not ruled out.

4) For individuals with a prostate, the one-time use of the 4Kscore test (either once prior to initial biopsy or once prior to repeat biopsy) **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:

a) The individual has confirmed (see Note 2), moderately elevated PSA levels:

i) For individuals ages 45 – 75 years, PSA levels greater than 3 and less than 10 ng/mL.

ii) For individuals over the age of 75, PSA levels greater than or equal to 4 and less than 10 ng/mL.

b) The individual has none of the following conditions for which a prostate biopsy is already indicated:

i) DRE suspicious for cancer.

ii) Persistently elevated PSA.

iii) Positive multiparametric MRI (if performed).

iv) Ethnicity at higher risk for prostate cancer (see Note 4)

v) First-degree relative (see Note 5) with prostate cancer.

vi) Known to have a high-penetrance prostate cancer risk gene(s) per NCCN guidelines (see Note 3).

c) The individual has no other relative contraindication for prostate biopsy, including **any** of the following:

i) A less than 10-year life expectancy.

ii) Benign disease not ruled out.

5) For individuals with a prostate, the one-time use of the IsoPSA test (either once prior to initial biopsy **or** once prior to repeat biopsy) **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:

a) For individuals 50 years of age or older who have confirmed (see Note 2) PSA levels greater than 4 and less than or equal to 25 ng/mL.

b) The individual has no other relative contraindication for prostate biopsy, including **any** of the following:

i) A less than 10-year life expectancy.

ii) Benign disease not ruled out.

6) For the assessment and/or monitoring of prostate cancer, the following tests **DO NOT MEET COVERAGE CRITERIA**:

a) Ki-67 immunohistochemistry

b) *PTEN* loss

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

7) The following tests **DO NOT MEET COVERAGE CRITERIA:**

a) All other urine testing for gene expression profile and/or protein biomarkers designed to assess prostate cancer.

b) Other screening tests for prostate cancer (e.g., alpha-methylacyl coenzyme A racemase [AMACR], ConfirmMDx, early prostate cancer antigen, endoglin, E twenty-six [ETS] gene fusions, human kallikrein 2, analysis of prostatic fluid electrolyte composition, interleukin-6, transforming growth factor-beta 1, *TMPRSS2:ERG* gene fusion, MyProstateScore, gene hypermethylation, *PCA3/KLK3* ratio, Prostate Health Index (PHI), *PCA3* score).

c) All other tests not described above that use cellular and biologic features of a tumor (e.g., those that are used to predict risk of recurrence in patients with prostate cancer).

NOTES:

Note 1: NCCN Prostate Cancer Initial Risk Stratification and Staging Workup for Clinically Localized Disease (NCCN, 2024a)

Risk Group	Clinical/Pathological Features
Very Low	Has all of the following: · cT1c; AND

	· Grade Group 1 · PSA <10 ng/mL · Fewer than 3 prostate biopsy fragments/cores positive, ≤50% cancer in each fragment/core · PSA density <0.15 ng/mL/g		
Low	Has all of the following but does not qualify for very low risk: · cT1-cT2a · Grade Group 1 · PSA <10 ng/mL		
Intermediate	Has all of the following: · No high-risk group features · No very-high-risk group features · Has one or more intermediate risk factors » cT2b-cT2c » Grade Group 2 or 3 » PSA 10-20 ng/mL	Favorable Intermediate	Has all of the following: · 1 IRF · Grade Group 1 or 2 · <50% biopsy cores positive
		Unfavorable Intermediate	Has one or more of the following: · 2 or 3 IRFs · Grade Group 3 · ≥50% biopsy cores positive
High	Has no very-high-risk features and has at least one high-risk feature: · cT3a OR · Grade Group 4 or Grade Group 5 OR · PSA >20 ng/mL		
Very High	Has at least one of the following: · T3b-T4 · Primary Gleason pattern 5 · 2 or 3 high-risk features · >4 cores with Grade Group 4 or 5		

Note 2: PSA elevation should be verified after a few weeks under standardized conditions (e.g., no ejaculation, manipulations, and urinary tract infections, no medications such as 5α-reductase) in the same laboratory or other Clinical Laboratory Improvement Amendments (CLIA) approved laboratory before considering a biopsy.

Note 3: According to the NCCN Prostate Cancer Early Detection guidelines, the main high-penetrance cancer risk genes include *BRCA1, BRCA2, ATM, MLH1, MSH2, MSH6, HOXB13, CHEK2, NBN, PALB2, RAD51D,* and *TP53* (NCCN, 2024b).

Note 4: According to the NCCN Prostate Cancer Early Detection guidelines, "Black/African American individuals have a significantly higher incidence of prostate cancer, increased prostate cancer mortality, and earlier age of diagnosis compared to white individuals" (NCCN, 2024b).

Note 5: First-degree relatives include parents, full siblings, and children of the individual.

IV. Table of Terminology

Term	Definition
ADT	Androgen deprivation therapy
AMACR	Alpha-methylacyl coenzyme A racemase
APC	*Adenomatous polyposis coli* gene
ARSI	Androgen receptor signaling inhibitor
AR-V7	Androgen receptor splice variant-7
AS	Active surveillance
ASCO	American Society of Clinical Oncology
ASTRO	American Society for Radiation Oncology
ATM	*ATM serine/threonine kinase gene*
AUA	American Urological Association
AUC	Area under the curve
BCR	Biochemical recurrence
BRCA1	*Breast cancer gene 1*
BRCA2	*Breast cancer gene 2*
CAPRA	Cancer of the prostate risk assessment
CCP	Cell-cycle progression
CCR	Cell-cycle risk
CDK12	*Cyclin dependent kinase 12 gene*
CDx	Companion diagnostic
CHEK2	*Checkpoint kinase 2 gene*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CNAs	Copy number alterations
CTCs	Circulating tumor cells
DDR	DNA damage and repair
DLX1	*Distal-less homeobox 1 gene*

DRE	Digital rectal examination
DX	Diagnosis
EANM	European Association of Nuclear Medicine
EAU	European Association of Urology
EBRT	External beam radiation therapy
EDTA	Ethylenediaminetetraacetic acid
EPI	ExoDx Prostate (IntelliScore)
ERG	*ETS Transcription Factor ERG*
ESMO	European Society for Medical Oncology
ESTRO	European Society for Radiotherapy and Oncology
ESUR	European Society of Urogenital Radiology
ETS	E-twenty-six
FANCA	*Fanconi anemia complementation group A gene*
FDA	Food and Drug Administration
FFPE	Formalin-fixed paraffin-embedded
FISH	Fluorescence *in situ* hybridization
GEC	Gene/genomic expression classifiers
GPS	Genomic prostate score
GSTP1	*Glutathione S-transferase pi 1 gene*
HGPC	High-grade prostate cancer
hK2	Human kallikrein-2
HOXB13	*Homeobox B13 gene*
HOXC6	*Homeobox C6 gene*
HT	Hormonal therapy
IHC	Immunohistochemistry
indels	Insertion and deletion alterations
IRF	Intermediate-risk factor
ISUP	International Society of Urological Pathology
KLK3	*Kallikrein related peptidase 3 gene*
LDTs	Laboratory-developed tests
mCRPC	Metastatic castration-resistant prostate cancer
MLH1	*MutL homolog 1 gene*
MRI	Magnetic resonance imaging
MSH2	*MutS homolog 2 gene*
MSH6	*MutS homolog 6 gene*
NBN	*Nibrin gene*
NCCN	National Comprehensive Cancer Network
NPV	Negative predictive value

PALB2	*Partner and localizer of BRCA2 gene*
PARP	Poly (ADP-ribose) polymerase
PCa	Prostate cancer
PCA3	Prostate cancer gene 3
PPCR	Polymerase chain reaction
PCRMP	Prostate Cancer Risk Management Programme
PHI	Prostate health index
PLA	Proprietary laboratory analyses
PPV	Positive predictive value
PSA	Prostate specific antigen
PTEN	*Phosphatase and tensin homolog gene*
QALY	Quality adjusted life-years
RAD51D	*RAD51 poaralog d gene*
RASSF1	*Ras association domain family 1 gene*
RNA	Ribonucleic acid
RP	Radical prostatectomy
RT	Radiation therapy
RT-PCR	Reverse transcription-polymerase chain reaction
TMPRSS2	*Transmembrane serine protease 2*
TP53	*Tumor protein 53 gene*
TRUS	Transrectal ultrasound guided biopsy

V. Scientific Background

Prostate cancer (PCa) is the most common cancer in American individuals who have a prostate and the second leading cause of death in the same group. In 2024, the American Cancer Society estimates that approximately 299,010new prostate cancer diagnoses and approximately 35.250prostate cancer deaths will occur; although, the five-year survival rate between 2012-2018 was 97%. About one individual in eight amongst those who have a prostate will be diagnosed with prostate cancer during their lifetime in the United States (ACS, 2024a, 2024b).

Many cases of prostate cancer do not become clinically evident, as indicated in autopsy studies, where prostate cancer is detected in approximately 30 percent of individuals with a prostate aged 55 or older and approximately 60 percent of individuals with a prostate by age 80 (Bell et al., 2015). These data suggest that prostate cancer often grows so slowly that most individuals die of other causes before the disease becomes clinically advanced (Hoffman, 2023).

Prostate cancer survival is related to many factors, especially the extent of tumor at the time of diagnosis. The five-year relative survival among individuals with cancer

localized to the prostate or with regional spread is 100%, compared with 31% among those diagnosed with distant metastases (Hoffman, 2023). Gene expression profiling has been proposed as a method of risk stratification for prostate cancer. Several tests evaluating the expression levels of various genes have been produced to be used in conjunction with other tools such as Gleason score and prostate-specific antigen (PSA) assessment. The Gleason score is a scoring system used to categorize a prostate cancer biopsy based on risk assessment.

Tissue-based gene expression classifiers (GEC) are now widely used to assist in prostate cancer prognosis. These tests are RNA-based prognostic biomarkers that analyze a distinct multigene panel to predict cancer progression, from the chance of having the disease to the probability of death at ten years due to prostate cancer. Genomic tests can predict prostate cancer aggressiveness, detect potentially dangerous prostate cancer-related genomic activity, and utilize biopsy samples to deliver prognostic information via immunofluorescence imaging. Additionally, researchers have identified the potential of microRNAs as human prostate cancer biomarkers (Song et al., 2018). While several types of biomarker tests exist, the NCCN specifically recommends Prolaris, Oncotype DX Genomic Prostate Score® (GPS™), and Decipher as tumor-based molecular assays to consider during initial risk stratification (NCCN, 2024a). Ki-67 and PTEN are also listed in NCCN guidelines, but are not recommended (NCCN, 2024a).

Proprietary Testing, Clinical Utility, and Analytical Validity

Hu et al. (2018) evaluated the utility of three genomic expression classifiers (GEC), including Decipher, Oncotype Dx, and Prolaris. A total of 747 patients underwent GEC testing. The authors found that "Among patients with clinical favorable risk of cancer, the rate of active surveillance (AS) differed significantly among patients with a GEC result above the threshold (46.2%), those with a GEC result below the threshold (75.9%), and those who did not undergo GEC (57.9%)." The authors further estimated that for every nine individuals "with favorable risk of cancer who undergo GEC testing, one additional patient may have their disease initially managed with AS" (Hu et al., 2018).

Prolaris

The test "Prolaris" (created by Myriad Genetics) has been used to inform decision making on AS and whether to proceed to a treatment option, such as radiation or surgery. Prolaris is an assessment of the average expression of 31 cell-cycle progression (CCP) genes compared to 15 reference genes. This score is combined with the patient's age, PSA, percent positive cores, clinical stage, Gleason score, and American Urological Association (AUA) risk category; it is intended to provide a 10-year prostate cancer-specific mortality risk. Scores range from zero to ten, with each

unit increase representing a doubling of disease-risk progression. Prolaris may also be used to assess risk post-prostatectomy, and the same scale of zero to ten is used. Each unit increase represents a doubling of risk of biochemical recurrence (BCR) (Alford et al., 2017).

Cell cycle progression expression has been found to correlate with mortality rate of prostate cancer and can provide important pretreatment prognostic information. Cuzick et al. (2015) found that not only was there a relationship between CCP expression and mortality rate, the increased expression of CCP was predictive of BCR after 10 years. Even after adjusting for factors such as PSA and Gleason score, the CCP was both "highly significant" and "independent" of prostate cancer mortality rate. The authors noted that the CCP score could be created from minimal tumor mass (as little as 0.5 mm), with a 90% success rate with >0.5 mm visible tumor, as well as Prolaris' objective criteria compared to the Gleason score (Cuzick et al., 2015).

Prolaris may be used to lower unnecessary treatment by providing a molecular indication of the disease's progression. Radical treatments, such as prostatectomies, are often unnecessary, and there is utility in a biomarker metric than can reliably inform providers of a course of treatment or condition. An AS status is preferable to treatment. Hu et al. (2018) used data provided by the CCP score (along with two other biomarker tests) to perform risk stratification and assess whether further treatment was needed or if the condition could be managed by active surveillance. Lin et al. (2018) clearly separated high- and low-risk patients using the CCP score. The study combined the CCP score as well as a clinical assessment from the Cancer of the Prostate Risk Assessment (CAPRA) into a cell-cycle risk (CCR) score. This CCR score was used to select patients for an AS status. The threshold created from both the molecular measures and the clinical measures has the advantage of including higher-risk patients whose clinical features may be lower-risk. Furthermore, the patients that fell below the threshold were found to have a mortality risk of 2.5%, and the probability of survival of patients with scores under the threshold was 100% (Hu et al., 2018; Lin et al., 2018). Finally, Prolaris has been used by providers to inform clinician decision making. A survey by Carneiro et al. (2018) found that the course of treatment for prostate cancer patients was influenced by Prolaris' results. About 65% of cases were reported to have shifted in the intended treatment based on the test results, and about 40% were reported to have opted for the AS choice (a "decrease" in treatment) (Carneiro et al., 2018).

Tward et al. (2020) studied the ability of CCR to predict prostate cancer metastasis using Prolaris. According to a CCR threshold of 2.112, 29.5% patients were hypothesized to be high risk metastasis (CCR>2.112) and 70.5% were unfavorable intermediate risk patients (CCR < 2.112). Patients were followed five years later to

determine if CCR accurately predicted metastasis in those undergoing multimodality therapy (androgen deprivation with surgery) or radiation therapy. According to the results, the CCR score does provide a clinically meaningful different risk of metastasis for patients receiving multimodality therapy or radiation therapy. Multimodality therapy reduced patients' risk of metastasis and treatment benefit can be evaluated as a function of the CCR score. For those with CCR scores below the threshold of 2.112 (27% of high-risk group and 73% of the unfavorable intermediate group), radiation therapy was considered after assessing the difference in the risk of metastasis (Tward et al., 2020).

Oncotype DX Genomic Prostate Score® (GPS™) is similar to Prolaris in that it assesses levels of gene expression, should be used for lower-risk patients, and can inform clinicians about the possible course of treatment. The primary difference is that Oncotype DX only tests 12 genes, with five reference genes (compared to 31 and 15, respectively, for Prolaris)(Exact Sciences, 2021). These expression levels are combined into an algorithm to produce a genomic prostate score (GPS) of 0-100. This GPS score correlated with prediction of cancer aggression (outcomes such as death or recurrence) (Cullen et al., 2015).

Cullen et al. (2015) found that the GPS score correlated well with BCR. The researchers noted that OncoType DX is a good predictor of both early and late BCR and is validated for adverse pathology whereas Prolaris is validated for 10-year mortality or BCR after radical prostatectomy (Alford et al., 2017; Cullen et al., 2015; Davis, 2014; NCCN, 2024a). Oncotype DX was recently validated in a group of individuals separated by race, showing that this tool is an independent predictor of adverse pathology with similar predictive accuracy in both African American (n=96) and European American (n=76) populations (Murphy et al., 2020).

AR-V7 Nucleus Detect test

The AR-V7 Nucleus Detect test is available through Epic Sciences. This test evaluates the Androgen Receptor Splice Variant-7 (AR-V7) protein in the nucleus of circulating tumor cells and is intended to identify metastatic castration-resistant prostate cancer patients who will not respond to androgen-receptor targeted therapies (Epic Sciences, 2023).

Scher et al. (2016) examined 161 patients with progressive metastatic castration-resistant prostate cancer (mCRPC) to assess its association with AR-V7. Out of 191 samples (128 pre-ARS inhibitor and 63 pretaxane), the investigators found AR-V7-positive circulating tumor cells in 34 samples, and those samples were found to have worse clinical outcomes and overall survival than those without AR-V7. Scher et al. (2016) concluded that "the results validate CTC nuclear expression of AR-V7 protein in

[individuals] with mCRPC as a treatment-specific biomarker that is associated with superior survival on taxane therapy over ARS-directed therapy in a clinical practice setting" (Scher et al., 2016).

Further, Chen et al. (2018) studied the overexpression of the nuclear AR-V7 protein in prostate cancer cases. A total of 401 individuals participated in this study. Participants were split into two cohorts: cohort I included those who were high-risk (n=238), and cohort II included those who were not considered high-risk (n=238). Analyses showed that high nuclear AR-V7 protein expression was detected in approximately 30-40% of participants, and a "High baseline expression of nuclear AR-V7 protein was associated with an unfavorable BCR-free survival in the high-risk patient cohort I but not in the unselected consecutive cohort II. Remarkably, AR-V7 was an independent negative prognostic factor in high-risk prostate cancer patients of cohort I who were selected to receive adjuvant treatment" (Chen et al., 2018).

Graf et al. (2020) studied the clinical utility of AR-V7 as a biomarker for patients with progressing metastatic castration-resistant prostate cancer (mCRPC). The results were used by physicians to make a second line of therapy choice of either an androgen receptor signaling inhibitor (ARSI) or taxane chemotherapy. There were 255 samples of circulating tumor cells (CTCs) tested for AR-V7. Patients with detectable AR-V7 in the CTCs had superior survival with taxane treatment over ARSIs and patients who were AR-V7- negative had superior survival on ARSIs over taxanes. These results showed that individuals who tested AR-V7- positive were more likely to survive longer on taxane chemotherapy. Overall, the authors suggest that the use of AR-V7 CTC test "to inform treatment choice can improve patient outcomes relative to decisions based solely on standard-of-care measures" (Graf et al., 2020).

Decipher

Decipher is a genomic prognostic test that is used to predict cancer outcomes in patients that have undergone a radical prostatectomy (RP), which is the removal of the prostate gland and surrounding tissues. Decipher relies on the expression levels of 22 RNA markers in the RP specimen and is primarily used to predict likeliness of metastases or mortality. The algorithm score ranges from zero to one, where a higher score corresponds with higher chance of metastasis. This algorithm was shown to have outperformed the traditional assessment of clinical and pathological features in predicting metastasis (0.75 accuracy compared to 0.69) as well as 17 other genetic tests (0.54 to 0.68 accuracy) (Alford et al., 2017; Dalela et al., 2016).

Van den Broeck et al. (2019) aimed to validate the Decipher test in the prediction of distant metastatic recurrence in individuals with high-risk nonmetastatic prostate cancer 10 years after the surgery was completed. A total of 298 people participated in

this study. Results showed that "the median Decipher scores were higher in the population that developed metastases" suggesting that this study "validates Decipher as a predictor for metastatic recurrence even in patients with high-risk, nonmetastatic PC [prostate cancer] within 10-yr follow-up" (Van den Broeck et al., 2019). Specifically, the data showed that each 10% increase in Decipher score resulted in an increased risk of distant metastatic prostate cancer recurrence.

In a prospective trial by Marascio et al. (2020), the clinical utility of the Decipher tumor test on postoperative management of prostate cancer post prostatectomy was discussed. There were 3,455 individuals with prostates enrolled in the study and the change in treatment decision-making was recorded. In the cohort, 61% of the patients had high-risk tumors with a two-year prostate cancer reoccurrence. As a result of genome classifier testing, providers' recommendations changed for 39% of the patients, translating to a number needed to test of three to change one treatment decision. This study demonstrated that genome classifier testing favorably impacts treatment decision making post radical prostatectomy, promoting more post-operative radiotherapy. This translated to improved patient reported quality of life (Marascio et al., 2020).

Nguyen et al. (2023) published a meta-analysis examining the prognostic ability of the Decipher Genomic Classifier for distant metastases, prostate cancer-specific mortality, and overall survival within the context of three randomized phase three high-risk definitive radiation therapy trials. The total cohort consisted of 265 individuals whose median age was 69 years and median pretreatment PSA of 25.8 ng/mL. The authors report that upon meta-analysis, the Decipher Genomic Classifier score was statistically significantly associated with time to distant metastasis, prostate cancer–specific mortality, and overall survival (Nguyen et al., 2023).

Spratt et al. (2023) reported on the Decipher Genomic Classifier's performance in the context of intermediate-risk prostate cancer. Through multivariable analysis of 215 individual samples, it was determined that the test was "independently prognostic for disease progression (subdistribution hazard ratio [sHR], 1.12; 95% confidence interval [CI], 1.00-1.26; P = .04), biochemical failure (sHR, 1.22; 95% CI, 1.10-1.37; P < .001), distant metastasis (sHR, 1.28; 95% CI, 1.06-1.55; P = .01), and prostate cancer-specific mortality (sHR, 1.45; 95% CI, 1.20-1.76; P < .001)." Beyond prognostic utility, the authors argue that the data herein support the predictive value of the Decipher Genomic Classifier for individuals with intermediate risk prostate cancer; among individuals with a test score of intermediate-high, radiation dose-escalation showed greater absolute benefit, with 10-year metastasis-free survival of 75% (95% CI, 55-95) compared with 54% (95% CI, 31-77) for standard dose (Spratt et al., 2023).

ExoDX Prostate IntelliScore (EPI)

ExoDX is a urinary test that detects the expression level of three genetic biomarkers (ERG, PCA3, and SPDEF) (ExoSome, 2024a, 2024b). This test integrates the expression levels of these three biomarkers and assigns an individualized risk score to predict the risk of high-grade prostate cancer (Gleason score ≥ seven). This test is intended for individuals 50 or over with a PSA level of two to ten ng/mL presenting for an initial biopsy (prior to a DRE) and as a useful test in the post-biopsy setting for patients thought to be higher risk despite a negative prostate biopsy(ExoSome, 2024a, 2024b; NCCN, 2024b).

McKiernan et al. (2016) used ExoDX to discriminate between benign prostate cancer (Gleason score 6 and under) and high-risk cancer (Gleason score ≥7). The prognostic score was derived from a sample of 499 patients with PSA levels of two to 20 ng/mL; it was then validated in a sample of 1064 patients and evaluated in a population of 255. The test was compared to the standard of care practices (SOC), and the area under the curve (AUC) of the test was 0.77 compared to the SOC's 0.66. An independent validation found the AUC of the test to be 0.73 compared to the SOC's 0.63. The authors calculated that 138 of 519 biopsies (27%) would have been avoided and that the test only missed five percent of patients with high-risk disease (McKiernan et al., 2016). Within a second phase of the long-term study, McKiernan and colleagues report that using the EPI validated cut-point of 15.6 results in avoiding 26% of unnecessary prostate biopsies and a 20% decrease in all biopsies. If the EPI cut-point is raised to 20, then 31% of total biopsies would be avoided, including 40% of unnecessary biopsies (McKiernan et al., 2018).

A study published in 2018 did a cost-effectiveness analysis and comparison of not only ExoDx (EPI), but also Prostate Health Index (PHI), 4Kscore, and SelectMDx to current standard care of care. Using 2017 US dollars for their calculations, the cost and quality adjusted life-years (QALY) for the current standard of care—transrectal ultrasound guided biopsy (TRUS biopsy)—was $3,863 and 18.0865, respectively. The authors of the study note that EPI, PHI, and SelectMDx cost less than performing TRUS biopsy. They note, "The EPI provided the highest QALY with an incremental cost-effectiveness ratio of $58,404 per QALY. The use of biomarkers could reduce the number of unnecessary biopsies by 24% to 34% compared to the current standard of care… Using SelectMDx or the EPI following elevated prostate specific antigen but before proceeding to biopsy is a cost-effective strategy in this setting" (Sathianathen Niranjan et al., 2018).

A randomized, blinded, two-armed clinical utility study was published in 2020 using ExoDx (EPI) in individuals presenting for initial biopsy with PSA values in the

intermediate range (two to ten ng/mL). This large study (n = 1,094) included 72 urologists from 24 different practices. All patients had an EPI test performed, but the patients were divided into two different groups (control and experimental) where only the experimental group received results prior to their biopsy decision. Of the individuals within the experimental group who received negative EPI scores, 74% deferred biopsy. For individuals within the experimental group who received positive EPI scores, 87% were recommended by their urologists to undergo the biopsy, and ultimately 72% did. As compared to the control arm of the study, there is a 30% increase in the detection of high-grade prostate cancer [HGPC], and the authors "estimate that 49% fewer HGPC were missed due to deferrals compared to standard of care (SOC). Overall, 68% of urologists reported that the EPI test influenced their biopsy decision" (Tutrone et al., 2020).

McKiernan et al. (2020) investigated the use of the EPI test in a prospective clinical validation study of 229 individuals who were undergoing repeat biopsy. The EPI test demonstrated an NPV of 92% and results evidenced avoidance of 26% of unnecessary biopsies while missing 2.1% of the incidences of high-grade prostate cancer (a total of five patients) (McKiernan et al., 2020).

4Kscore

4Kscore is intended to assess the risk for "aggressive" prostate cancer. The test incorporates total PSA, free PSA, "intact" PSA, and "hk2" [human kallikrein 2] (NCCN, 2024a; OPKO, 2021). These biomarkers, along with other patient clinical information (such as age and prior biopsy status) are evaluated by the 4Kscore algorithm, which generates a risk score for aggressive cancer (percent risk of Gleason seven or higher, if a biopsy were to be performed).

Zappala et al. (2017) performed a meta-analysis of 4kScore validation studies. A total of 12 studies encompassing 11134 patients were included, and the pooled area under curve (AUC) for the test to "discriminate for high-grade PCa [prostate cancer] was found to be 0.81" (Zappala et al., 2017).

Two key prospective and blinded investigations were completed in 2015 and 2018, attempting to validate 4Kscore in a total of 937 patients, defined as the "intended use" population. The test demonstrated an overall sensitivity, specificity, negative predictive value (NPV), and positive predictive value (PPV) of 96.9%, 27.4%, 95.9%, and 33.7%, respectively. These metrics showed little variation between African American and non-African American individuals, with the exception of PPV (46.7% compared to 28.1%, respectively) (Parekh et al., 2015; Punnen et al., 2018).

Wysock et al. (2020) compared the performance of 4K score to SelectMDx in detecting prostate cancer in 114 patients who received both tests. These tests were analyzed to provide guidance on whether to perform biopsy. Based on the results, the two scores lead to different biopsy recommendations. A total of 50 out of 144 patients underwent biopsy based on the test results. Of the 50 patients, 22 (44%) were found to have clinically significant prostate cancer. In addition, the specificity of 4K score was significantly greater compared to SelectMDx while sensitivity was similar. The area under the curve for 4K score was 0.830 and SelectMDx was 0.672. The authors state that "the 4Kscore when combined with magnetic resonance imaging was superior to the SelectMDx" in detecting prostate cancer (Wysock et al., 2020).

Mi et al. (2021) completed a meta-analysis to help inform the diagnostic accuracy of 4Kscore in detecting high-grade prostate cancer, covering a total of nine studies and 1,689 patients. The investigators reported a pooled sensitivity, specificity, and AUC of 0.90 (95%CI: 0.86-0.92), 0.44 (95%CI: 0.36-0.52), and 0.81 (95%CI: 0.77-0.84), respectively, and concluded that "4Kscore can be used as a model for the diagnosis of high-grade CaP [prostate cancer]. However, we detected significant heterogeneity among studies that was not explained by subgroup or meta-regression analysis, thus lowering our confidence in these results."

Further validation of the test will be useful; however, to date, 4Kscore has demonstrated relatively high sensitivity and AUC compared to other molecular testing for the assessment of high-grade prostate cancer risk.

ConfirmMDX

ConfirmMDX uses methylation-specific polymerase chain reaction (PCR) to identify methylation of three genes (*GSTP1*, *APC*, and *RASSF1*), and determine whether a patient with a previously negative prostate biopsy should undergo a repeat biopsy (MDxHealth, 2023a). This test has been evaluated by Van Neste, Partin, et al. (2016) and was found to have an NPV of 96% for high-grade prostate cancer. A total of 7899 prostate core biopsies from 803 patients were assessed, and the NPV of finding low levels of DNA methylation was 89.2% for all cancers. The PPV of the genetic assay was found to be 28.2% (for detection of any cancer on a repeat biopsy), and this was calculated to be "significantly higher" than the PPV of standard of care practices. The final algorithm was optimized to a maximum of 0.742 AUC (Van Neste, Partin, et al., 2016). Wojno et al. (2014) evaluated the utility of this test and found that out of 138 patients that the test had been performed on, only six with a negative result had undergone a repeat biopsy.

SelectMDX

SelectMDX evaluates two mRNA cancer-related biomarkers (HOXC6 and DLX1 with *KLK3* as a reference gene) to assist a clinician in deciding to continue routine screening or to order a prostate biopsy. This test is considered a "non-invasive urine test" and reports a binary result of "increased risk" or "very low risk" (MDxHealth, 2023b). Van Neste, Hendriks, et al. (2016) evaluated this test at a 0.90 AUC in a validation cohort. The authors concluded that the mRNA signature was one of the most significant components of the validation results (Van Neste, Hendriks, et al., 2016). Shore (2018) assessed the effect of SelectMDX results on clinical decision making, and found that out of 253 patients that SelectMDX evaluated as "negative," only 12% underwent a biopsy (Shore, 2018).

IsoPSA®

IsoPSA® is a blood test indicated for use in individuals with a prostate who are over 50 years of age with elevated PSA, to help inform the likelihood of having high-grade prostate cancer. Utilizing a proprietary, 2-phase aqueous polymer and salt mixture, PSA isoforms separate between the two aqueous phases, where the discriminatory power between benign and cancerous clinical phenotypes purportedly resides primarily in the top phase. The PSA isoform content in the top layer is then measured with conventional, FDA-approved PSA ELISA immunoassays, and a single numerical score (IsoPSA Index) that is either above or below an established cutoff is generated, providing a binary positive or negative result.

The clinical validity of IsoPSA® was demonstrated in several studies. Stovsky et al. (2019) performed a multicenter, prospective validation in 271 individuals scheduled for prostate biopsy, and found that the test yielded an area under the receiver operating characteristic curve of 0.784 for high grade cancer. Klein et al. (2022) completed an additional multicenter study of 888 individuals scheduled for prostate biopsy and found similar results, establishing an AUC of 0.783 for IsoPSA®. These investigators further reported a sensitivity, specificity, NPV, and PPV of 0.902, 0.455, 0.893, and 0.477, respectively.

To investigate the clinical utility of IsoPSA®, Scovell et al. (2022) performed a "real-world" observational study engaging 38 providers across the Cleveland Clinic health system. The authors examined whether an IsoPSA® result changed the number of biopsy and magnetic resonance imaging recommendations for a cohort of 734 individuals with total serum prostate specific antigen [PSA] ≥ four and <100 ng/ml and no history of prostate cancer. The authors determined that "IsoPSA testing resulted in a 55% (284 vs 638) net reduction in recommendations for prostate biopsy" for those "with total PSA ≥ four ng/ml."

Progensa PCA3

Progensa *PCA3* is an FDA-approved assay that examines the concentration of the prostate cancer gene three (*PCA3*) and compares it to the amount of prostate-specific antigen RNA. This test is intended for assistance in decision making for a repeat biopsy in individuals with a prostate who are 50 years or older, and a *PCA3* score under 25 was associated with a decreased likelihood of a positive biopsy. However, the manufacturer states this test should not be used for those with atypical small acinar proliferation on their most recent biopsy (Hologic, 2024). A total of 466 samples were provided, and 102 of these samples were evaluated to require a repeat biopsy. This assay was evaluated at a 77.5% sensitivity, a 57.1% specificity, a 33.6% positive predictive value, and a 90.0% negative predictive value (Gittelman et al., 2013).

Rodríguez and García-Perdomo (2020) performed a systematic review and meta-analysis of the diagnostic accuracy of PCA3 prior to a patient's first prostate biopsy. They found that with a cutoff of 35, the sensitivity of the diagnostic tests was 0.69 (95% confidence interval 0.61-0.75), specificity was 0.65 (95% confidence interval 0.553-0.733), the diagnostic odds ratio was 4.244 (95% confidence interval 3.487-5.166), and the AUC was 0.734 (95% confidence interval 0.674-0.805). This study suggests that there may be a greater clinical utility with 35 as the cutoff as opposed to the 25 approved by the FDA, and ultimately urinary PCA3 can "be used as a guide for directing the performance of the first prostate biopsy and decreasing unnecessary biopsies" (Matuszczak et al., 2021; Rodríguez & García-Perdomo, 2020).

MyProstateScore

MyProstateScore is a panel that measures urinary prostate cancer antigen three (PCA3), urinary TMPRSS2:ERG gene fusion (T2:ERG), and serum PSA, to predict the likelihood of prostate cancer in biopsy-naïve patients. Validating the test in a cohort of 1225 patients, Tomlins et al. (2016) found that MyProstateScore was superior to PSA alone, yielding an AUC of 0.693 (compared to 0.585 for PSA). Tosoian et al. (2021) aimed to validate an optimal MyProstateScore threshold for ruling out clinically significant (grade group ≥ two) cancer, finding that a threshold of 10 resulted in 97% sensitivity and 98% NPV. The investigators further concluded that use of the test could have prevented about one out of three of the biopsies that patients received.

ProMark

Another test that may have utility is ProMark. It measures the levels of eight proteins through the quantitative immunofluorescence of a biopsy specimen. ProMark is used to predict cancer aggression in patients with a Gleason score of 3+3 or 3+4. The proteins chosen have roles in cell proliferation, signaling, or stress response, and the score is reported from one to 100. This score represents individualized risk. Blume-Jensen et al. (2015) narrowed down the eight primary protein biomarkers used (down

from the 12 proposed by an earlier study) as well as assessed its ability to predict clinical endpoints of favorable and nonfavorable disease. They recommended a cutoff of 0.33 (on a scale of zero to one) for "nonfavorable" pathology (83.6% of patients with favorable disease fell below this cutoff). Conversely, a cutoff of 0.8 was recommended for favorable pathology as 76.9% of patients with nonfavorable pathology were above this cutoff. The authors concluded that this assay provided useful information, especially when differentiating between Gleason scores (Alford et al., 2017; Blume-Jensen et al., 2015).

Prostate Health Index

Prostate Health Index (PHI) measures total PSA, fPSA (free non-protein bound PSA), and p2PSA (an isoform of fPSA). Levels of these three proteins are combined and calculated, implying that individuals with a higher total PSA and p2PSA and a lower fPSA have a higher risk of presenting with prostate cancer (Couñago et al., 2020). PHI is clinically used to reduce the number of unnecessary biopsies in those with border-line PSA levels, predict biochemical recurrence after radical prostatectomy, and enhance the predictive value of multi-parametric MRI. PHI is not recommended in primary screening for prostate cancer (Duffy, 2020).

Jia et al. (2020) compared the diagnostic value of PCA3 and PHI for detection of prostate cancer at initial biopsy in a meta-analysis of 10,376 patients from 20 studies. The pooled sensitivity for PCA3 and PHI was 0.55 and 0.88, respectively. The pooled specificity for PCA3 and PHI was 0.74 and 0.36. The area under the curve, measuring overall quality of the diagnostic test, was 0.72 for PCA3 and 0.76 for PHI. The combination use of PCA3 and PHI resulted in a higher area under the curve of 0.79. Overall, this study suggests that both PCA3 and PHI show acceptable results and a "combination of these two diagnostic tests may be more helpful than the use of either test alone in prostate cancer management" (Jia et al., 2020).

White et al. (2018) evaluated the clinical utility of the PHI on "biopsy decision management" among patients with "non-suspicious DRE findings and tPSA in the four to ten ng/mL range" in an observational study at several large urology group practices. They found that there was a "significant reduction in biopsy procedures performed" in individuals receiving a PHI test when comparing to the control group (36.4% biopsy vs 60.3% biopsy), and that the "PHI score impacted physician's patient management plan in 73% of cases, including biopsy deferrals when the PHI score was low, and decisions to perform biopsies when the PHI score indicated an intermediate or high probability of prostate cancer," defined as a score greater than or equal to 36. This altogether conveyed the importance of the PHI score in clinical decision making in terms of how

to proceed with individual patient circumstances (Matuszczak et al., 2021; White et al., 2018)

Ki-67 and PTEN

Finally, the NCCN specifically recommends *against* two particular tests in assessment of prostate cancer; Ki-67 staining and phosphatase and tensin homolog (*PTEN*) loss (NCCN, 2024a).

Ki-67 is a nuclear protein involved in cell cycle proliferation and is intended to provide prognostic information on metastasis and prostate cancer-specific mortality (NCCN, 2024a; Ross et al., 2022). Ki-67 staining has shown some promising results. However, the primary limitation with these studies is that most active surveillance populations will have a Gleason Score of 6 or less, which is considered "low-risk." This population will most likely have low Ki-67 levels, clouding its utility in populations trying to decide between immediate and deferred treatment (Ross et al., 2022).

PTEN loss is a relatively early event in the course of prostate cancer. *PTEN* is a tumor suppressor gene on chromosome 10q and is involved in cell cycle regulation. PTEN is intended to provide prognostic information on prostate cancer-specific mortality, biochemical recurrence, and cancer progression (NCCN, 2024a; Ross et al., 2022). Data on prognostic value of PTEN loss post-treatment have been conflicting. It is possible that active treatments contribute to the disruption of the PTEN pathway or the high correlation between PTEN loss and clinicopathologic factors. Lotan et al. (2011) found that when clinicopathologic factors, such as Gleason Score and surgical margin status, were included in their multivariable analysis, PTEN's association with metastasis and prostate cancer-specific mortality decreased significantly.

ArteraAI Prostate Cancer

ArteraAI Prostate Cancer is a multimodal artificial intelligence (MMAI) digital pathology-based post-radical prostatectomy biomarker test that stratifies the risk of metastasis as well as identifies the potential benefits of additional hormone therapy. It is for patients who have been diagnosed with localized prostate cancer who have not yet received radiation therapy (RT) or androgen-deprivation therapy (ADT) before getting a biopsy. The current standard for individuals with intermediate-risk localized prostate cancer includes treatment with ST-ADT in combination with radiation therapy, but a clinical study of the predictive biomarker used in the ArteraAI Prostate test showed that only 34% of patients require radiation therapy. The AI portion of the test "learns" from digital pathology images and clinical data inputs to then predict the likelihood of additional therapy being beneficial, as well provides details as to the

prognosis of the patient. Test results do not require tissue, but rather a validated algorithm is used to assess the "digital image" from a patient's biopsy and clinical data.

The development of the ArteraAI model relied on two trials and utilized clinical data and digital pathology. The 5-year DM area under the curve was 0.83 for ArteraAI, compared with 0.72 for NCCN risk group (P < .001). Results show promising risk stratification for hormonal therapy (Results identified 40% of biochemical recurrence (BCR) patients who benefited from therapy intensification vs. 60% of patients who did not) indicating potential benefits for high-risk patients; this tool is purported to be of use with both newly-diagnosed patients and those that show biochemical recurrence (ArteraAI, 2024; Hannah Clarke, 2024).

Esteva et al. (2022) performed a study to demonstrate the usage of multimodal deep learning architecture to personalize therapy for prostate cancer by predicting long-term outcomes using clinical data and digital histopathology from prostate biopsies. The models, trained and validated on data from the five phase III randomized trials, outperformed the National Cancer Center Network (NCCN) risk groups in terms of discriminatory performance on all endpoints. The AI-based tool (ArteraAI) provided superior prognostication with a relative improvement over these current risk group tools (based on digital rectal exam, serum prostate-specific antigen (PSA) level, and tumor biopsy grade) of between 9.2% to 14.6% in a held-out validation set (Esteva et al., 2022).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

Patients with low or favorable intermediate-risk disease and life expectancy ≥10 y may consider the use of the following tumor-based molecular assays: Decipher, Oncotype DX Prostate, and Prolaris. Patients with unfavorable intermediate- and high-risk disease and life expectancy ≥10 y may consider the use of Decipher and Prolaris tumor-based molecular assays. Retrospective studies have shown that molecular assays performed on prostate biopsy or RP specimens provide prognostic information independent of NCCN or CAPRA risk groups. These include, but are not limited to, "likelihood of death with conservative management, likelihood of biochemical recurrence after radical prostatectomy or EBRT, likelihood of adverse pathologic features after radical prostatectomy, and likelihood of developing metastasis after operation, definitive EBRT, or post-recurrence EBRT" (NCCN, 2024a). Furthermore, they note that clinicians may consider testing patients with metastatic prostate cancer and regional prostate cancer for alterations in homologous recombination DNA repair genes *BRCA1*, *BRCA2*, *ATM, PALB2, FANCA, RAD51D*, *CHEK2,* and *CDK12*; "Post-test genetic counseling is recommended if pathogenic/likely pathogenic somatic mutations in any gene that has

clinical implications if also identified in germline (e.g., *BRCA2*, *BRCA1*, *ATM, PALB2, CHEK2, HOXB13, MLH1, MSH2, MSH6, PMS2)"* (NCCN, 2024a). The NCCN noted that somatic tumor testing of the aforementioned genes has potential for early use of platinum chemotherapy, use of PARP inhibitors, or eligibility for clinical trials. Lastly, they recommend that individuals with regional disease, metastatic castration-resistant disease, or castration-naïve metastatic disease should additionally consider tumor testing for microsatellite instability or mismatch repair deficiency. The NCCN also specifically does not recommend either Ki-67 or *PTEN* testing (NCCN, 2024a).

The NCCN does include available tissue-based tests for prostate cancer risk stratification/prognosis within their table of possible testing as indicated below. Regarding Decipher testing, NCCN states that Decipher "may be considered to inform adjuvant treatment if adverse events are found after radical prostatectomy and during workup for radical prostatectomy PSA persistence or recurrence." NCCN discourages repeat molecular tumor analysis (NCCN, 2024a, 2024b):

Test	Platform	Recommendation
Decipher	Whole-Transcriptome 1.4M RNA expression (46,050 genes and non-coding RNA), oligonucleotide microarray optimized for FFPE tissue	Cover post-biopsy for NCCN very-low-, low-risk, favorable intermediate, and unfavorable intermediate risk prostate cancer in patients with at least 10 years life expectancy who have not yet received treatment for prostate cancer and are candidates for active surveillance or definitive therapy. Cover post-RP for 1) pT2 with positive margins; 2) any pT3 disease; 3) rising PSA (above nadir)
KI-67	IHC	Not recommended
Oncotype DX Prostate	Quantitative RT-PCR for 12 prostate cancer-related genes and 5 housekeeping controls	Cover post-biopsy for NCCN very-low-, low-risk, and favorable intermediate-risk prostate cancer in patients with at least 10 years life expectancy who have not yet received treatment for prostate cancer and are candidates for active surveillance or definitive therapy.
Prolaris	Quantitative RT-PCR for 31	Cover post-biopsy for NCCN very-

	cell cycle-related genes and 15 housekeeping controls	low-, low-risk, and favorable intermediate-risk prostate cancer in patients with at least 10 years life expectancy who have not yet received treatment for prostate cancer and are candidates for active surveillance or definitive therapy.
PTEN	Fluorescence in situ hybridization or IHC	Not recommended

The NCCN, within the algorithm for the indications for prostate biopsy, says to "consider biomarkers that improve the specificity of screening" for individuals who have had elevated levels of PSA (above three ng/mL for those ages 45 – 75 years or four ng/mL or higher for those individuals over the age of 75 years. The NCCN goes on to state, "Biomarkers that improve the specificity of detection are not, as yet, mandated as first-line screening tests in conjunction with serum PSA. However, there may be some patients who meet PSA standards for consideration of prostate biopsy, but for whom the patient and/or the physician wish to further define risk. Lower percent-free PSA and/or higher PSA density are associated with a greater risk of high-grade prostate cancer. The probability of high-grade cancer (Gleason score ≥ 3+4, Grade Group two or higher) may be further defined utilizing the Prostate Health Index (PHI), SelectMDx, 4Kscore, and ExoDx Prostate Test, MyProstateScore (MPS), and IsoPSA. Extent of validation of these tests across diverse populations is variable. It is not yet known how such tests could be applied in optimal combination with MRI" (NCCN, 2024b).

The NCCN notes that "Tests that improve specificity in the post-biopsy setting—including percent-free PSA, 4Kscore, PHI, PCA3, ConfirmMDx, ExoDx Prostate Test, MPS, and IsoPSA—should be considered in patients thought to be higher risk despite a negative prostate biopsy" (NCCN, 2024b).The NCCN panel remarks that 4Kscore "can be considered for patients prior to biopsy and for those with a prior negative biopsy who are thought to be at higher risk for clinically significant prostate cancer" The NCCN further remarks that SelectMDx is "potentially informative" in patients who have never undergone biopsy and can therefore be "considered" in these patients. The NCCN also acknowledged that ConfirmMDX can be considered an option for individuals contemplating repeat biopsy and is approved for limited coverage by MolDX to reduce unnecessary repeat biopsies. Further, ExoDx Prostate (IntelliScore), also called EPI, "can be considered as an option for individuals contemplating initial or repeat biopsy because the assay may identify individuals at higher risk of prostate

cancer diagnosis on repeat biopsy." IsoPSA and MyProstrateScore "can be considered for patients prior to biopsy." Lastly, the PCA3 assay can be used to help "decide, along with other factors, whether a repeat biopsy in individuals aged ≥50 years with one or more previous negative prostate biopsies is necessary" (NCCN, 2024b).

The NCCN also lists ArteraAI Prostate Cancer in "Table 2: Risk Stratification, Selected Advanced Tools for Localized Prostate Cancer." The category of the listing is "AI Pathology" and it is listed as "predictive" and "prognostic" for "biochemical recurrence," "distant metastases," and "prostate cancer specific mortality" with a IB category for predictive and IB for prognostic (IB meaning: "Prospective clinical trial(s) using archived samples with design that accommodates tumor marker utility, ≥1 validation study available with consistent results"), it also falls under "**Category 2A:** Based upon lower-level evidence, there is uniform NCCN consensus that the intervention is appropriate."(NCCN, 2024a).

American Society of Clinical Oncology (ASCO)

In 2020, an ASCO multidisciplinary panel published guidelines on molecular biomarkers in localized prostate cancer. These guidelines are below.

- "Commercially available molecular biomarkers (i.e., Oncotype Dx Prostate, Prolaris, Decipher, and ProMark) may be offered in situations in which the assay result, when considered as a whole with routine clinical factors, is likely to affect management. Routine ordering of molecular biomarkers is not recommended."
- "Any additional molecular biomarkers evaluated do not have sufficient data to be clinically actionable or are not commercially available and thus should not be offered"
- "The Expert Panel recommends consideration of a commercially available molecular biomarker (e.g., Decipher Genomic Classifier) in situations in which the assay result, when considered as a whole with routine clinical factors, is likely to affect management. In the absence of prospective clinical trial data, routine use of genomic biomarkers in the postprostatectomy setting to determine adjuvant versus salvage radiation or to initiate systemic therapies should not be offered."
- In individuals "with newly diagnosed prostate cancer who are eligible for active surveillance, both genomics and MRI intend to identify clinically significant cancers. The Expert Panel endorses their use only in situations in which the result, when considered as a whole with routine clinical factors, is likely to have an impact on patient management" (Eggener et al., 2020).

In 2020, an ASCO panel published guidelines on the use of molecular biomarkers in localized prostate cancer. In concordance with the 2018 and 2019, ASCO recommends

the use of commercially available tests (Oncotype Dx Prostate, Prolaris, Decipher, and ProMark) when the assay result "is likely to have an impact on patient management. Examples include select individuals with high-volume low-risk or favorable intermediate-risk prostate cancer who are considering active surveillance or in individuals with high-risk features for treatment intensification. While testing may influence management decisions, there is no high-level evidence that the results from these panels will improve quality of life or cancer-specific outcomes" (Eggener et al., 2020).

European Association of Urology (EAU), European Association of Nuclear Medicine (EANM), European Society for Radiotherapy and Oncology (ESTRO), European Society of Urogenital Radiology (ESUR), International Society of Urological Pathology (ISUP), and the International Society of Geriatric Oncology (SIOG)

In 2023, the EAU, EANM, ESTRO, ESUR, ISUP and SIOG released joint guidelines on prostate cancer. These guidelines state that asymptomatic individuals with a prostate-specific antigen level between three and ten ng/mL and a normal digital rectal examination, use one of the following tools for biopsy indication:

- "risk-calculator, provided it is correctly calibrated to the population prevalence(strong);
- magnetic resonance imaging of the prostate (strong).
- An additional serum, urine biomarker test (weak)."

These joint guidelines acknowledged PHI, Progensa *PCA3*, and SelectMDX as tests used to select for repeat biopsies, but stated that "given the limited available data and the fact that the role of MRI in tumour detection was not accounted for, no recommendation can be made regarding the routine application of ConfirmMDX, in particular in light of current use of MRI before biopsy." They also noted that the "clinically added value of SelectMDX in the era of upfront MRI and targeted biopsies remains unclear."

Other tests recognized as having use in the evaluation of prostate cancer included Oncotype Dx, Prolaris, Decipher, Decipher PORTOS and Promark. These five commercially available tests have "extensive validation in large retrospective studies and evidence that their tests results might actually impact clinical decision-taking." However, "since the long-term impact of the use of these commercially available tests on oncological outcome remains unproven and prospective trials are largely lacking, the Panel concluded that these tests should not be offered routinely but only in subsets of patients where the test result provides clinically actionable information." They provide the examples of an individual with favorable intermediate-risk PCa who

decides to continue with active surveillance or an individual with unfavorable intermediate-risk PCa who opts for radiotherapy (RT) to consider treatment intensification with hormonal therapy" (Mottet et al., 2023).

European Society for Medical Oncology (ESMO)

European Society for Medical Oncology (ESMO) provided recommendations on the use of precision medicine in providing prognostic information for prostate cancer. These are the following recommendations provided:

- ESMO does not recommend the use of AR-V7 testing, stating that the test is of limited value in therapy selection.
- Other tissue-based molecular assays may be used on conjunction with clinicopathological factors to make treatment decision.
- Germline testing for *BRCA2* and other DDR [DNA damage and repair] genes is recommended in patients with a family history of cancer and should be considered in patients with metastatic cancer (Parker et al., 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81313	PCA3/KLK3 (prostate cancer antigen 3 [non-protein coding]/kallikrein-related peptidase 3 [prostate specific antigen]) ratio (eg, prostate cancer)

CPT	Code Description
81479	Unlisted molecular pathology procedure
81539	Oncology (high-grade prostate cancer), biochemical assay of four proteins (Total PSA, Free PSA, Intact PSA, and human kallikrein-2 [hK2]), utilizing plasma or serum, prognostic algorithm reported as a probability score.
81541	Oncology (prostate), mRNA gene expression profiling by real-time RT-PCR of 46 genes (31 content and 15 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a disease-specific mortality risk score
81542	Oncology (prostate), mRNA, microarray gene expression profiling of 22 content genes, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as metastasis risk score
81551	Oncology (prostate), promoter methylation profiling by real-time PCR of 3 genes (GSTP1, APC, RASSF1), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a likelihood of prostate cancer detection on repeat biopsy
0005U	Oncology (prostate) gene expression profile by real-time RT-PCR of 3 genes (ERG, PCA3, and SPDEF), urine, algorithm reported as risk score Proprietary test: ExoDx® Prostate (IntelliScore) Lab/manufacturer: Exosome Diagnostics, Inc.
0113U	Oncology (prostate), measurement of PCA3 and TMPRSS2-ERG in urine and PSA in serum following prostatic massage, by RNA amplification and fluorescence-based detection, algorithm reported as risk score Proprietary test: MyProstateScore Lab/Manufacturer: Lynx DX
0021U	Oncology (prostate), detection of 8 autoantibodies (ARF 6, NKX3-1, 5'-UTR-BMI1, CEP 164, 3'-UTR-Ropporin, Desmocollin, AURKAIP-1, CSNK2A2), multiplexed immunoassay and flow cytometry serum, algorithm reported as risk score Proprietary test: Apifiny® Lab/Manufacturer: Armune BioScience, Inc.
0047U	Oncology (prostate), mRNA, gene expression profiling by real-time RT-PCR of 17 genes (12 content and 5 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a risk score Proprietary test: Genomic Prostate Score® (GPS) Test Lab/manufacturer: MDxHealth, Inc
0053U	Oncology (prostate cancer), FISH analysis of 4 genes (ASAP1, HDAC9, CHD1 and PTEN), needle biopsy specimen, algorithm reported as probability of higher tumor grade

CPT	Code Description
	Proprietary test: Prostate Cancer Risk Panel Lab/Manufacturer: Mayo Clinic Laboratory
0228U	Oncology (prostate), multianalyte molecular profile by photometric detection of macromolecules adsorbed on nanosponge array slides with machine learning, utilizing first morning voided urine, algorithm reported as likelihood of prostate cancer Proprietary test: PanGIA Prostate Lab/Manufacturer: Genetics Institute of America/Entopsis, LLC
0339U	Oncology (prostate), mRNA expression profiling of HOXC6 and DLX1, reverse transcription polymerase chain reaction (RT-PCR), first-void urine following digital rectal examination, algorithm reported as probability of high-grade cancer Protietary test: SelectMDx® for Prostate Cancer Lab/Manufacturer: MDxHealth®, Inc
0359U	Oncology (prostate cancer), analysis of all prostate-specific antigen (PSA) structural isoforms by phase separation and immunoassay, plasma, algorithm reports risk of cancer Proprietary test: IsoPSA® Lab/Manufacturer: Cleveland Diagnostics, Inc
0403U	Oncology (prostate), mRNA, gene expression profiling of 18 genes, first-catch post-digital rectal examination urine (or processed first-catch urine), algorithm reported as percentage of likelihood of detecting clinically significant prostate cancer Proprietary test: MyProstateScore 2.0 Lab/Manufacturer: LynxDX
0424U	Oncology (prostate), exosome- based analysis of 53 small noncoding RNAs (sncRNAs) by quantitative reverse transcription polymerase chain reaction (RT-qPCR), urine, reported as no molecular evidence, low-, moderate- or elevated-risk of prostate cancer. Proprietary test: miR Sentinel™ Prostate Cancer Test Lab/Manufacturer: miR Scientific®, LLC
0433U	Oncology (prostate), 5 DNA regulatory markers by quantitative PCR, whole blood, algorithm, including prostate-specific antigen, reported as likelihood of cancer. Proprietary test: EpiSwitch® Prostate Screening Test (PSE) Lab/Manufacturer: Oxford BioDynamics PLC

General Genetic Testing, Germline Disorders

Policy Number: AHS – M2145 – General Genetic Testing Germline Disorders	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUNDU | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Germline variants or mutations are defined as genetic alterations that occur within the germ cells (egg or sperm), such that the alteration becomes incorporated into the DNA of every cell in the body of the offspring. It may also be called a hereditary mutation (Li et al., 2017; NCI, 2024).

Genetic testing refers to the use of technologies that identify genetic variation, which include genomic, transcriptional, proteomic, and epigenetic alterations, for the prevention, diagnosis, and treatment of disease (Kohlmann & Slavotinek, 2024; Li et al., 2017).

II. Related Policies

Policy Number	Policy Title
AHS-M2066	Genetic Cancer Susceptibility Using Next Generation Sequencing
AHS-M2146	General Genetic Testing, Somatic Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Single gene or multi-gene panel testing (see Note 1 and Note 2) for inherited diseases **MEETS COVERAGE CRITERIA** (once per patient lifetime) when **one** of the following criteria are met:

   a) The individual is currently symptomatic with the suspicion of a known genetic disease in which knowledge of the likely pathogenic or pathogenic variant will assist in the diagnosis, treatment, or procreative management.

b) For asymptomatic individuals who are judged to be at significant risk (based on family history and/or ethnicity) for an inherited disorder or an inherited cancer risk factor, **and** meet one of the following conditions:

   i) The individual is being tested for their risk of an adult-onset condition and is at or above the age of majority, (e.g., 18 years).

   ii) An individual not at or above the age of majority is being tested for their risk of an adult-onset condition for which there is documented evidence that early intervention during childhood may prevent disease severity or time of disease onset.

c) For asymptomatic individuals who are **both**:

   i) judged to be at risk as a carrier of an inherited disorder or cancer risk factor based on family history and/or ethnicity;

   ii) would benefit from procreative management.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) The following genetic tests for inherited diseases **DO NOT MEET COVERAGE CRITERIA**:

   a) Tests for genes that do not meet the above criteria.

   b) Inherited disease diagnosis or carrier assessment using panels of genes that include genes outside of those specifically related to the disease being investigated.

   c) Repeat germline testing of a unique gene using the identical method of gene analysis.

   d) Testing as a screening tool for the general population.

   e) Direct-to-consumer genetic testing (e.g., mail order, online ordering, pharmacy, retail).

NOTES:

Note 1: Genetic tests being considered must meet all of the following conditions:

a) Scientific literature shows that a specific a gene likely pathogenic or pathogenic variant (or variants) is associated with the disease in question and that

identification of the variant is clinically actionable (there is clinical utility) with a non-investigational treatment;

b) When confirmation of a gene likely pathogenic or pathogenic variant is standard of care for the disease state and other testing for the disease is either equivocal or does not exist;
c) The disease in question is associated with significant morbidity and/or mortality;
d) The results of testing can impact clinical management (via surveillance or treatment strategies) and will guide decisions on healthcare management to mitigate symptoms or progression of the disorder.

Note 2: For two or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics and Genomics
AMP	Association For Molecular Pathology
APC	*Adenomatous polyposis coli*
ASCO	American Society of Clinical Oncology
ATM	*Ataxia telangiectasia mutated*
BRCA1/2	*Breast cancer gene 1/2*
CAP	College of American Pathologists
CDH1	*Cadherin-1*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CNV	Copy number variant
CSG	Cancer susceptibility gene
ctDNA	Circular tumor deoxyribonucleic acid
FDA	Food and Drug Administration
EMSO	European Society for Medical Oncology
LDTs	Laboratory-developed tests
LOF	Loss-of-function
MGPT	Multi-gene panel testing
NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
PALB2	*Partner and localizer of BRCA2*
PCR	Polymerase chain reaction
PTEN	*Phosphatase and tensin homolog*
PVG	Pathogenic germline variants

smMIPS	Single molecule molecular inversion probes
SNPs	Single nucleotide polymorphisms
TP53	*Tumor protein P53*
VUS	Variant of uncertain significance

V. Scientific Background

Gene mutations are referred to as "germline" if they are within gametes (ova and sperm). Therefore, these mutations may be passed on from parent to offspring (Raby & Blank, 2024). There are many different types of germline mutations, such as single nucleotide polymorphisms (SNPs), structural variations such as deletions, inversions, or translocations, as well as smaller chromosomal abnormalities such as short tandem repeats, or gene fusions. Mutations may not necessarily result in disease (Christensen & Hulick, 2024).

Single nucleotide polymorphisms are the most common type of genetic mutation, such as missense mutations. These mutations are single base-pair changes where one nucleotide is replaced with a different nucleotide. Millions of SNPs have been identified through genome-wide association studies, approximately 4000 SNPs have a potential association with disease (Attia, 2024). Insertion/deletion (indel) polymorphisms are often a single nucleotide but may be up to four nucleotides. SNPs often lead to frameshift mutations, which can cause premature stop codons and the failure of the allele (Kohlmann & Slavotinek, 2024).

Structural variations are usually classified as larger than 1000 base pairs. These include deletions, duplications, inversions, translocations, or ring chromosome formation. Due to the large number of bases affected, these variations may lead to severe genetic abnormalities. For example, a major cause of Duchenne muscular dystrophy is the deletion of large portions of exons (coding portions of genes). The most common structural variation is the copy number variant (CNV), which refers to differing amounts of DNA segments in different individuals. For example, one person may have three copies of a specific segment whereas another may only have two. These variations may lead to dysregulation, gain-of-function, or loss-of-function of the affected genes. The sensitive genes that require or produce precise amounts of a protein product tend to suffer more from these variations (Bacino, 2023).

Germline mutations are unique in that the risk for certain conditions, including many forms of cancer, may be passed from parent to offspring. Testing for these conditions will often involve testing entire families if one member is found to have a germline

mutation; for example, the National Comprehensive Cancer Network (NCCN) guidelines for hereditary breast cancer recommend testing for high-penetrance breast cancer susceptibility genes such as *BRCA1/2, CDH1, PALB2, PTEN, STK*, and *TP53* mutations if any blood relative has a known or likely pathogenic variant in a cancer susceptibility gene (NCCN, 2024a). Wilson et al. (2020) estimate that 21,800 adult survivors of childhood cancer in the United States carry a pathogenic or likely pathogenic variant in one of 156 cancer predisposition genes.

Some types of mutations are unique to germline mutations. Errors in chromosome number (aneuploidy) are typically caused by nondisjunctions in meiosis, causing either a monosomic (one chromosome) or a trisomic (three chromosomes) set of chromosomes. Some aneuploidies, trisomy 21, or Down Syndrome, being most notable, are compatible with life. Aneuploidies may also result with sex chromosomes, resulting in conditions such as Turner's Syndrome (one X chromosome) or Klinefelter's Syndrome (XXY) (Bacino, 2024; Schrijver & Zehnder, 2024).

Any size mutation may be pathogenic and must be classified as to how likely they are to cause disease. The American College of Medical Genetics and Genomics (ACMG) has classified mutations in five categories, which are as follows: pathogenic, likely pathogenic, uncertain significance, likely benign, and benign. The "likely pathogenic" and "likely benign" refer to weaker evidence than their respective pathogenic and benign categories, and "uncertain significance" refers to evidence that does not meet criteria for benignity or pathogenicity or has conflicting evidence from both sides (Christensen & Hulick, 2024). Prediction algorithms have been used to interpret variants and to predict whether a variant will affect the gene function or splicing of the gene. These algorithms are publicly available but have a tendency of predicting harmful impact of a variant. The specificity of these databases has been estimated at 60-80% (Li et al., 2017).

Due to the enormous number of variants, as well as the rate that variants are discovered, comprehensive databases of genetic variants have been published and are easily available. For example, the Haplotype Reference Consortium contains over 40 million identified SNPs (Christensen & Hulick, 2024). Databases focusing on cancer-specific variants, reference sequences, and the general population are all available publicly (Li et al., 2017).

For many years, single-gene testing was the standard approach for germline mutation testing. In recent years, multi-gene panel testing (MGPT) has been introduced and

widely accepted as the first-tier test. MGPT increases the probability of identifying pathogenic mutations and represents an affordable application of next-generation sequencing (NGS) into clinical practice. However, the clinical utility of MGPT is not well established, especially in cases where more than one pathogenic variant is identified. The risk for a specific malignancy is complex and if a gene panel discovers a mutation incidentally, management can be difficult. Many guidelines call for radical procedures for these disease states and it may cause unnecessary harm for the patient concerned about predisposition to the disease. Additionally, a combination of mutations may interact to alter the profile of the disease. For instance, certain combinations of mutations may be detrimental and increase the overall risk of cancer malignancy, while other combinations may reduce overall risk of malignancy. In this regard, identifying clinically actionable mutations may be unclear with MGPT (Slaught et al., 2021).

Clinical Utility and Validity

Genetic testing for germline mutations "can be conducted on virtually any tissue type," although many laboratories prefer blood samples, check swabs or saliva samples (Kohlmann & Slavotinek, 2024). Advancements in technology and availability of sequencing, previously constrained by limitations of sequential single-gene testing on limited patient samples, have led to significant strides in the understanding of the genetic basis of inherited and somatic conditions.

Variants detected by genetic testing include inherited germline variants and somatic mutations; NGS has allowed for superior detection for these mutations (Konnick & Pritchard, 2016). The accuracy of NGS varies depending on how many genes are sequenced; fewer genes tend to result in higher accuracy since there will be more "probe-template overlap." Although Sanger sequencing remains the most accurate at >99.99% accuracy, it cannot sequence a large quantity of genes in a timely fashion and is best used for sequencing of a specific gene (Hulick, 2024). Pogoda et al. (2019) identified rare variants in the *ATM* gene by using single molecule molecular inversion probes (smMIPSs), an NGS-based screening method. A total of 373 patients with dystonia and six positive controls with previously identified *ATM* variants participated in this study. Results generated by the smMIPs "produced similar results as routinely used NGS-based approaches" (Pogoda et al., 2019). This suggests that *ATM* screening should be routinely used when genetic testing dystonia patients. Further, smMIPs may be an important technique for the germline screening for all rare neurodegenerative disorders.

The clinical validity of a genetic test depends primarily on the expressivity and penetrance of a given phenotype. Penetrance refers to the likelihood of developing a disease when the pathogenic mutation is present, and expressivity refers to the variations in the way the disease is expressed. For example, virtually any mutation in the *APC* gene will cause symptoms of familial adenomatous polyposis, thereby increasing the clinical validity of an *APC* assessment while other conditions may not clinically manifest at all despite a mutated genotype (Kohlmann & Slavotinek, 2024).

The clinical utility of a genetic test generally relies on available treatments for a condition. Conditions such as Huntington Disease that do not have many options for treatment will have limited clinical utility compared to another condition even though the actual test is highly valid. Factors, such as severity of the disease and management options, affect the clinical utility of a genetic test (Kohlmann & Slavotinek, 2024).

Lincoln et al. (2020) performed a retrospective study to investigate the yield and utility of germline testing on cancer patients following tumor DNA sequencing. The authors calculated the prevalence of pathogenic germline variants (PVG) and the potential actionability of the PVGs in 2023 cancer patients. A total of 30.5% (n=617) of participants had PVGs. Participants with PVGs spanned all ages and cancer types. Tumor DNA sequencing missed 8.1% of PGVs. A total of 11.2% of missed PVGs were only detected after developing a second primary cancer. The results suggest that missed PVGs could have been detected earlier and the second cancer could have been treated earlier or prevented. The authors concluded that germline testing following tumor DNA sequencing can result in important findings that can impact patient care (Lincoln et al., 2020).

There is an ethical concern associated with genetic testing for germline disorders, and patients can have mixed preferences about receiving their results. Although the information can be clinically useful, it can also be burdensome knowledge on patients and their families. Best et al. (2022) studied the preferences on receiving results in patients who have undergone germline genome sequencing. The study included 335 cancer patients and 199 of their relatives, all of whom were undergoing germline genome sequencing. "A significantly higher percentage of probands thought people would like to be informed about genetic conditions for which there is prevention or treatment that can change cancer risk compared to conditions for which there is no prevention or treatment (93% [311] versus 65% [216]; $p < 0.001$). Similar results were obtained for relatives (91% [180] versus 61% [121]; $p < 0.001$)." The authors also conducted interviews with 40 participants and identified four themes: "1) Recognised benefits of GS, (2) Balancing benefits with risks, (3) Uncertain results are perceived as unhelpful and (4) Competing obligations." The authors conclude by noting the

importance in ensuring patient understanding of the relevant test validity and consent options (Best et al., 2022).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP)

The ACMG and AMP released criteria on the types and severity of mutations, which are as follows:

- **Very strong evidence of pathogenicity**: Null variants (nonsense, frameshifts, canonical +/- one to two splice sites, initiation codon, exon deletions) in a gene where loss-of-function (LOF) is a known mechanism of disease. The guidelines note to use caution in genes where LOF is not a mechanism, if LOF variants are at the 3' end, if exon skipping occurs, and if multiple transcripts are present.
- **Strong:** Amino acid change to a pathogenic version, de novo mutations, established studies supporting a damaging gene or gene product, or if the prevalence of the variant is increased in affected individuals compared to healthy controls. The guidelines note to be careful of changes impacting splicing and if only the paternity has been confirmed.
- **Moderate:** Located in a mutational hot spot or well-established functional domain (e.g., active site of an enzyme) without a benign variation, absent from controls in Exome Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium, detected in *trans* with pathogenic variants for a recessive disorder, protein length changes, novel missense changes where a different missense change has been pathogenic before, and a possible de novo mutation.
- **Supporting:** Cosegregation with disease in multiple affected family members in a gene definitively known to cause the disease, missense variant in a gene with low rate of benign missense variation, if the mutation has evidence that it is deleterious, or if the patient's phenotype is highly specific for disease with a single genetic cause.

The guidelines also list criteria for benign gene variants.

- **Stand-alone evidence of benignity:** Allele frequency is > five percent in Exome Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium.

- **Strong:** Allele frequency is greater than expected for disorder, observed in healthy adult with full penetrance at early age, lack of segregation in affected family members (although pathogenic variants may masquerade as nonsegregated), or well-established studies that show no damaging effect on protein production.
- **Supporting:** Missense variant of a gene for which truncating mutations are pathogenic, indels in repetitive region of unknown function, silent variants, variants of unknown significance, or a *trans* version of a *cis* mutation (Richards et al., 2015).

National Comprehensive Cancer Network (NCCN)

Germline mutations have been incorporated into the diagnostic workups recommended by the NCCN. Furthermore, the NCCN has several guidelines which recommend that gene expression profiling, or multiple gene testing, may be helpful, more efficient and/or cost effective for selected patients (NCCN, 2024b).

The NCCN includes some general testing criteria. They believe that testing is indicated in the following scenarios:

- "Individuals with any blood relative with a known P/LP variant in a cancer susceptibility gene"
- "Individuals meeting the criteria below but who tested negative with previous limited testing (eg, single gene and/or absent deletion duplication analysis) and are interested in pursuing multi-gene testing"
- "A P/LP variant identified on tumor genomic testing that has clinical implications if also identified in the germline"
- "To aid in systemic therapy and surgical decision-making" (NCCN, 2024a).

It is also notes that testing may be considered in the following scenario with appropriate pre-test education and access to post-test management: an individual of Ashkenazi Jewish ancestry without additional risk factors and with a personal history of serous endometrial cancer (NCCN, 2024a).

Regarding the choice of multi-gene testing, the NCCN states that:

- "The introduction of multi-gene testing for hereditary forms of cancer has rapidly altered the clinical approach to hereditary cancer testing of patients at increased risk of inherited susceptibility to cancer and their families. Based on next-

generation sequencing (NGS) technology, these tests simultaneously analyze a set of genes that are associated with a specific family cancer phenotype or multiple phenotypes."

- "An individual's personal and/or family history may be explained by more than one inherited cancer syndrome; thus, phenotype-directed testing based on personal and family history through a tailored multi-gene panel test is often more efficient and cost effective and increases the yield of detecting a P/LP variant in a gene that will impact medical management for the individual or their family members with increased risk."
    - The NCCN explains here that 'tailored' is "defined as a disease-focused multi-gene panel of clinically actionable cancer susceptibility genes, in contrast to large multi-gene panels of uncertain or unknown clinical relevance."
- "There may also be a role for multi-gene testing in individuals who have tested negative for a single syndrome, but whose personal or family history remains suggestive of an inherited susceptibility."
- "Some individuals may carry P/LP germline variants in more than one cancer susceptibility gene; thus, consideration of a multi-gene panel for individuals already known to carry a single P/ LP germline variant from phenotype-directed testing may be considered on a case-by-case basis, based on the degree of suspicion for there being additional variants."
- "Because commercially available tests differ in the specific genes analyzed, variant classification, and other factors (eg, methods of DNA/RNA analysis or option to reflex from a narrow to a larger panel; provision of financial assistance for cascade testing of relatives), it is important to consider the indication for testing and expertise of the laboratory when choosing the specific laboratory and test panel."
- "Multi-gene testing can include "intermediate" penetrant (moderate-risk) genes." This is because "For many of these genes, there are limited data on the degree of cancer risk, and there may currently be no clear guidelines on risk management for carriers of P/LP variants. Not all genes included on available multi-gene tests will change risk management compared to that based on other risk factors such as family history."
- "It may be possible to refine risks associated with both moderate and high penetrance genes, taking into account the influence of gene/gene or gene/ environment interactions. In addition, certain P/LP variants in a gene may pose higher or lower risk than other P/LP variants in that same gene. This information

should be taken into consideration when assigning risks and management recommendations for individuals and their relatives who also have increased risk."
- "P/LP variants in many breast, ovarian, pancreatic, and prostate cancer susceptibility genes involved in DNA repair may be associated with rare autosomal recessive conditions, thus posing risks to offspring if the partner is also a carrier."
- "As more genes are tested, there is an increased likelihood of finding VUS, mosaicism, and clonal hematopoiesis of indeterminate potential."
- "When a P/LP variant with clinical implications for the patient and/or their family members is found on tumor genomic testing, germline confirmatory testing should be recommended."
- "There are significant limitations in interpretation of polygenic risk scores (PRS). PRS should not be used for clinical management at this time and use is recommended in the context of a clinical trial, ideally including diverse populations" (NCCN, 2024a).

For more information, please see the individual policies.

Association for Molecular Pathology (AMP), American Society of Clinical Oncology (ASCO), and College of American Pathologists (CAP)

The Joint Commission noted that germline variants should focus on the pathogenicity of a given variant rather than their impact on clinical care. The guidelines recommend reporting germline variants with known clinical impact, such as *BRCA1* or *2*. A genetic counseling recommendation should also be provided if a pathogenic germline mutation is found (Li et al., 2017).

The guidelines note that it is critical to identify a somatic vs a germline mutation as the type of mutation may have significant clinical consequences (Li et al., 2017).

American Society of Clinical Oncology (ASCO)

The ASCO published guidelines regarding genetic and genomic testing for cancer susceptibility. These guidelines state that the "ASCO recognizes that concurrent multigene testing (i.e., panel testing) may be efficient in circumstances that require evaluation of multiple high-penetrance genes of established clinical utility as possible explanations for a patient's personal or family history of cancer. Depending on the specific genes included on the panel employed, panel testing may also identify mutations in genes associated with moderate or low cancer risks and mutations in

high-penetrance genes that would not have been evaluated on the basis of the presenting personal or family history… ASCO affirms that it is sufficient for cancer risk assessment to evaluate genes of established clinical utility that are suggested by the patient's personal and/or family history" (Robson et al., 2015).

The ASCO released guidelines regarding germline testing for epithelial ovarian cancer. ASCO recommends that "all [individuals] diagnosed with epithelial ovarian cancer should be offered germline genetic testing for *BRCA1, BRCA2*, and other ovarian cancer susceptibility genes, irrespective of their clinical features or family cancer history." In addition, "first- or second-degree blood relatives of a patient with ovarian cancer with a known germline pathogenic cancer susceptibility gene mutation or variant should be offered individualized genetic risk evaluation, counseling, and genetic testing." Lastly, "clinical decisions should not be based on a variant of uncertain significance (VUS)." In this case, the patient's clinical features and family history should be taken into consideration and should inform clinical decision making" (Konstantinopoulos et al., 2020).

The ASCO released guidelines for the selection of germline genetic testing panels in patients with cancer. ASCO recommends "all patients should have a family history taken and recorded that includes details of cancers in first- and second-degree relatives and the patient's ethnicity." The guidelines went on to add that "when germline genetic testing is indicated for a patient with cancer, multi-gene panel testing should be offered if more than one gene is relevant" (Tung et al., 2024).

European Society for Medical Oncology (EMSO)

The EMSO published recommendations on the use of circular tumor DNA (ctDNA) assays in patients with cancer. Regarding germline disorders, the authors report that "Pathogenic germline variants in cancer susceptibility genes may be detected in ctDNA (such as BRCA1, BRCA2, PALB2), and detection of such variants requires reflex germline testing with a validated assay to confirm somatic versus germline nature." They also note that "Caution should be carried out in interpretation of pathogenic variants in high penetrance cancer susceptibility genes (such as BRCA1, BRCA2, PALB2); validated germline testing should be carried out to confirm germline or somatic nature" (Pascual et al., 2022).

The ESMO reports that ctDNA assays are validated and sensitive enough to "genotype advanced cancers and select patients for targeted therapies." They note that ctDNA assay results are limited by false-negative results and lower sensitivity for fusion and

copy number changes, and ctDNA should not be used to detect molecular residual disease (Pascual et al., 2022).

The ESMO released recommendations for germline-focussed analysis of tumor-only sequencing:

1. Germline-focussed tumour analysis should be carried out in all laboratories as part of routine analysis of a large tumour panel.
2. Germline-focussed tumour analysis can be delivered via an automated pipeline so as not to add substantial additional manual work, cost or delay to tumour analysis.
3. Variants in should be flagged which are (i) predicted to result in protein truncation in genes acting through LOF and/or (ii) classified as Pathogenic/Likely Pathogenic via a well-maintained, comprehensive and curated clinical resource (ClinVar is recommended).
4. Germline-focussed tumour analysis can be restricted to variants of VAF >30% (SNVs) or >20% (small insertions/deletions). Local validation will be required to confirm the accuracy of tumour VAF estimates, especially for PCR-based NGS methodologies.
5. Samples known or suspected to be hypermutated should be included for germline-focussed tumour analysis.
6. Germline-focussed tumour analysis in the off-tumour context should be restricted to 'High Actionability- [cancer susceptibility genes] CSGs'.
7. Recessively acting 'High Actionability-CSGs' (currently *MUTYH* alone) should be included for germline-focussed tumour analysis but reporting and germline follow-up testing should be undertaken only on detection of two pathogenic variants.
8. Germline-focussed tumour analysis of 'standard actionability'-CSGs should be restricted to the on-tumour setting.
9. 'Standard actionability'-CSGs included for germline-focussed tumour analysis can be restricted to genes of high penetrance.
10. Germline-focussed tumour analysis can be restricted to gene-scenarios for which the germline conversion rate is >10%. For selected genes, it may therefore be appropriate to restrict germline-focussed tumour analysis to just those tumours arising age <30 years.
11. Formal variant review and classification should be undertaken by an experienced clinical scientist before initiation of patient re-contact and/or germline testing.
12. Before analysis of their germline sample for the pathogenic variant, adequate information should be provided to the patient regarding the implications of germline testing, along with documentation of their consent.

13. The tumour-observed pathogenic variant should be analyzed in an appropriate germline sample (lymphocytes, saliva/buccal swab, normal tissue) in a laboratory accredited for germline analysis.
14. A patient in whom a germline pathogenic variant is detected should be referred to a specialist genetics service for long term follow-up and management of the family.
15. A normal/negative tumour sequencing result should not be taken as equivalent to a normal/negative germline result unless robust analysis of dosage has been carried out. This distinction is particularly important for genes such as *BRCA1* and *MSH2*, for which whole exon deletion/duplications constitute a substantial proportion of pathogenic variants.
16. Re-evaluation of this workflow, revised analyses and update of these recommendations should be undertaken at least 2-yearly. Reanalysis should include updated data regarding pathogenicity of variants and penetrance of CSGs, along with review of thresholds for 'germline conversion rates' and VAF cut-offs (Mandelker et al., 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81105	Human Platelet Antigen 1 genotyping (HPA-1), ITGB3 (integrin, beta 3 [platelet glycoprotein IIIa], antigen CD61 [GPIIIa]) (eg, neonatal alloimmune

	thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-1a/b (L33P)
81106	Human Platelet Antigen 2 genotyping (HPA-2), GP1BA (glycoprotein Ib [platelet], alpha polypeptide [GPIba]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-2a/b (T145M)
81107	Human Platelet Antigen 3 genotyping (HPA-3), ITGA2B (integrin, alpha 2b [platelet glycoprotein IIb of IIb/IIIa complex], antigen CD41 [GPIIb]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-3a/b (I843S)
81108	Human Platelet Antigen 4 genotyping (HPA-4), ITGB3 (integrin, beta 3 [platelet glycoprotein IIIa], antigen CD61 [GPIIIa]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-4a/b (R143Q)
81109	Human Platelet Antigen 5 genotyping (HPA-5), ITGA2 (integrin, alpha 2 [CD49B, alpha 2 subunit of VLA-2 receptor] [GPIa]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant (eg, HPA-5a/b [K505E])
81110	Human Platelet Antigen 6 genotyping (HPA-6w), ITGB3 (integrin, beta 3 [platelet glycoprotein IIIa, antigen CD61] [GPIIIa]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-6a/b (R489Q)
81111	Human Platelet Antigen 9 genotyping (HPA-9w), ITGA2B (integrin, alpha 2b [platelet glycoprotein IIb of IIb/IIIa complex, antigen CD41] [GPIIb]) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-9a/b (V837M)
81112	Human Platelet Antigen 15 genotyping (HPA-15), CD109 (CD109 molecule) (eg, neonatal alloimmune thrombocytopenia [NAIT], post-transfusion purpura), gene analysis, common variant, HPA-15a/b (S682Y)
81161	DMD (dystrophin) (eg, Duchenne/Becker muscular dystrophy) deletion analysis, and duplication analysis, if performed
81173	AR (androgen receptor) (eg, spinal and bulbar muscular atrophy, Kennedy disease, X chromosome inactivation) gene analysis; full gene sequence
81174	AR (androgen receptor) (eg, spinal and bulbar muscular atrophy, Kennedy disease, X chromosome inactivation) gene analysis; known familial variant
81177	ATN1 (atrophin 1) (eg, dentatorubral-pallidoluysian atrophy) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81178	ATXN1 (ataxin 1) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles

81179	ATXN2 (ataxin 2) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81180	ATXN3 (ataxin 3) (eg, spinocerebellar ataxia, Machado-Joseph disease) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81181	ATXN7 (ataxin 7) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81182	ATXN8OS (ATXN8 opposite strand [non-protein coding]) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81183	ATXN10 (ataxin 10) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81187	CNBP (CCHC-type zinc finger nucleic acid binding protein) (eg, myotonic dystrophy type 2) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81188	CSTB (cystatin B) (eg, Unverricht-Lundborg disease) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81189	CSTB (cystatin B) (eg, Unverricht-Lundborg disease) gene analysis; full gene sequence
81190	CSTB (cystatin B) (eg, Unverricht-Lundborg disease) gene analysis; known familial variant(s)
81204	AR (androgen receptor) (eg, spinal and bulbar muscular atrophy, Kennedy disease, X chromosome inactivation) gene analysis; characterization of alleles (eg, expanded size or methylation status)
81228	Cytogenomic constitutional (genome-wide) microarray analysis; interrogation of genomic regions for copy number variants (eg, bacterial artificial chromosome [BAC] or oligo-based comparative genomic hybridization [CGH] microarray analysis)
81229	Cytogenomic constitutional (genome-wide) microarray analysis; interrogation of genomic regions for copy number and single nucleotide polymorphism (SNP) variants for chromosomal abnormalities
81233	BTK (Bruton's tyrosine kinase) (eg, chronic lymphocytic leukemia) gene analysis, common variants (eg, C481S, C481R, C481F)
81234	DMPK (DM1 protein kinase) (eg, myotonic dystrophy type 1) gene analysis; evaluation to detect abnormal (expanded) alleles
81236	EZH2 (enhancer of zeste 2 polycomb repressive complex 2 subunit) (eg, myelodysplastic syndrome, myeloproliferative neoplasms) gene analysis, full gene sequence
81237	EZH2 (enhancer of zeste 2 polycomb repressive complex 2 subunit) (eg, diffuse large B-cell lymphoma) gene analysis, common variant(s) (eg, codon 646)

81238	F9 (coagulation factor IX) (eg, hemophilia B), full gene sequence
81239	DMPK (DM1 protein kinase) (eg, myotonic dystrophy type 1) gene analysis; characterization of alleles (eg, expanded size)
81247	G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; common variant(s) (eg, A, A-)
81248	G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; known familial variant(s)
81249	G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; full gene sequence
81252	GJB2 (gap junction protein, beta 2, 26kDa, connexin 26) (eg, nonsyndromic hearing loss) gene analysis; full gene sequence
81260	IKBKAP (inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase complex-associated protein) (eg, familial dysautonomia) gene analysis, common variants (eg, 2507+6T>C, R696P)
81271	HTT (huntingtin) (eg, Huntington disease) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81274	HTT (huntingtin) (eg, Huntington disease) gene analysis; characterization of alleles (eg, expanded size)
81283	IFNL3 (interferon, lambda 3) (eg, drug response), gene analysis, rs12979860 variant
81284	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; evaluation to detect abnormal (expanded) alleles
81285	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; characterization of alleles (eg, expanded size)
81286	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; full gene sequence
81289	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; known familial variant(s)
81305	MYD88 (myeloid differentiation primary response 88) (eg, Waldenstrom's macroglobulinemia, lymphoplasmacytic leukemia) gene analysis, p.Leu265Pro (L265P) variant
81307	PALB2 (partner and localizer of BRCA2) (eg, breast and pancreatic cancer) gene analysis; full gene sequence
81308	PALB2 (partner and localizer of BRCA2) (eg, breast and pancreatic cancer) gene analysis; known familial variant
81312	PABPN1 (poly[A] binding protein nuclear 1) (eg, oculopharyngeal muscular dystrophy) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81320	PLCG2 (phospholipase C gamma 2) (eg, chronic lymphocytic leukemia) gene analysis, common variants (eg, R665W, S707F, L845F)

81329	SMN1 (survival of motor neuron 1, telomeric) (eg, spinal muscular atrophy) gene analysis; dosage/deletion analysis (eg, carrier testing), includes SMN2 (survival of motor neuron 2, centromeric) analysis, if performed
81333	TGFBI (transforming growth factor beta-induced) (eg, corneal dystrophy) gene analysis, common variants (eg, R124H, R124C, R124L, R555W, R555Q)
81336	SMN1 (survival of motor neuron 1, telomeric) (eg, spinal muscular atrophy) gene analysis; full gene sequence
81337	SMN1 (survival of motor neuron 1, telomeric) (eg, spinal muscular atrophy) gene analysis; known familial sequence variant(s)
81343	PPP2R2B (protein phosphatase 2 regulatory subunit Bbeta) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg,
81344	TBP (TATA box binding protein) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP] by techniques such as restriction enzyme digestion or melt curve analysis)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81402	Molecular pathology procedure, Level 3 (eg, >10 SNPs, 2-10 methylated variants, or 2-10 somatic variants [typically using non-sequencing target variant analysis], immunoglobulin and T-cell receptor gene rearrangements, duplication/deletion variants of 1 exon, loss of heterozygosity [LOH], uniparental disomy [UPD])
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)

81407	Molecular pathology procedure, Level 8 (eg, analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)
81408	Molecular pathology procedure, Level 9 (eg, analysis of >50 exons in a single gene by DNA sequence analysis)
81437	Hereditary neuroendocrine tumor-related disorders (eg, medullary thyroid carcinoma, parathyroid carcinoma, malignant pheochromocytoma or paraganglioma), genomic sequence analysis panel, 5 or more genes, interrogation for sequence variants and copy number variants
81438	Hereditary neuroendocrine tumor disorders (eg, medullary thyroid carcinoma, parathyroid carcinoma, malignant pheochromocytoma or paraganglioma); duplication/deletion analysis panel, must include analyses for SDHB, SDHC, SDHD, and VHL
81441	Inherited bone marrow failure syndromes (IBMFS) (eg, Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan anemia, Shwachman-Diamond syndrome, GATA2 deficiency syndrome, congenital amegakaryocytic thrombocytopenia) sequence analysis panel, must include sequencing of at least 30 genes, including BRCA2, BRIP1, DKC1, FANCA, FANCB, FANCC, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCL, GATA1, GATA2, MPL, NHP2, NOP10, PALB2, RAD51C, RPL11, RPL35A, RPL5, RPS10, RPS19, RPS24, RPS26, RPS7, SBDS, TERT, and TINF2
81442	Noonan spectrum disorders (eg, Noonan syndrome, cardio-facio-cutaneous syndrome, Costello syndrome, LEOPARD syndrome, Noonan-like syndrome), genomic sequence analysis panel, must include sequencing of at least 12 genes, including BRAF, CBL, HRAS, KRAS, MAP2K1, MAP2K2, NRAS, PTPN11, RAF1, RIT1, SHOC2, and SOS1
81443	Genetic testing for severe inherited conditions (eg, cystic fibrosis, Ashkenazi Jewish-associated disorders [eg, Bloom syndrome, Canavan disease, Fanconi anemia type C, mucolipidosis type VI, Gaucher disease, Tay-Sachs disease], beta hemoglobinopathies, phenylketonuria, galactosemia), genomic sequence analysis panel, must include sequencing of at least 15 genes (eg, ACADM, ARSA, ASPA, ATP7B, BCKDHA, BCKDHB, BLM, CFTR, DHCR7, FANCC, G6PC, GAA, GALT, GBA, GBE1, HBB, HEXA, IKBKAP, MCOLN1, PAH)
81470	X-linked intellectual disability (XLID) (eg, syndromic and non-syndromic XLID); genomic sequence analysis panel, must include sequencing of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL, RPS6KA3, and SLC16A2

81471	X-linked intellectual disability (XLID) (eg, syndromic and non-syndromic XLID); duplication/deletion gene analysis, must include analysis of at least 60 genes, including ARX, ATRX, CDKL5, FGD1, FMR1, HUWE1, IL1RAPL, KDM5C, L1CAM, MECP2, MED12, MID1, OCRL, RPS6KA3, and SLC16A2
81479	Unlisted molecular pathology procedure
0130U	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis), targeted mRNA sequence analysis panel (APC, CDH1, CHEK2, MLH1, MSH2, MSH6, MUTYH, PMS2, PTEN, and TP53) (List separately in addition to code for primary procedure - 81435, 0101U) Proprietary test: RNAinsight™ for ColoNext® Lab/Manufacturer: Ambry Genetics
0138U	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) mRNA sequence analysis (List separately in addition to code for primary procedure) Proprietary test: RNAinsight™ for BRCA1/2 Lab/Manufacturer: Ambry Genetics
0230U	AR (androgen receptor) (eg, spinal and bulbar muscular atrophy, Kennedy disease, X chromosome inactivation), full sequence analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, short tandem repeat (STR) expansions, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® AR Analysis Lab/Manufacturer: Variantyx Inc
0232U	CSTB (cystatin B) (eg, progressive myoclonic epilepsy type 1A, Unverricht-Lundborg disease), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, short tandem repeat (STR) expansions, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® CSTB Analysis Lab/Manufacturer: Variantyx Inc
0236U	SMN1 (survival of motor neuron 1, telomeric) and SMN2 (survival of motor neuron 2, centromeric) (eg, spinal muscular atrophy) full gene analysis, including small sequence changes in exonic and intronic regions, duplications and deletions, and mobile element insertions Proprietary test: Genomic Unity® SMN1/2 Analysis Lab/Manufacturer: Variantyx Inc
0269U	Hematology (autosomal dominant congenital thrombocytopenia), genomic sequence analysis of 14 genes, blood, buccal swab, or amniotic fluid

	Proprietary test: Versiti™ Autosomal Dominant Thrombocytopenia Panel Lab/Manufacturer: Versiti™ Diagnostic Laboratories/Versiti™
0270U	Hematology (congenital coagulation disorders), genomic sequence analysis of 20 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Coagulation Disorder Panel Lab/Manufacturer: Versiti™ Diagnostic Laboratories/Versiti™
0271U	Hematology (congenital neutropenia), genomic sequence analysis of 23 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Congenital Neutropenia Panel Lab/Manufacturer: Versiti™ Diagnostic Laboratories/Versiti™
0272U	Hematology (genetic bleeding disorders), genomic sequence analysis of 51 genes, blood, buccal swab, or amniotic fluid, comprehensive Proprietary test: Versiti™ Comprehensive Bleeding Disorder Panel Lab/Manufacturer: Versiti™ Diagnostic Laboratories/Versiti™
0273U	Hematology (genetic hyperfibrinolysis, delayed bleeding), genomic sequence analysis of 8 genes (F13A1, F13B, FGA, FGB, FGG, SERPINA1, SERPINE1, SERPINF2, PLAU), blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Fibrinolytic Disorder Panel Lab/Manufacturer: Versiti™ Diagnostic Laboratories/Versiti™
0274U	Hematology (genetic platelet disorders), genomic sequence analysis of 43 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Comprehensive Platelet Disorder Panel Lab/Manufacturer: Versiti™ Diagnostic Laboratories/Versiti™
0276U	Hematology (inherited thrombocytopenia), genomic sequence analysis of 23 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Inherited Thrombocytopenia Panel Lab/Manufacturer: Versiti™ Comprehensive Bleeding Disorder Panel
0277U	Hematology (genetic platelet function disorder), genomic sequence analysis of 31 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Platelet Function Disorder Panel Lab/Manufacturer: Versiti™ Comprehensive Bleeding Disorder Panel
0318U	Pediatrics (congenital epigenetic disorders), whole genome methylation analysis by microarray for 50 or more genes, blood Proprietary test: EpiSign Complete Lab/Manufacturer: Greenwood Genetic Center
S3840	DNA analysis for germline mutations of the RET proto-oncogene for susceptibility to multiple endocrine neoplasia type 2

General Genetic Testing, Somatic Disorders

Policy Number: AHS – M2146 – General Genetic Testing, Somatic Disorders	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Genetic testing refers to the use of technologies that identify genetic variation, which include genomic, transcriptional, proteomic, and epigenetic alterations, for the prevention, diagnosis, and treatment of disease (Kohlmann & Slavotinek, 2024; Li et al., 2017).

Somatic variations or mutations are defined as a genetic alteration that occurs after conception in any of the cells of the body, except the germ cells, and therefore are not passed on to offspring (Li et al., 2017).

For guidance concerning Tumor Mutational Burden Testing (TMB) and/or Microsatellite instability analysis please refer to the AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing policy.

II. Related Policies

Policy Number	Policy Title
AHS-M2145	General Genetic Testing, Germline Disorders
AHS-M2032	Whole Genome and Whole Exome Sequencing
AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

This policy addresses the general use of somatic (tumor) genetic testing and applies to all tests for which a policy addressing a specific clinical condition is not available.

1) For diagnosis, selection of therapy, or prognostication (when there is a documented benefit based on the presence of such mutations in the tumor or neoplastic cells), genetic testing for a specific genetic mutation or mutations that have documented clinical utility **MEETS COVERAGE CRITERIA**.

2) Repeat testing **MEETS COVERAGE CRITERIA** in **either** of the following situations:

   a) For recurrence monitoring.

   b) When there is the possibility of further genetic alterations in the hematologic malignancy, primary tumor, or metastasis **and** knowledge of these changes would result in the addition, elimination, or alteration of non-investigational therapies.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For all situations not described above, genetic testing (single gene or multi-gene panel testing) for somatic disorders **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For two or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics and Genomics
ACTC1	*Actin alpha cardiac muscle 1*
AMP	Association For Molecular Pathology
APC	*Adenomatous polyposis coli*
APOB	*Apolipoprotein B*
ASCO	American Society of Clinical Oncology
ATP7B	*ATPase copper transporting beta*
BAG3	*BAG cochaperone 3*
BMPR1A	*Bone morphogenetic protein receptor type 1A*
BRCA	*Breast cancer gene*
BRCA1	*Breast cancer gene 1*
BRCA2	*Breast cancer gene 2*

BSG	British Sarcoma Group
CACNA1S	*Calcium voltage-gated channel subunit alpha1 S*
CALM1	*Calmodulin I*
CALM2	*Calmodulin 2*
CALM3	*Calmodulin 3*
CAP	College Of American Pathologists
CD	*Cluster of differentiation*
CD34	*Cluster of differentiation 34*
CGP	Comprehensive genomic profiling
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid Services
CNAs	Copy number alterations
CNV	Copy number variant
COL3A1	*Collagen type III alpha 1*
CTLA-4	*Cytotoxic T-lymphocyte-associated protein 4*
D842V	*Platelet-derived growth factor receptor alpha*
DES	*Desmin*
dMMR	Mismatch repair deficiency
DNA	Deoxyribonucleic acid
DOG1	Delay of germination
DSC2	*Desmocollin-2*
DSG2	*Desmoglein 2*
DSP	*Desmoplakin*
EGISTs	Extragastrointestinal stromal tumors
EP	Expected pathogenic
ESCAT	European Society for Medical Oncology Scale for Clinical Actionability of Molecular Targets
ESMO	European Society for Medical Oncology
EZH2	*Enhancer of zeste 2 polycomb repressive complex 2 subunit*
FBN1	*Fibrillin-1*
FDA	Food and Drug Administration
FFPE	Formalin-fixed paraffin embedded
FISH	Fluorescence in situ hybridization
GIS	Genomic instability score
GISTs	Gastrointestinal stromal tumors
GLA	*Alpha-galactosidase A*
GRASP	Genome-Wide Repository of Associations Between SNPs And Phenotypes
HGSC	High-grade serous ovarian, fallopian tube, and peritoneal carcinoma

HOXC6	*Homeobox C6*
HRD	Homologous recombination deficiency
HRR	Homologous recombination repair
Indel	Insertion/deletion
KCNH2	*Potassium voltage-gated channel subfamily H member 2*
KCNQ1	*Potassium voltage-gated channel subfamily Q member 1*
KIT	*KIT proto-oncogene receptor tyrosine kinase*
LP	Likely pathogenic
LDLR	Low density lipoprotein receptor
LDTs	Laboratory-developed tests
LMNA	Lamin A/C
LOF	Loss of function
LOH	Loss of heterozygosity
LST	Large scale state transitions
MBR	Major breakpoint region
MCR	Minor cluster region
MLH1	*MutL homolog 1*
MSH2	*MutS homolog 2*
MSH6	*MutS homolog 6*
MSI	Microsatellite instability
MSK-IMPACT	Memorial Sloan Kettering- integrated mutation profiling of actionable cancer targets
MUTYH	*MutY DNA glycosylase*
MYBPC3	*Myosin binding protein C*
MYH7	*Myosin heavy chain 7*
MYH11	*Myosin heavy chain 11*
MYL2	*Myosin light chain 2*
MYL3	*Myosin light chain 3*
NCCN	National Comprehensive Cancer Network
NF2	*Neurofibromin 2*
NGS	Next generation sequencing
NSCLC	Non-small cell lung cancer
OCEANs	Oncogene Concatenated Enriched Amplicon Nanopore Sequencing
ORR	Overall response rate
OTC	*Ornithine transcarbamylase*
PARPi	Poly-ADP ribose inhibitors
PCR	Polymerase chain reaction
PCSK9	*Proprotein convertase subtilisin/kexin type 9*
PD-1/PD-L1	*Programmed death-1/ programmed death ligand-1*

PDGFRA	*Platelet-derived growth factor receptor alpha*
PKP2	*Plakophilin 2*
PMS2	*PMS1 homolog 2, mismatch repair system component*
poly-ADP	Polymeric adenosine diphosphate
PRKAG2	*Protein kinase AMP-activated non-catalytic subunit gamma 2*
PTEN	*Phosphatase and tensin homolog*
RB1	*RB transcriptional corepressor 1*
RBM20	*RNA binding motif 20*
RNA	Ribonucleic acid
RYR1	*Ryanodine receptor 1*
RYR2	*Ryanodine receptor 2*
SCL	Small cell lung cancer
SCN5A	*Sodium voltage-gated channel alpha subunit 5*
SCNEC	Small cell neuroendocrine carcinoma
SDHAF2	*Succinate dehydrogenase complex assembly factor 2*
SDHB	*Succinate dehydrogenase complex subunit B*
SDHC	*Succinate dehydrogenase complex subunit C*
SDHD	*Succinate dehydrogenase cytochrome b*
SMAD4	*Mothers against decapentaplegic homolog 4*
SNP	Single nucleotide polymorphism
SNV	single nucleotide variant
STK11	*Serine/threonine kinase 11*
STR	Short tandem repeat
TAI	Telomeric allelic imbalance
TF	Tumor fraction
TGFBR1	*Transforming growth factor, beta receptor I*
TGFBR2	*Transforming growth factor, beta receptor II*
TMB	Tumor mutational burden
TMEM43	*Transmembrane protein 43*
TNNC1	*Troponin C1, slow skeletal and cardiac type*
TP53	*Tumor protein P53*
TSC1	*Tuberous sclerosis complex 1*
TSC2	*Tuberous sclerosis complex 2*
UPD	Uniparental disomy
VUS	Variants of unknown significance
WES	Whole-exome sequencing
WT1	*Wilms' tumor 1*

V. Scientific Background

Gene mutations are referred to as "somatic" if they are not within the germline (i.e., within gametes); therefore, these mutations are not passed on from parent to offspring. Somatic mutations may arise *de novo* or later in life and are very common in neoplasms (Raby & Blank, 2024). There are many different types of somatic mutations, including single nucleotide polymorphisms (SNPs); structural variations such as deletions, inversions, or translocations, and smaller chromosomal abnormalities such as short tandem repeats or gene fusions. Most mutations do not result in disease (Kohlmann & Slavotinek, 2024).

Single nucleotide polymorphisms are the most common type of genetic mutation, including missense mutations. These mutations are single base-pair changes where one nucleotide replaces a different nucleotide. More than 65% of the diseases caused by genetic mutations are due to SNPs (Kohlmann & Slavotinek, 2024). Estimates based on whole genome sequencing have placed the average amount of SNPs in any given individual at 2.8 to 3.9 million (Kohlmann & Slavotinek, 2024). Insertion/deletion (Garrett et al.) polymorphisms are often a single nucleotide but may be up to four nucleotides. SNPs often lead to frameshift mutations that can cause premature stop codons and the failure of the allele (Kohlmann & Slavotinek, 2024).

Structural variations are usually classified as larger than 1000 base pairs. These include deletions, duplications, inversions, translocations, or ring chromosome formations. Due to the large number of genes affected, these variations commonly lead to severe genetic abnormalities; for example, a major cause of chronic myeloid leukemia is due to the translocation between chromosomes nine and 22, resulting in a fused gene. The most common structural variation is the copy number variant (CNV), referring to a differing number of DNA segment copies in different individuals. For example, one person may have three copies of a particular segment whereas another may only have two. These variations may lead to dysregulation, gain-of-function, or loss of function of the affected genes (Kohlmann & Slavotinek, 2024). The sensitive genes that require or produce precise quantities of a protein product tend to suffer more from these variations (Bacino, 2023).

Any size mutation may be pathogenic and must be categorized as to how likely the mutation is to cause disease. The American College of Medical Genetics and Genomics (ACMG) has classified mutations in five categories, which are as follows: pathogenic, likely pathogenic, uncertain significance, likely benign, and benign. The "likely pathogenic" and "likely benign" refer to weaker evidence than their respective pathogenic and benign categories, and "uncertain significance" refers to evidence that

does not meet criteria for benignity or pathogenicity or has conflicting evidence from both sides (Kohlmann & Slavotinek, 2024). Prediction algorithms have been used to interpret variants and to predict whether a variant will affect the gene function or splicing of the gene. These algorithms are publicly available but have a tendency of predicting the harmful impact of a variant. The specificity of these databases has been estimated at 60-80% (Li et al., 2017).

Due to the enormous number of variants, as well as the rate that variants are discovered, comprehensive databases of genetic variants have been published and are easily available. For example, the Genome-Wide Repository of Associations Between SNPs and Phenotypes (GRASP) database includes information from over 2000 studies and over one million variant-related results (Kohlmann & Slavotinek, 2024). Databases focusing on cancer-specific variants, reference sequences, and the general population are all available publicly (Li et al., 2017).

Spontaneous mutations accumulate in somatic cells over a lifetime. Early somatic mutations can cause developmental disorders while the accumulation of mutations throughout life can lead to cancer and contribute to aging (Martincorena & Campbell, 2015). Molecular profiles of tumors have clinical utility in guiding the clinical management of cancer patients, providing diagnostic or prognostic information, or identifying a potential treatment regimen (Li et al., 2017). Increasingly, somatic mutations are being identified in diseases other than cancer, such as neurodevelopmental diseases (Poduri et al., 2013).

A malignant neoplasm is another term for cancer, which may encompass many types including breast, prostate, skin, lung, rectum, colon, and brain. Gastrointestinal stromal tumors (GISTs) are considered rare neoplasms with approximately 95% of these cancers non-hereditary; GISTs are mainly identified by KIT protein expression with typical mutations in the *KIT* or platelet-derived growth factor receptor alpha (*PDGFRA*) genes (Morgan et al., 2023). These GISTs are the most common mesenchymal tumor of the gastrointestinal tract that originate from the cell of Cajal (Comandini et al., 2017). Primary prostate and lung tumors have been associated with different types of GISTs such as gastric and small bowel; genetic analysis of one patient found "that the gastric GIST and abdominal tumors were characterized by two different c-KIT mutations" (Comandini et al., 2017). Extragastrointestinal stromal tumors (EGISTs) are another type of rare neoplasm which also arise in the gastrointestinal tract. Liu et al. (2014) report that an EGIST was identified in the prostate of a patient. "The results of immunohistochemical staining showed positive immunoreactivity for cluster of

differentiation (CD)117 (c-kit), CD34 and DOG1 in the tumor. On mutation analysis, loss of heterozygosity of the c-kit gene was observed in the prostatic EGIST; however, the platelet-derived growth factor receptor-α (*PDGFRA*) gene was normal" (Liu et al., 2014). Due to the rarity of EGIST of the prostate, immunohistochemistry analysis is important to confirm a diagnosis.

Mutations of the *KIT* and *PDGFRA* genes in small cell neuroendocrine carcinoma (SCNEC) of the prostate have been researched by Terada (2012). A total of 706 malignant prostate tumors were identified, and four of these tumors were classified as SCNEC. Of these four tumors, three tumors were positive for *KIT*, and *PDGFRA,* among other genes. Molecular genotyping via PCR showed no *KIT* or *PDGFRA* mutations (Terada, 2012). Another study completed by McCabe et al. (2008) noted that homeobox C6 (HOXC6) is overexpressed in prostate cancers and completed an analysis of prostate cancer cells to identify which promoters are bound by HOXC6. "We show that HOXC6 directly regulates expression of bone morphogenic protein 7, fibroblast growth factor receptor 2, insulin-like growth factor binding protein 3, and platelet-derived growth factor receptor alpha (*PDGFRA*) in prostate cells" (McCabe et al., 2008). The researchers also note that *PDGFRA* is able to reduce the proliferation of prostate cancer cells, and that if HOXC6 is overexpressed, the effects of *PDGFRA* inhibition may be overcome. The fusion gene *FIP1L1-PDGFRA* has also been associated with chronic eosinophilic leukemia (Legrand et al., 2013).

Proprietary Testing

Clinical biomarkers are widely used for making personalized and actionable decisions for cancer treatment. TMB, the number of somatic mutations per mega base of the DNA in cancer cells, is an emerging biomarker associated with predicting the response to immunotherapy treatment (NCI, 2024). A high TMB value indicates better treatment outcomes, which is observed in patients with melanoma on CTLA-4 inhibitors and patients with melanoma, non-small cell lung carcinoma, bladder cancer, microsatellite instability cancers, and pan-tumors on PD-1/PD-L1 inhibitors. High TMB has also been associated with improved outcomes in patients on a combination of PD-1/PD-L1 and CTLA-4 inhibitors (Merino et al., 2020). TMB was originally measured with whole-exome sequencing (WES), but this method has limited clinical utility due to a six to eight week sequencing period and expensive costs. Alternatively, targeted NGS panels can reliably estimate TMB from a subset of the exome with reduced sequencing time and increased clinical application. Two FDA-approved products for calculating TMB include the FoundationOne CDx assay (Foundation Medicine Inc.) and MSK-IMPACT (Memorial

Sloan Kettering Cancer Center). Both of these tests, referred to as comprehensive genomic profiling (CGP), can identify all types of "molecular alterations (i.e., single nucleotide variants, small and large insertion-deletion alterations, copy number alterations, and structural variants) in cancer-related genes, as well as genomic signatures such as microsatellite instability (Bauml et al.), loss of heterozygosity, and TMB (Klempner et al., 2020). Studies show that TMB calculation from CGP has high concordance with TMB" measured from WES. On June 16, 2020, the FDA approved pembrolizumab for the treatment of adult and pediatric patients with a TMB value of greater than 10 mutations per mega base as determined by the FoundationOne CDx assay (FDA, 2020b).

Analysis of somatic mutations in solid tumors and hematologic malignancies using next generation sequencing has become common practice in oncology clinics as well as clinical trials. There are several known approved NGS tests for detection of somatic mutations. MyChoice HRD CDx, by Myriad Genetic Laboratories, was FDA-approved on October 23, 2019, and ONCO/Reveal Dx Lung & Colon Cancer Assay (O/RDx-LCCA) by Pillar Biosciences was FDA-approved on July 30, 2021. Myriad MyChoice® CDx is a next generation sequencing based in vitro diagnostic test that detects single nucleotide variants, insertions and deletions, and large rearrangement variants in protein coding regions and intron/exon boundaries of the *BRCA1* and *BRCA2* genes (Myriad Genetics, 2024). The ONCO/Reveal Dx Lung & Colon Cancer Assay (O/RDx-LCCA) by Pillar Biosciences, is a next generation sequencing test for detection of somatic mutations for non-small cell lung cancer (NSCLC) and colorectal cancer (CRC) tumor tissue. The test simultaneously detects clinically relevant mutations in *KRAS* for CRC and epidermal growth factor receptor (EGFR) for NSCLC in a single assay. In the accuracy study, positive percent agreement (Pappas et al.) and negative percent agreement (NPA) between O/RDx-LCCA and externally validated comparator method (CompO) was >99%. The authors conclude that O/RDx-LCCA "is a highly accurate assay for the detection of clinically relevant *KRAS* variants in CRC and EGFR variants in NSCLC" (Pillar Biosciences, 2020, 2021).

In 2020, the FDA approved Guardant360® CDx for tumor mutation profiling in patients with any solid malignant neoplasm. The Guardant360 CDx is also approved as a companion diagnostic to identify NSCLC patients with *EGFR* alterations who may benefit from treatment with Tagrisso® (osimertinib) (Guardant, 2020). In an analytical study, the positive and NPA for Guardant360 CDx relative to Therascreen® KRAS RGQ PCR was 0.71 and 1.00 respectively; overall percent agreement was 0.82 (Bauml et al.,

2021). In 2020, the FDA also approved Therascreen BRAF V600E RGQ PCR Kit by QIAGEN. This is a real-time PCR test for the qualitative detection of V600E mutations in the *BRAF* gene in human colorectal cancer (CRC) tumor tissue. Therascreen can help select patients with metastatic colorectal cancer (mCRC) whose tumors carry the *BRAF* V600E mutation for treatment with BRAFTOVI (encorafenib) in combination with cetuximab (QIAGEN, 2024).

Analytical Validity

Woodhouse et al. (2020) evaluated the analytical performance of FoundationOne Liquid CDx assay to detect genomic alterations in cancer patients. The assay was evaluated across more than 30 different cancer types in over 300 genes and greater than 30,000 gene variants. "Results demonstrated a 95% limit of detection of 0.40% variant allele fraction for select substitutions and insertions/deletions, 0.37% variant allele fraction for select rearrangements, 21.7% tumor fraction (USPSTF) for copy number amplifications, and 30.4% TF for copy number losses. The false positive variant rate was 0.013% (approximately one in 8,000). Reproducibility of variant calling was 99.59%" (Woodhouse et al., 2020). In comparison to in situ hybridization and immunohistochemistry, FoundationOne had an overall 96.3% positive percent agreement and > 99.9% negative percent agreement. "These study results demonstrate that FoundationOne Liquid CDx accurately and reproducibly detects the major types of genomic alterations in addition to complex biomarkers such as microsatellite instability, blood tumor mutational burden, and tumor fraction" (Woodhouse et al., 2020).

Thirunavukarasu et al. (2021) developed the Oncogene Concatenated Enriched Amplicon Nanopore Sequencing (OCEANS) method for rapid, accurate, and affordable somatic mutation detection. The OCEANS method involves amplified variants with low variant allele frequency and subsequently concatenating with Nanopore Sequencing. In this study, the 15-plex OCEANS melanoma panel was compared to NGS. OCEANS had a 100% sensitivity relative to NGS. Of the 9584 NGS-negative loci, OCEANS was able to detect an additional 97 variants; thus, relative to NGS, OCEANS had a 99.0% specificity and very low false positive rate. These 97 NGS-negative and OCEANS-positive results were believed to be true mutations, and droplet digital PCR (ddPCR) confirmation experiments supported this hypothesis. The authors conclude that "Integrating OCEANS with long-read and base modification detection capabilities of Nanopore Sequencing can enable development of comprehensive oncology panels" (Thirunavukarasu et al., 2021).

Clinical Utility and Validity

Advancements in technology and availability of sequencing, previously constrained by limitations of sequential single-gene testing on limited patient samples, have led to significant strides in our understanding of the genetic basis of inherited and somatic conditions. Variants detected by genetic testing include inherited germline variants and somatic mutations; next generation sequencing (Lamont et al.) has allowed for superior detection of these mutations (Konnick & Pritchard, 2016). The accuracy of NGS varies depending on how many genes are sequenced; fewer genes tend to result in higher accuracy since there will be more "probe-template overlap." Although Sanger sequencing remains the most accurate at >99.99% accuracy, it cannot sequence a large amount of genes in a timely fashion and is best used for sequencing of a specific gene (Hulick, 2024). NGS also can be used clinically to guide screening, preventive options, and cancer treatment such as the "analysis of tumor tissue or non-tumor tissue to identify genetic abnormalities that may be present in the germline and/or the tumor that could potentially match molecularly targeted therapies. As an example, a poly(ADP ribose) polymerase (PARP) inhibitor could be considered in a patient with an identified BRCA1 or BRCA2 mutation" (Hulick, 2024).

Next generation sequencing has been used to identify several types of somatic mutations associated with cancer and may help to single out therapeutic targets. Genetic mutations in *BRCA*1 & 2 are associated with breast and ovarian cancer. Kowalik et al. (2019) have identified somatic genetic mutations in *BRCA*1 & 2 for ovarian cancer prognostic purposes using NGS. Ovarian cancer tissue samples were used for the analysis. A total of three percent of mutations (6/201) were identified as somatic; with only 24% (49/201) of samples identified with a pathogenic mutation overall (Kowalik et al., 2019). The other 35 mutations were of germline origin. This corroborated the report by Nagahashi et al. (2019) which states that approximately 2.5% of *BRCA*1 & 2 mutations are somatic. Detection of a BRCA1/2 germline mutation is essential for planning individual therapy, where indicated, testing should be arranged as early as possible. It is the only way of identifying patients suitable for PARPi therapy and ensuring they receive the best possible treatment (Lux & Fasching, 2023).

The clinical validity of a genetic test depends primarily on the expressivity and penetrance of a given phenotype. Penetrance refers to the likelihood of developing a disease when the pathogenic mutation is present, and expressivity refers to the variations in the way the disease is expressed. For example, virtually any mutation in the *APC* gene will cause symptoms of familial adenomatous polyposis, thereby increasing the clinical validity of an *APC* assessment. Some conditions may not clinically manifest

at all despite a mutated genotype (Kohlmann & Slavotinek, 2024).

The clinical utility of a genetic test generally relies on available treatments for a condition. Conditions such as Huntington's Disease that do not have many options for treatment will have limited clinical utility compared to another condition even though the actual test is highly valid. Factors such as severity of the disease and management options affect the clinical utility of a genetic test (Kohlmann & Slavotinek, 2024).

Hayano et al. (2016); McCabe et al. (2008) noted that homeobox C6 (HOXC6) is overexpressed in prostate cancers and completed an analysis of prostate cancer cells to identify which promoters are bound by HOXC6.

In a multi-cohort, open-label, non-randomized study to establish the relationship between TMB and pembrolizumab treatment response, 790 patients were tested for TMB with the FoundationOne CDx assay. A total of 102/790 patients had high TMB (≥10 mutations per mega base) in solid tumors of anal, biliary, cervical, endometrial, mesothelioma, neuroendocrine, salivary, small cell lung, thyroid, and vulvar cancers. The overall response rate (ORR) in patients with a high TMB was 29%, with a 4% complete response rate and 25% partial response rate compared to an ORR of 6% in patients with a low TMB. The ORR was nearly 5-fold in patients with a high TMB. The authors conclude "TMB could be a novel and useful predictive biomarker for response to pembrolizumab monotherapy in patients with previously treated recurrent or metastatic advanced solid tumours" (Marabelle et al., 2020).

In a prospective study, Takeda evaluated the clinical application of the FoundationOne CDx Assay in decision-making for patients with advanced solid tumors. A total of 175 samples were analyzed using the FoundationOne assay and 153 of these patients were assessed for TMB. "The most common known or likely pathogenic variants were *TP53* mutations (n = 113), *PIK3CA* mutations (n = 33), *APC* mutations (n = 32), and *KRAS* mutations (n = 29). The median TMB was four mutations/Mb, and tumors with a high TMB (≥10 mutations/Mb) were more prevalent for lung cancer (11/32) than for other solid tumor types." From the 175 samples found to have known or likely pathogenic variants, 24 subjects (14%) received the optimal targeted therapy. The authors conclude that "such testing may inform the matching of patients with cancer with investigational or approved targeted drugs" (Takeda et al., 2021).

VI. Guidelines and Recommendations

Association for Molecular Pathology (AMP), American Society of Clinical

Oncology (ASCO), and College of American Pathologists (CAP)

The Joint Commission recommended that somatic variants be categorized by and reported based on their impact on clinical care. The Joint Commission notes that somatic variants include indels, single nucleotide variants (SNVs), fusion genes from genomic rearrangements, and CNVs and should focus on their impact on clinical care. Any variant may be considered a biomarker if it predicts response to therapy, influences prognosis, diagnosis, treatment decisions, or the gene function itself. The Joint Commission proposes four levels for these biomarkers which are as follows:

> "1. Level A, biomarkers that predict response or resistance to US FDA-approved therapies for a specific type of tumor or have been included in professional guidelines as therapeutic, diagnostic, and/or prognostic biomarkers for specific types of tumors;
> 2. Level B, biomarkers that predict response or resistance to a therapy based on well-powered studies with consensus from experts in the field, or have diagnostic and/or prognostic significance of certain diseases based on well-powered studies with expert consensus;
> 3. Level C, biomarkers that predict response or resistance to therapies approved by FDA or professional societies for a different tumor type (i.e., off-label use of a drug), serve as inclusion criteria for clinical trials, or have diagnostic and/or prognostic significance based on the results of multiple small studies;
> 4. Level D, biomarkers that show plausible therapeutic significance based on preclinical studies, or may assist disease diagnosis and/or prognosis themselves or along with other biomarkers based on small studies or multiple case reports with no consensus" (Li et al., 2017).

The Joint Commission also includes variants in different tiers based on the amount of evidence there is to support its significance. For example, tier 1 variants include significance of levels A and B, while tier 2 includes significance of levels C and D. Tier 3 is variants of unknown significance (VUS), such as variants in cancer genes that have not been reported in any other cancers. These variants are not typically seen in significant frequencies in the general population. When evaluating these variants, the type of mutation and gene function should be considered. Tier 4 is benign variants or likely benign variants. These alleles are often observed in significant amounts in general populations. Tier 3 variants should be reported while ensuring that the most important information is communicated to the patient (Li et al., 2017).

National Comprehensive Cancer Network (NCCN)

Multiple somatic mutations have been incorporated into the diagnostic workups recommended by the NCCN. Furthermore, the NCCN has several guidelines which recommend that gene expression profiling, or multiple gene testing, may be helpful, more efficient and/or cost-effective for selected patients (NCCN, 2024). Please see the individual policies.

American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP)

The ACMG and AMP released criteria on the types and severity of mutations, which are as follows:

- **Very strong evidence of pathogenicity**: Null variants (nonsense, frameshifts, canonical +/- 1-2 splice sites, initiation codon, exon deletions) in a gene where loss of function (LOF) is a known mechanism of disease. The guidelines note to use caution in genes where LOF is not a mechanism, if LOF variants are at the 3' end, if exon skipping occurs, and if multiple transcripts are present.
- **Strong:** Amino acid change to a pathogenic version, de novo mutations, established studies supporting a damaging gene or gene product, or if the prevalence of the variant is increased in affected individuals compared to healthy controls. The guidelines note to be careful of changes impacting splicing and if only the paternity has been confirmed.
- **Moderate:** Located in a mutational hot spot or well-established functional domain (e.g., active site of an enzyme) without a benign variation, absent from controls in Exome Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium, detected in *trans* with pathogenic variants for a recessive disorder, protein length changes, novel missense changes where a different missense change has been pathogenic before, and a possible de novo mutation.
- **Supporting:** Cosegregation with disease in multiple affected family members in a gene definitively known to cause the disease, missense variant in a gene with low rate of benign missense variation, if the mutation has evidence that it is deleterious, if the patient's phenotype is highly specific for disease with a single genetic cause.

The guidelines also list criteria for benign gene variants.

- **Stand-alone evidence of benignity:** Allele frequency is >5% in Exome

Sequencing Project, 1000 Genomes Project, or Exome Aggregation Consortium.

- **Strong:** Allele frequency is greater than expected for disorder, observed in healthy adult with full penetrance at early age, lack of segregation in affected family members (although pathogenic variants may masquerade as nonsegregated), or well-established studies that show no damaging effect on protein production.
- **Supporting:** Missense variant of a gene for which truncating mutations are pathogenic, indels in repetitive region of unknown function, silent variants, VUS, or a *trans* version of a *cis* mutation (Richards et al., 2015).

American College of Medical Genetics and Genomics (ACMG)

The ACMG has released a list of genes for which secondary findings should be disclosed. Secondary findings refer to incidental findings unrelated to why a genetic test was originally ordered but are of significant clinical value to the patient. The portion of the table containing the conditions, the associated genes, and which variants should be report is listed below (Kalia et al., 2016; Miller et al., 2023; Miller et al., 2021):

Condition	Gene(s)	Variants to Report
Breast/ovarian cancer	*BRCA1, BRCA2*	LP (likely pathogenic), P (pathogenic)
Li-Fraumeni syndrome	*TP53*	LP, P
Peutz-Jeghers syndrome	*STK11*	LP, P
Juvenile polyposis syndrome	*BMPR1A, SMAD4*	LP, P
PTEN hamartoma syndrome	*PTEN*	LP, P
Lynch syndrome	*MLH1, MSH2, MSH6, PMS2*	LP, P
Familial adenomatous polyposis	*APC*	LP, P
MYH-associated polyposis	*MUTYH*	LP, P
Von Hippel Lindau syndrome	*VHL*	LP, P

Retinoblastoma	*RB1*	LP, P
Tuberous sclerosis complex	*TSC1, TSC2*	LP, P
Wilms tumor	*WT1*	LP, P
Multiple endocrine neoplasia 1 or 2	*MEN1 (1), RET (2)*	LP, P
Familial medullary thyroid cancer	*RET*	LP, P
Hereditary paraganglionoma-pheochromocytoma syndrome	*SDHD, SDHAF2, SDHC, SDHB*	LP, P
Neurofibromatosis type 2	*NF2*	LP, P
Marfan syndrome, Loeys-Dietz syndrome, familial thoracic aortic aneurysms and dissections	*FBN1, TGFBR1, TGFBR2, SMAD3, ACTA2, MYH11*	LP, P
Malignant hyperthermia	*RYR1, CACNA1S*	LP, P
Wilson disease (copper metabolism)	*ATP7B*	LP, P
Ornithine transcarbamylase deficiency (urea cycle)	*OTC*	All hemi, het, homozygous P and LP
Hereditary hemochromatosis	*HFE*	HFE p.Cys282Tyr homozygotes only
Hereditary hemorrhagic telangiectasia	*ACVRL1, ENG*	LP, P
Maturity-onset diabetes of the young	*HNF1A*	LP, P
RPE65-related retinopathy	*RPE65*	LP, P
Hereditary TTR amyloidosis	*TTR*	LP, P

Cardiac and/or blood vessel related		
Condition	Gene(s)	Variants to Report

Aortopathies	*FBN1, TGFBR1, TGFBR2, SMAD3, ACTA2, MYH11*	LP, P
Arrhythmogenic right ventricular cardiomyopathy	*PKP2, DSP, DSC2, TMEM43, DSG2*	LP, P
Catecholaminergic polymorphic ventricular tachycardia	*RYR2, CASQ2, TRDN*	LP, P
Dilated cardiomyopathy	*TNNT2, LMNA, FLNC, TTN, BAG3, DES, RBM20, TNNC1*	LP, P
Ehlers–Danlos syndrome, vascular type	*COL3A1*	LP, P
Familial hypercholesterolemia	*LDLR, APOB, PCSK9*	LP, P
Hypertrophic cardiomyopathy	*MYH7, MYBPC3, TNNI3, TPM1, MYL3, ACTC1, PRKAG2, MYL2*	LP, P
Long QT syndrome types 1 and 2	*KCNQ1, KCNH2*	LP, P
Long QT syndrome 3; Brugada syndrome	*SCN5A*	LP, P
Long QT syndrome types 14-16	*CALM1, CALM2, CALM3*	LP, P
Genes related to inborn errors of metabolism phenotypes		
Condition	Gene(s)	LP, P
Biotinidase deficiency	*BTD*	LP, P (2 variants)
Fabry disease	*GLA*	All hemi, het, homozygous P and LP
Ornithine transcarbamylase deficiency	*OTC*	All hemi, het, homozygous P and LP

Pompe disease	*GAA*	P and LP (2 variants)

American Society of Clinical Oncology (ASCO)

The ASCO published guidelines regarding genetic and genomic testing for cancer susceptibility. These guidelines state that the "ASCO recognizes that concurrent multigene testing (i.e., panel testing) may be efficient in circumstances that require evaluation of multiple high-penetrance genes of established clinical utility as possible explanations for a patient's personal or family history of cancer. Depending on the specific genes included on the panel employed, panel testing may also identify mutations in genes associated with moderate or low cancer risks and mutations in high-penetrance genes that would not have been evaluated on the basis of the presenting personal or family history… ASCO affirms that it is sufficient for cancer risk assessment to evaluate genes of established clinical utility that are suggested by the patient's personal and/or family history" (Robson et al., 2015).

ASCO released guidelines regarding somatic tumor testing for ovarian cancer. ASCO recommends that, forindividuals with ovaries "diagnosed with clear cell, endometrioid, or mucinous ovarian cancer should be offered somatic tumor testing for mismatch repair deficiency (dMMR). Somatic tumor testing for *BRCA1* and *BRCA2* pathogenic or likely pathogenic variants may be reserved for time of recurrence for [those] who have completed upfront therapy and are currently in observation, as presence of these mutations qualifies the patient for FDA-approved treatments" (Konstantinopoulos et al., 2020). In a 2021 update of these guidelines, ASCO adds "Implementation of techniques and pipelines enabling both SNV and CNV detection should be preferred, optimally by next-generation sequencing" (Pujol et al., 2021).

In 2022, a provisional opinion was released by ASCO. It addressed the appropriate use of tumor genomic testing in patients with metastatic or advanced solid tumors. A lack of clarity in clinical practice "as to when tumor genomic sequencing should be ordered, what type of assays should be performed, and how to interpret the results for treatment selection," was the impetus. In the opinion of ASCO, patients with metastatic or advanced cancer "should undergo genomic sequencing in a certified laboratory if the presence of one or more specific genomic alterations has regulatory approval as biomarkers to guide the use of or exclusion from certain treatments for their disease."

Additionally:

- "Multigene panel-based assays should be used if more than one biomarker-linked therapy is approved for the patient's disease."
- "Site-agnostic approvals for any cancer with a high tumor mutation burden, mismatch repair deficiency, or neurotrophic tyrosine receptor kinase (*NTRK*) provide a rationale for genomic testing for all solid tumors."
- "Multigene testing may also assist in treatment selection by identifying additional targets when there are few or no genotype-based therapy approvals for the patient's disease. For treatment planning, the clinician should consider the functional impact of the targeted alteration and expected efficacy of genomic biomarker-linked options relative to other approved or investigational treatments" (Chakravarty et al., 2022).

European Society for Medical Oncology (ESMO)

The ESMO recommends that "Mutational analysis inclusion in the diagnostic work-up of all GISTs should be considered standard practice [II, A] (with the possible exclusion of < 2 cm non-rectal GISTs)" (Casali et al., 2018). The article also states that "Mutational analysis for known mutations involving *KIT* and *PDGFRA* can confirm the diagnosis of GIST, if doubtful (particularly in rare CD117/DOG1-negative suspect GIST). Mutational analysis has a predictive value for sensitivity to molecular-targeted therapy and to prognostic value. Its inclusion in the diagnostic work-up of all GISTs should be considered standard practice" (Casali et al., 2018; Casali et al., 2022).

The ESMO Translational Research and Precision Medicine Working Group released clinical practice guidelines to define best practice for homologous recombination deficiency (HRD) testing in high-grade serous ovarian, fallopian tube and peritoneal carcinoma (HGSC). ESMO recommends that "pathological evaluation of the tumour tissue specimens used for assessment of somatic molecular alterations is essential" (Miller et al., 2020). Regarding homologous recombination repair (HRR) tests, *BRCA* germline and somatic mutation tests are recommended as they consistently identify the subgroup of ovarian cancer patients who benefit the most from poly-ADP ribose inhibitors (PARPi) therapy. There is insufficient evidence to determine the clinical validity of a panel of non-*BRCA* HRR genes and *BRCA1* or *RAD51C* promoter methylation to predict PARPi benefit. "In the first-line maintenance setting, germline and somatic *BRCA* mutation testing is routinely recommended to identify HGSC patients who should receive a PARPi" (Miller et al., 2020).

British Sarcoma Group (BSG)

The BSG has published guidelines on the management of GIST and state that most GIST cases are associated with a *KIT* or *PDGFRA* mutation. The guidelines recommend the following:

- "The diagnosis should be made by a pathologist experienced in the disease and include the use of immunohistochemistry and mutational analysis, which should be performed by an accredited laboratory.
- If neoadjuvant treatment with imatinib is planned, it is vital to confirm the diagnosis, since there is a wide differential. It may be necessary to perform a percutaneous core needle biopsy if the tumour is inaccessible to endoscopic ultrasound-guided biopsy. Mutational analysis is obligatory, since some GISTs are insensitive to imatinib (e.g. those with *D842V* mutation in exon 18 of *PDGFRA*)" (Judson et al., 2017).

These guidelines were updated in 2024 and recommended with the following minor changes:

- "The diagnosis of GIST should be established by a pathologist experienced in the disease and should include the use of IHC and, if necessary, molecular analysis (which should be performed by an accredited laboratory).
- If initial treatment with imatinib is planned, it is essential to confirm the diagnosis of GIST, since there is a wide differential. It may be necessary to perform a percutaneous core needle biopsy if the tumour is inaccessible to EUS biopsy. Molecular analysis is particularly critical, since some GISTs are insensitive to tyrosine kinase inhibitors (e.g. the PDGFRA exon 18 D842V mutation)" (Judson et al., 2024).

European Association of Urology (EAU)-European Association of Nuclear Medicine (EANM)-European Society for Radiotherapy and Oncology (ESTRO)-European Society of Urogenital Radiology (ESUR)-International Society of Geriatric Oncology (SIOG)

The EAU/EANM/ESTRO/ESUR/SIOG released guidelines on prostate cancer in 2021. These guidelines strongly recommend offering patients with Metastatic Castration-Resistant Prostate Cancer (mCRPC) "somatic molecular testing to identify patients

suitable for treatment with PARP inhibitors" (Mottet et al., 2021).

The American Urological Association / American Society for Radiation Oncology / Society of Urologic Oncology (AUA/ASTRO/SUO)

The AUA/ASTRO/SUO released guidelines on prostate cancer in 2021. These guidelines recommend that "clinicians should offer germline and somatic tumor genetic testing to identify DNA repair deficiency mutations and microsatellite instability status that may inform prognosis in patients with mCRPC and counseling regarding family risk as well as potential targeted therapies" (Lowrance et al., 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On July 30, 2021, the FDA approved ONCO/Reveal Dx Lung & Colon Cancer Assay (O/RDx-LCCA) by Pillar Biosciences. "The device is a qualitative next generation sequencing based in vitro diagnostic test that uses amplicon-based target enrichment technology for detection of single nucleotide variants (SNVs) and deletions in 2 genes from DNA isolated from formalin-fixed paraffin-embedded (FFPE) non-small cell lung cancer (NSCLC) and colorectal cancer (CRC) tumor tissue specimens" (FDA, 2021).

On July 18, 2020, the FDA approved Cobas® EZH2 Mutation Test, a somatic gene mutation detection system by Roche Molecular System, Inc. "The device is a real-time allele-specific PCR test for qualitative detection of single nucleotide mutations for *Y646N, Y646F or Y646X (Y646H, Y646S,* or *Y646C), A682G*, and *A692V* of the *EZH2* gene in DNA extracted from formalin fixed paraffin embedded (FFPE) human follicular lymphoma tumor tissue specimens" (FDA, 2020a).

On August 7, 2020, the FDA approved Guardant360 CDx, by Guardant Health, Inc. This device is a next generation sequencing based in vitro diagnostic device that uses targeted high throughput hybridization-based capture technology to detect SNVs, insertions, and deletions in 55 genes, copy number amplifications in two genes, and

fusions in four genes. Guardant360 CDx also utilizes circulating cell-free DNA collected in Streck Cell-Free DNA Blood Collection Tubes to identify NSCLC patients who may benefit from treatment with the targeted therapy (FDA, 2020c).

On April 15, 2020, the FDA approved Therascreen *BRAF* V600E RGQ PCR Kit by QIAGEN. The Therascreen *BRAF* V600E RGQ PCR Kit is a real-time PCR test for the qualitative detection of V600E mutations in the *BRAF* gene using genomic DNA extracted from FFPE human colorectal cancer (CRC) tumor tissue. The Therascreen *BRAF* V600E RGQ PCR Kit is an in vitro diagnostic device intended to be used as an aid in selecting patients with metastatic colorectal cancer (mCRC) whose tumors carry the *BRAF* V600E mutation for treatment with BRAFTOVI (encorafenib) in combination with cetuximab" (FDA, 2020d).

On October 23, 2019, the FDA approved MyChoice HRD CDx, by Myriad Genetic Laboratories, Inc. This device is a next generation sequencing based in vitro diagnostic device for detection of SNVs, insertions, deletions, and large rearrangement variants of the BRCA1 and BRCA2 genes. This test also determines the Genomic Instability Score (GIS), a measurement of Loss of Heterozygosity (LOH), Telomeric Allelic Imbalance (TAI), and Large Scale State Transitions (LST), which is used to identify ovarian cancer patients with positive HRD status (FDA, 2019).

On November 30, 2017, the FDA approved FoundationOne CDx, by Foundation Medicine, Inc. This device is a next generation sequencing based in vitro diagnostic device for detection of substitutions, insertion and deletion alterations (indels), and copy number alterations (CNAs) in 324 genes and select gene rearrangements, as well as genomic signatures including microsatellite instability (Bauml et al.) and TMB using DNA isolated from FFPE tumor tissue specimens (FDA, 2017).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81168	CCND1/IGH (t(11;14)) (eg, mantle cell lymphoma) translocation analysis, major breakpoint, qualitative and quantitative, if performed
81191	NTRK1 (neurotrophic receptor tyrosine kinase 1) (eg, solid tumors) translocation analysis

CPT	Code Description
81192	NTRK2 (neurotrophic receptor tyrosine kinase 2) (eg, solid tumors) translocation analysis
81193	NTRK3 (neurotrophic receptor tyrosine kinase 3) (eg, solid tumors) translocation analysis
81194	NTRK (neurotrophic-tropomyosin receptor tyrosine kinase 1, 2, and 3) (eg, solid tumors) translocation analysis
81233	BTK (Bruton's tyrosine kinase) (eg, chronic lymphocytic leukemia) gene analysis, common variants (eg, C481S, C481R, C481F)
81261	IGH@ (Immunoglobulin heavy chain locus) (eg, leukemias and lymphomas, B-cell), gene rearrangement analysis to detect abnormal clonal population(s); amplified methodology (eg, polymerase chain reaction)
81262	IGH@ (Immunoglobulin heavy chain locus) (eg, leukemias and lymphomas, B-cell), gene rearrangement analysis to detect abnormal clonal population(s); direct probe methodology (eg, Southern blot)
81263	IGH@ (Immunoglobulin heavy chain locus) (eg, leukemia and lymphoma, B-cell), variable region somatic mutation analysis
81264	IGK@ (Immunoglobulin kappa light chain locus) (eg, leukemia and lymphoma, B-cell), gene rearrangement analysis, evaluation to detect abnormal clonal population(s)
81265	Comparative analysis using Short Tandem Repeat (STR) markers; patient and comparative specimen (eg, pre-transplant recipient and donor germline testing, post-transplant non-hematopoietic recipient germline [eg, buccal swab or other germline tissue sample] and donor testing, twin zygosity testing, or maternal cell contamination of fetal cells)
81266	Comparative analysis using Short Tandem Repeat (STR) markers; each additional specimen (eg, additional cord blood donor, additional fetal samples from different cultures, or additional zygosity in multiple birth pregnancies) (List separately in addition to code for primary procedure)
81267	Chimerism (engraftment) analysis, post transplantation specimen (eg, hematopoietic stem cell), includes comparison to previously performed baseline analyses; without cell selection
81268	Chimerism (engraftment) analysis, post transplantation specimen (eg, hematopoietic stem cell), includes comparison to previously performed baseline analyses; with cell selection (eg, CD3, CD33), each cell type
81277	Cytogenomic neoplasia (genome-wide) microarray analysis, interrogation of genomic regions for copy number and loss-of-heterozygosity variants for chromosomal abnormalities

CPT	Code Description
81278	IGH@/BCL2 (t(14;18)) (eg, follicular lymphoma) translocation analysis, major breakpoint region (MBR) and minor cluster region (mcr) breakpoints, qualitative or quantitative
81305	MYD88 (myeloid differentiation primary response 88) (eg, Waldenstrom's macroglobulinemia, lymphoplasmacytic leukemia) gene analysis, p.Leu265Pro (L265P) variant
81314	PDGFRA (platelet-derived growth factor receptor, alpha polypeptide) (eg, gastrointestinal stromal tumor [GIST]), gene analysis, targeted sequence analysis (eg, exons 12, 18)
81315	PML/RARalpha, (t(15;17)), (promyelocytic leukemia/retinoic acid receptor alpha) (eg, promyelocytic leukemia) translocation analysis; common breakpoints (eg, intron 3 and intron 6), qualitative or quantitative
81316	PML/RARalpha, (t(15;17)), (promyelocytic leukemia/retinoic acid receptor alpha) (eg, promyelocytic leukemia) translocation analysis; single breakpoint (eg, intron 3, intron 6 or exon 6), qualitative or quantitative
81340	TRB@ (T cell antigen receptor, beta) (eg, leukemia and lymphoma), gene rearrangement analysis to detect abnormal clonal population(s); using amplification methodology (eg, polymerase chain reaction)
81341	TRB@ (T cell antigen receptor, beta) (eg, leukemia and lymphoma), gene rearrangement analysis to detect abnormal clonal population(s); using direct probe methodology (eg, Southern blot)
81342	TRG@ (T cell antigen receptor, gamma) (eg, leukemia and lymphoma), gene rearrangement analysis, evaluation to detect abnormal clonal population(s)
81347	SF3B1 (splicing factor [3b] subunit B1) (eg, myelodysplastic syndrome/acute myeloid leukemia) gene analysis, common variants (eg, A672T, E622D, L833F, R625C, R625L)
81348	SRSF2 (serine and arginine-rich splicing factor 2) (eg, myelodysplastic syndrome, acute myeloid leukemia) gene analysis, common variants (eg, P95H, P95L)
81357	U2AF1 (U2 small nuclear RNA auxiliary factor 1) (eg, myelodysplastic syndrome, acute myeloid leukemia) gene analysis, common variants (eg, S34F, S34Y, Q157R, Q157P)
81360	ZRSR2 (zinc finger CCCH-type, RNA binding motif and serine/arginine-rich 2) (eg, myelodysplastic syndrome, acute myeloid leukemia) gene analysis, common variant(s) (eg, E65fs, E122fs, R448fs)
81370	HLA Class I and II typing, low resolution (eg, antigen equivalents); HLA-A, -B, -C, -DRB1/3/4/5, and -DQB1
81371	HLA Class I and II typing, low resolution (eg, antigen equivalents); HLA-A, -B, and -DRB1 (eg, verification typing)

CPT	Code Description
81372	HLA Class I typing, low resolution (eg, antigen equivalents); complete (ie, HLA-A, -B, and -C)
81373	HLA Class I typing, low resolution (eg, antigen equivalents); one locus (eg, HLA-A, -B, or -C), each
81374	HLA Class I typing, low resolution (eg, antigen equivalents); one antigen equivalent (eg, B*27), each
81375	HLA Class II typing, low resolution (eg, antigen equivalents); HLA-DRB1/3/4/5 and -DQB1
81376	HLA Class II typing, low resolution (eg, antigen equivalents); one locus (eg, HLA-DRB1, -DRB3/4/5, -DQB1, -DQA1, -DPB1, or -DPA1), each
81377	HLA Class II typing, low resolution (eg, antigen equivalents); one antigen equivalent, each
81378	HLA Class I and II typing, high resolution (ie, alleles or allele groups), HLA-A, -B, -C, and -DRB1
81379	HLA Class I typing, high resolution (ie, alleles or allele groups); complete (ie, HLA-A, -B, and -C)
81380	HLA Class I typing, high resolution (ie, alleles or allele groups); one locus (eg, HLA-A, -B, or -C), each
81381	HLA Class I typing, high resolution (ie, alleles or allele groups); one allele or allele group (eg, B*57:01P), each
81382	HLA Class II typing, high resolution (ie, alleles or allele groups); one locus (eg, HLA-DRB1, -DRB3/4/5, -DQB1, -DQA1, -DPB1, or -DPA1), each
81383	HLA Class II typing, high resolution (ie, alleles or allele groups); one allele or allele group (eg, HLA-DQB1*06:02P), each
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP] by techniques such as restriction enzyme digestion or melt curve analysis)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81402	Molecular pathology procedure, Level 3 (eg, >10 SNPs, 2-10 methylated variants, or 2-10 somatic variants [typically using non-sequencing target variant analysis], immunoglobulin and T-cell receptor gene rearrangements, duplication/deletion variants of 1 exon, loss of heterozygosity [LOH], uniparental disomy [UPD])
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)

CPT	Code Description
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81449	Solid organ neoplasm, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants and copy number variants or rearrangements, if performed; RNA analysis
81456	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; RNA analysis
81479	Unlisted molecular pathology procedure
81599	Unlisted multianalyte assay with algorithmic analysis
88237	Tissue culture for neoplastic disorders; bone marrow, blood cells
88239	Tissue culture for neoplastic disorders; solid tumor
88240	Cryopreservation, freezing and storage of cells, each cell line
88241	Thawing and expansion of frozen cells, each aliquot
88269	Chromosome analysis, in situ for amniotic fluid cells, count cells from 6-12 colonies, 1 karyotype, with banding
88271	Molecular cytogenetics; DNA probe, each (eg, FISH)
88272	Molecular cytogenetics; chromosomal in situ hybridization, analyze 3-5 cells (eg, for derivatives and markers)
88273	Molecular cytogenetics; chromosomal in situ hybridization, analyze 10-30 cells (eg, for microdeletions)
88274	Molecular cytogenetics; interphase in situ hybridization, analyze 25-99 cells
88275	Molecular cytogenetics; interphase in situ hybridization, analyze 100-300 cells
88280	Chromosome analysis; additional karyotypes, each study
88283	Chromosome analysis; additional specialized banding technique (eg, NOR, C-banding)
88285	Chromosome analysis; additional cells counted, each study
88289	Chromosome analysis; additional high resolution study
88291	Cytogenetics and molecular cytogenetics, interpretation and report
88299	Unlisted cytogenetic study
0268U	Hematology (atypical hemolytic uremic syndrome [aHUS]), genomic sequence analysis of 15 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ aHUS Genetic Evaluation Lab/Manufacturer: Versiti™ Diagnostic Laboratories

CPT	Code Description
0444U	Oncology (solid organ neoplasia), targeted genomic sequence analysis panel of 361 genes, interrogation for gene fusions, translocations, or other rearrangements, using DNA from formalin-fixed paraffin-embedded (FFPE) tumor tissue, report of clinically significant variant(s) Proprietary test: Aventa FusionPlus ™ Lab/Manufacturer: Aventa Genomics, LLC
0523U	Oncology (solid tumor), DNA, qualitative, next-generation sequencing (NGS) of singlenucleotide variants (SNV) and insertion/deletions in 22 genes utilizing formalin-fixed paraffinembedded tissue, reported as presence or absence of mutation(s), location of mutation(s), nucleotide change, and amino acid change Proprietary test: oncoRevealTMCDx Lab/Manufacturer: Pillar Biosciences Inc, Pillar Biosciences Inc

Genetic Markers for Assessing Risk of Cardiovascular Disease

Policy Number: AHS – M2180 – Genetic Markers for Assessing Risk of Cardiovascular Disease	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Cardiovascular risk assessment comprises the means and processes to predict the probability of developing a cardiovascular disease. These are a group of tests and health factors that have been proven to indicate a person's chance of having a cardiovascular event such as a heart attack or stroke. This policy addresses genetic markers that are associated with cardiovascular disease risk. Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS-G2050	Cardiovascular Disease Risk Assessment
AHS-M2082	Genetic Testing for Lipoprotein(a) Variant(s) as a Decision Aid for Aspirin Treatment and/or CVD Risk Assessment
AHS-M2137	Genetic Testing for Familial Hypercholesterolemia
AHS-M2141	Testing of Homocysteine Metabolism-Related Conditions

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

1) To predict the risk of developing cardiovascular disease and/or the effectiveness of statin therapy, *KIF6* genotyping **DOES NOT MEET COVERAGE CRITERIA**.

2) To assess an individual's risk of developing cardiovascular disease, the following tests **DO NOT MEET COVERAGE CRITERIA**:

   a) Gene expression profiling.

   b) Genotyping for 9p21 single nucleotide polymorphisms.

   c) Panels that incorporate genetic risk factors with nongenetic biomarkers.

3) All other genetic tests for assessing cardiovascular disease risk **DO NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ABI	Ankle-brachial index
ACC	American College of Cardiology
AHA	American Heart Association
Apo B	Apolipoprotein B
ASCVD	Atherosclerotic cardiovascular disease
CAC	Coronary artery calcium
CAD	Coronary artery disease
CCS	Canadian Cardiovascular Society
CHD	Coronary heart disease
CVD	Cardiovascular disease
EAS	European Atherosclerosis Society
ES	Endocrine Society
ESC	European Society of Cardiology
FDA	Food and Drug Administration
GRS	Genomic risk score
GWAS	Genome-wide association study
HDL	High-density lipoprotein
hsCRP	High-sensitivity C reactive protein
IDEAL	Incremental decrease in end points through aggressive lipid-lowering
KIF6	*Kinesin family member 6*
LDL	Low-density lipoprotein
LDL-C	Low-density lipoprotein cholesterol
LDT	Laboratory developed test

Lp(a)	Lipoprotein A
LPA	Apolipoprotein(a) locus
Lp-PLA2	Lipoprotein-associated phospholipase A2
MI	Myocardial infarction
PRSs	Polygenic risk scores
RNA	Ribonucleic acid
SNPs	Single nucleotide polymorphisms
TNT	Treating to new targets study
VLDL	Very low-density lipoprotein

V. Scientific Background

Statistics show that cardiovascular disease (including coronary heart disease, stroke, and hypertension) is America's leading health problem and the leading cause of death. According to the 2024 update of the heart disease and stroke statistics report released by the American Heart Association (AHA):

- Approximately 127.9 million people in this country suffer from some form of cardiovascular disease (encompassing coronary heart disease, heart failure, hypertension, and stroke).
- The direct and indirect costs of cardiovascular disease and stroke are about $422.3 billion and increasing every year.
- Coronary heart disease (CHD) was the leading cause (40.3%) of deaths attributable to CVD in the United States, followed by stroke (17.5%), other CVD (17.1%), high blood pressure (13.4%), heart failure (9.1%), diseases of the arteries (2.6%).
- Heart disease and stroke claim more lives each year in the United States than all forms of cancer and Chronic Lower Respiratory disease combined.
- On average, someone dies of a stroke every three minutes fourteen seconds in the United States.
- 11.5% of US adults reported cigarette use every day or some days (13.1% of males and 10.1% of females).
- Worldwide, high body mass index was attributed to 3.69 million deaths (AHA, 2024; Seth S. Martin, 2024).

Cardiovascular Risk Assessment

Traditionally, the most important indicators for cardiac risk are those of a person's health history. These include factors such as family history, age, weight, exercise, and cigarette smoking status (Wilson, 2023). Research has begun examining genetic markers and their ability to predict an individual’s risk of developing cardiovascular

disease.

Genetic Markers

According to the AHA in 2013, genomics serves several roles in cardiovascular health and disease, including disease prediction, discovery of genetic loci influencing CVD, functional evaluation of these genetic loci to understand mechanisms, and identification of therapeutic targets (Ganesh et al., 2013). The AHA notes that several clinically useful diagnostic tests have been discovered for single-gene CVDs. However, it is laborious to develop genetic testing for complex CVD because individual common variants have a smaller impact on risk. Furthermore, the influence of factors such as environmental variables, phenotypic heterogeneity, and pathogenic complexity, makes understanding the genomics behind complex CVDs more difficult. Characterization of the clinical phenotype requires consideration of the clinical details of the diseases and traits under study (Ganesh et al., 2013). Many genetic loci and polymorphisms have been proposed to influence cardiovascular risk. Palotie et al. (2016) identified 49,310 single nucleotide polymorphisms (SNPs), created a genomic risk score (GRS) based on those SNPs, and evaluated the GRS with five population cohorts totaling over 15,000 samples. The GRS was found to result in a hazard ratio of 1.74 for the three Finnish population cohorts (n = 12676) and a hazard ratio of 1.28 for the two Framingham cohorts (n = 3406). The GRS was also found to capture different trajectories of absolute risk, with men in the top 20% attaining 10% cumulative coronary heart disease (CHD) risk 12–18 years earlier than those in the bottom 20% (Palotie et al., 2016).

Gene expression changes, particularly in peripheral blood cells, may provide some information on CVD risk. Gene expression is thought to reflect the pathological state of the current cell, tissue, or organ system, therefore providing molecular insight on the status of cardiac tissue before clinical symptoms start to appear (Elashoff et al., 2011). Genetic variation may lead to vastly differing concentrations of many genetic products. For example, Zhernakova et al. (2018) evaluated the plasma concentrations of 92 cardiovascular disease-related proteins, of which 73 had a genetic association. Cis- and trans- isoforms of the protein quantitative trait loci produced genetic variation; this, combined with microbial variation, is responsible for 17.5% of inter-individual variation in plasma proteins (Zhernakova et al., 2018).

9p21 SNP

Genetic determinants of the development of CHD have been investigated in multiple studies with 46 SNPs across the genome significantly associated with an increased risk of disease (Deloukas et al., 2013). The strongest association with CHD risk was linked to SNPs around locus 9p21 (Palomaki et al., 2010; Patel et al., 2014; Paynter et al., 2009;

Samani et al., 2007; Wilson, 2023). However, despite clear association between variants and incident CHD, locus 9p21 SNPs have not been definitively shown to significantly improve CHD risk prediction compared with traditional risk factors (Dutta et al., 2011; Palomaki et al., 2010; Paynter et al., 2009; Virani et al., 2012). Trenkwalder et al. (2019) identified an association between the LPA locus and an increased risk of aortic valve stenosis, particularly in patients without CAD; however, 9p21 was not associated with aortic valve stenosis. The pathophysiologic impact of these genetic variants likely varies depending on other environmental factors or comorbid conditions (Wilson, 2023). Proprietary labs such as Celera Corporation (now owned by Quest Diagnostics) and deCODE Genetics offer tests revolving around analysis of this locus mutation (Quest, 2024).

Palomaki et al. (2010) performed a targeted systematic review of published literature to evaluate the clinical utility of 9p21 single nucleotide polymorphism testing. Forty-seven distinct data sets from 22 articles were analyzed, including 35,872 cases and 95,837 controls. The authors found a statistically significant association between 9p21 SNPs and heart disease that varied by age at disease onset, but the magnitude of the association was small. These risk alleles were found to associate more strongly with cardiovascular events in younger persons than cardiovascular events overall. However, the authors noted that the clinical utility of 9p21-related biomarkers cannot be assumed due to numerous complicating factors such as patient adherence (Palomaki et al., 2010).

Gransbo et al. (2013) evaluated if testing for 9p21 SNP adds useful information to CVD prediction beyond assessment of traditional risk factors. The common SNP variant rs4977574 on chromosome 9p21 was genotyped in 24,777 subjects who were free from CVD prior to the baseline examination. The genotyping of the 9p21 gene was not found to significantly improve predictive accuracy of CVD, although 9p21 significantly predicted CVD in the whole population in additive models. The authors evaluated the attributable risk conferred by 9p21 to be 13%. The investigators concluded that a variation of chromosome 9p21 alone "does not add clinically meaningful information in terms of CVD prediction beyond traditional risk factors at any age" (Gransbo et al., 2013).

Dehghan et al. (2016) evaluated the genome-wide association study (GWAS) for incident myocardial infarction (MI) and CHD in prospective cohort studies, which analyzed a total of 64297 individuals, including 3898 MI cases and 5465 CHD cases. A modest association between the 9p21 locus SNP (rs1333049) and MI, as well as marginal association with CHD was found. Among an inception cohort of those who experienced MI during follow-up, this risk allele was associated with a decreased risk of subsequent mortality. The authors concluded that the role of 9p21 locus may be

complex and that the protective effect of the risk alleles at 9p21 is unclear; however, the authors note that several other studies have found that the 9p21 locus increases the CHD risk for the first event only and not for subsequent events. Overall, the authors suggest further investigation of genetic causes of complex disorders (Dehghan et al., 2016).

Kessler et al. (2016) reviewed the impact of GWAS on the pathophysiology and therapy of CVD. The researchers found a correlation between the number of individuals participating in the study and the number of genome-wide significant variants detected by the GWAS. Technological advancement has led to denser genotyping, resulting in increased number of loci with genome-wide significant association for CAD. Over 50 genetic variants associated with cardiovascular risk have so far been identified. Almost all risk variants identified by GWAS were found in European individuals with the average European carrying several risk alleles associated with CHD. Most of these risk alleles were found in non-coding parts of the genome, suggesting that these variants affect gene regulation rather than protein structure. For example, the 9p21 locus encodes different isoforms of antisense non-coding RNA in the INK4 locus (ANRIL) which is involved in the preferred synthesis of non-circular/circular forms of the long non-coding RNA, affecting expression of multiple genes (Kessler et al., 2016). The authors state, however, that variants identified represent no more than 10% of the heritable risk. Although important progress was made with GWAS, further understanding of inheritance patterns is needed. The results available so far provide valuable insights into the pathophysiology of CAD and MI, but they are only a starting point for individualized treatment strategies (Kessler et al., 2016).

In summary, no studies were found that outlined changes to preventive and monitoring strategies, patient management, or improvement in clinical outcomes due to genotyping for 9p21 SNPs. There is a lack of published evidence regarding the clinical utility of genetic testing. Based on current literature, the contribution of 9p21 genotyping to overall cardiovascular risk assessment, above that of traditional risk factors, is not likely to be clinically important.

Kinesin family member 6 (KIF6)

Kinesin family member 6 (KIF6) is a protein encoded by the *KIF6* gene. This protein is involved in transport along microtubules, and the primary mutation of Trp719Arg affects its ability to bind its cargo. KIF6 has been studied as a marker for coronary artery disease and effectiveness of statin therapy. Initial studies of two trials with statins found an association between the *KIF6* p.Trp719Arg (rs20455, c.2155T>C) polymorphism and clinical outcomes with statin therapy, showing carriers of the 719Arg allele having greater reduction in clinical events compared with noncarriers

(Iakoubova et al., 2008). However, subsequent studies dispute the reported associations.

Hopewell et al. (2011) studied the effects of the *KIF6* Trp719Arg polymorphism (rs20455) on vascular risk and response to statin therapy in 18,348 participants from the Heart Protection Study. Participants received 40 mg simvastatin daily for four to six weeks before being randomly allocated 40 mg simvastatin daily or placebo for five years. The *KIF6* genotype was not significantly associated, among placebo-allocated participants, with the risks of incident major vascular events, major coronary events, revascularizations, or strokes. The investigators concluded that statin therapy significantly reduces the incidence of coronary and other major vascular events to a similar extent, irrespective of *KIF6* genotype. The authors further stated that use of *KIF6* genotyping to guide statin therapy is not warranted (Hopewell et al., 2011).

Ridker et al. (2011) evaluated the effect of polymorphism at rs20455 encoding the *KIF6* 719Arg allele on outcomes of 8,781 Caucasian trial participants in the Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER) study. Rosuvastatin was equally effective at reducing cardiovascular event rates among carriers and noncarriers of the *KIF6* 719Arg allele, and carriers of the 719Arg allele were not found to have more vascular events or a significant difference in hsCRP or lipid levels. The authors concluded that for rosuvastatin there appears to be no clinical utility to screening for the *KIF6* genotype as a method to determine vascular risk or to predict statin efficacy (Ridker et al., 2011).

Arsenault et al. (2012) investigated if carriers of the *KIF6* 719Arg variant benefit more from statin therapy, in terms of CVD risk reduction, than noncarriers through two large prospective, randomized, double-blinded, controlled trials. A total of 10,001 patients with stable CHD and LDL-C levels <130 mg/dL (3.4 mmol/L) of the Treating to New Targets (TNT) study were randomly assigned to receive either 10- or 80-mg of atorvastatin per day and followed up for a median of 4.9 years. A total of 8,888 patients with a history of myocardial infarction from the Incremental Decrease in End Points Through Aggressive Lipid-Lowering (IDEAL) study were randomly assigned to receive 20–40 mg of simvastatin or 80 mg of atorvastatin and followed up for a median of 4.8 years. The investigators concluded that carriers of the *KIF6* 719Arg allele were not at increased cardiovascular risk and did not obtain consistent cardiovascular benefit from high-dose statin therapy compared with noncarriers (Arsenault et al., 2012).

Charland et al. (2014) investigated the impact of providing *KIF6* test results and risk information directly to 647 tested patients on six month statin adherence and persistence compared with concurrent non-tested matched controls. The investigators

observed that significantly more tested patients were adherent and persisted on therapy compared to the control group, with tested patients rating out at a 63.4% adherence (defined as ingesting medication on 80% of days), compared to 45% for the control group over six months (Charland et al., 2014). The test group also persisted on therapy more often than the control group (69.1% for the testing group, 53.3% for the control). The investigators concluded that the study provided the first evidence that pharmacogenetic testing may modify patient adherence (Charland et al., 2014).

Ruiz-Ramos et al. (2015) performed a systematic review and meta-analysis of previously published association studies between Trp719Arg polymorphism of *KIF6* and the development of CHD. This electronic search included papers published between 1993 and 2014. Twenty-three studies consisting of 38,906 subjects were identified (17,812 cases, 21,094 controls). A significant association was not found between Caucasian populations and the polymorphism or the CAD subgroup and the polymorphism, though the authors concluded that allele 719Arg may have a protective association to present CHD in all populations and the Trp719Arg polymorphism of the *KIF6* gene is an important risk factor for developing MI (Ruiz-Ramos et al., 2015).

Proprietary Testing

Cardiovascular Risk Panels/Profiles

Cardiovascular risk panels refer to combinations of cardiac markers that are used to assess risk of developing cardiovascular disease, major adverse cardiovascular events, or ischemic cerebrovascular events. Commercially available risk panels use different combinations of lipids, inflammatory, genetic, and metabolic markers. Risk panel's report the results of multiple individual tests, whereas quantitative risk scores generally use proprietary algorithms to combine the results of multiple markers into one score. The clinical utility of risk panels is lacking as the impact of results on patient management is unknown.

Quest Diagnostics currently offers cardiogenetic testing for CVD risk. Tests include Cardio IQ® 9p21 and Cardio IQ® KIF6 (Quest, 2024).

VI. Guidelines and Recommendations

U.S. Preventative Services Task Force (USPSTF)

In a 2018 recommendation, the USPSTF provided a general statement regarding nontraditional risk factors in CVD risk assessment, but did not directly address the use of commercial CVD risk panels:

"The USPSTF concludes that there are insufficient adequately powered clinical trials

evaluating the incremental effect of the ankle-brachial index (ABI), high-sensitivity C-reactive protein (hs-CRP) level, or coronary artery calcium (CAC) score in risk assessment and initiation of preventive therapy.
Furthermore, the clinical meaning of improvements in measures of calibration, discrimination, and reclassification risk prediction studies is uncertain" (Lin et al., 2018).

American College of Cardiology (ACC) and the American Heart Association (AHA)

The 2019 ACC and AHA guidelines do not address arterial compliance, lipoprotein-associated phospholipase, long-chain omega-3 fatty acids, 9p21 polymorphisms, *KIF6* genotyping, or endothelial function assessment as methods to assess initial CVD risk (Arnett et al., 2019). The 2013 ACC and AHA guidelines on the assessment of cardiovascular risk did not address assessment of 9p21 polymorphisms or KIF6 genotyping. However, the 2010 guidelines recommended against genotype testing for "CHD risk assessment in asymptomatic adults" (Goff et al., 2014; Greenland et al., 2010).

American Heart Association (AHA)

A policy statement from the AHA on genetics and cardiovascular disease states "although robust GWAS [genome wide association studies] evidence exists linking common variants to complex CVD, studies are not yet available to inform the clinical benefit of providing such genetic information to patients" (Ashley et al., 2012).

A 2022 statement notes that the use of polygenic risk factors shows promise for the prediction of cardiovascular disease, as "the identification of monogenic risk variants predisposing to cardiovascular conditions has been used clinically to inform surveillance and management plans. Relatively recent advances in population genetics have uncovered the polygenic basis of these and other cardiovascular conditions in most patients. These observations point to the possibility of using genetic profiling to inform clinical practice… Such PRSs [Polygenic Risk Scores] may be appropriately considered in select scenarios, given the current evidence base."

The AHA statement points to coronary artery disease (CAD) as one of the main areas where polygenic risk factors show promise; the discovery of common genetic variants associated with coronary artery disease has enabled this development of polygenic risk profiling. They also note that "scores have been shown to be strong predictors of subclinical coronary atherosclerosis and independently prognostic of CAD risk." The statement does not specifically mention individual genes such as 9p21 single nucleotide polymorphisms or *KIF6* genotyping—focusing instead on genome wide association studies (O'Sullivan et al., 2022).

Endocrine Society (ES)

This guideline was published with the intent to assess and treat dyslipidemia in patients with endocrine disorders. The guideline remarks that certain "advanced" lipid testing (assessment of markers such as Apo B, lipid fractionation, and Lp(a)) may be helpful in "characterizing" lipid abnormalities, but "add little" to risk prediction beyond the standard lipid profile. The guideline also notes that genetic tests for risk stratification may "modestly" improve risk prediction but are not available in clinical practice. The guideline does remark that Apo B and non-HDL cholesterol should be considered "risk-enhancing" factors (Newman et al., 2020).

Canadian Cardiovascular Society (CCS)

In 2021, the CCS published updated recommendations on the management of dyslipidemia for the prevention of cardiovascular disease in adults. A summary of the society's recommendations that involve genetic associations relevant to CVD risk assessment is provided below:

- We suggest that CAC (coronary artery calcium) screening might be considered for a subset of low-risk individuals 40 years or older with a family history of premature ASCVD (men 55 years or younger; women 65 years or younger), in addition to identifying known genetic causes of ASCVD such as elevated Lp(a) or FH (Weak Recommendation; Low-Quality Evidence)" (Pearson et al., 2021).

The 2021 guidelines reaffirmed those from 2016, stating that "Screening should be repeated every five years for men and women aged 40-75 years using the modified FRS or Cardiovascular Life Expectancy Model (CLEM) to guide therapy to reduce major CV events" (Pearson et al., 2021).

2021 European Society of Cardiology (ESC) and Other Societies on Cardiovascular Disease Prevention in Clinical Practice

In 2021, the Joint Task Force of the ESC and Other Societies on Cardiovascular Disease Prevention in Clinical Practice published an update to guidelines on cardiovascular disease prevention in clinical practice. The Task Force recognized that genetic screening could be useful in some conditions such as familial hypercholesterolemia. The authors note that the etiology of atherosclerotic cardiovascular disease (ASCVD) has genetic associations; but, genetic information is not currently used to guide preventive practice.

However, the ESC does not recommend genetic screening in the general population or the use of genetics in "preventive approaches." According to the Task Force, there is no consensus regarding which genes and their corresponding single nucleotide

polymorphisms that should be included in a genetic risk score. In terms of polygenic risk scores, they acknowledge potential towards using genetics for prevention, but a lack of clarity towards whether to use "risk factor-specific" or "outcome-specific" polygenic risk scores. Further evaluation of clinical utility is required (Frank L. J. Visseren et al., 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/Medicare-Coverage-Database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81402	Molecular pathology procedure, Level 3 (eg, >10 SNPs, 2-10 methylated variants, or 2-10 somatic variants [typically using non-sequencing target variant analysis], immunoglobulin and T-cell receptor gene rearrangements, duplication/deletion variants of 1 exon, loss of heterozygosity [LOH], uniparental disomy [UPD])
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)

CPT	Code Description
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81407	Molecular pathology procedure, Level 8 (eg, analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)
81408	Molecular pathology procedure, Level 9 (eg, analysis of >50 exons in a single gene by DNA sequence analysis)
81479	Unlisted molecular pathology procedure
81493	Coronary artery disease, mRNA, gene expression profiling by real-time RT-PCR of 23 genes, utilizing whole peripheral blood, algorithm reported as a risk score Proprietary test: Corus®CAD Lab/Manufacturer: CardioDx, Inc.
0401U	Cardiology (coronary heart disease [CAD]), 9 genes (12 variants), targeted variant genotyping, blood, saliva, or buccal swab, algorithm reported as a genetic risk score for a coronary event Proprietary test: CARDIO inCode-Score (CIC-SCORE) Lab/Manufacturer: GENinCode U.S. Inc
0439U	Cardiology (coronary heart disease [CHD]), DNA, analysis of 5 single-nucleotide polymorphisms (SNPs) (rs11716050 [LOC105376934], rs6560711 [WDR37], rs3735222 [SCIN/LOC107986769], rs6820447 [intergenic], and rs9638144 [ESYT2]) and 3 DNA methylation markers (cg00300879 [transcription start site {TSS200} of CNKSR1], cg09552548 [intergenic], and cg14789911 [body of SPATC1L]), qPCR and digital PCR, whole blood, algorithm reported as a 4-tiered risk score for a 3-year risk of symptomatic CHD Proprietary test: Epi+Gen CHD ™ Lab Manufacturer: Cardio Diagnostics, Inc
0440U	Cardiology (coronary heart disease [CHD]), DNA, analysis of 10 single-nucleotide polymorphisms (SNPs) (rs710987 [LINC010019], rs1333048 [CDKN2B-AS1], rs12129789 [KCND3], rs942317 [KTN1-AS1], rs1441433 [PPP3CA], rs2869675 [PREX1], rs4639796 [ZBTB41], rs4376434 [LINC00972], rs12714414 [TMEM18], and rs7585056 [TMEM18]) and 6 DNA methylation markers (cg03725309 [SARS1], cg12586707 [CXCL1, cg04988978 [MPO], cg17901584 [DHCR24-DT], cg21161138 [AHRR], and cg12655112 [EHD4]),

CPT	Code Description
	qPCR and digital PCR, whole blood, algorithm reported as detected or not detected for CHD Proprietary test: PrecisionCHDTM Lab/Manufacturer: Cardio Diagnostics, Inc
0466U	Cardiology (coronary artery disease [CAD]), DNA, genomewide association studies (564856 single-nucleotide polymorphisms [SNPs], targeted variant genotyping), patient lifestyle and clinical data, buccal swab, algorithm reported as polygenic risk to acquired heart disease Proprietary test: CardioRisk+ Lab/Manufacturer: Gene by Gene, Ltd, Open DNS, Ltd

Genetic Testing and Genetic Expression Profiling in Patients with Uveal Melanoma

Policy Number: AHS – M2071 – Genetic Testing and Genetic Expression Profiling in Patients with Uveal Melanoma	Prior Policy Name and Number, as applicable: AHS-M2071-Gene Expression Profiling for Uveal Melanoma
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Uveal melanoma develops from melanocytes in any part of the uveal tract, including the iris, ciliary body, and choroid (Diener-West et al., 2005). UM is the most common primary cancer of the eye and has a strong propensity for metastasis (Harbour & Chen, 2013). These melanomas have significant differences from cutaneous melanomas so the management of these two classes differ considerably (Albert et al., 1996; Harbour, 2022).

Gene expression assays measure the concentration of specific mRNAs being transcribed to assess the genes that are active in a particular cell or tissue. Analyses of gene expression can be clinically useful for disease classification, diagnosis, prognosis, and tailoring treatment to underlying genetic determinants of pharmacologic response (Steiling, 2023). Gene expression profiling has been proposed as a method of risk stratification for UM.

II. Related Policies

Policy Number	Policy Title
AHS-M2029	Molecular Testing for Cutaneous Melanoma

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" of this policy document.

1) For patients with primary, localized uveal melanoma (UM), gene expression profiling for uveal melanoma (e.g., DecisionDx-UM) **MEETS COVERAGE CRITERIA**.

2) For patients with primary, localized UM, the following genetic markers for UM **MEET COVERAGE CRITERIA** based on NCCN guidelines:
   a) Copy number assessment for chromosomes 3, 6, and/or 8
   b) Sequence analysis of the following genes:
      i) *BAP1*
      ii) *EIF1AX*
      iii) *PRAME*
      iv) *SF3B1*

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) All other testing for uveal melanoma (e.g., Uveal Melanoma Prognostic Genetic Test, DecisionDx-PRAME, DecisionDx-UMSeq) **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
aCGH	Array comparative genomic hybridization
AJCC	American Joint Committee on Cancer
ATRIP	*ATR interacting irotein*
BAP1	*BRCA1-Associated Protein 1*
BRAF	*Proto-oncogene B-Raf and v-Raf murine sarcoma viral oncogene homolog B*

BRCA1	*Hereditary breast and ovarian cancer-causing gene product*
CDC45	*Cell division cycle 45*
CDH1	*Cadherin 1*
CHEK1	*Checkpoint kinase 1*
CIZ1	*Cip1-interacting zinc finger protein*
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers for Medicare and Medicaid Services
COMS	Collaborative Ocular Melanoma Study
CYSLTR2	*Cysteinyl leukotriene receptor 2*
DNA	deoxyribonucleic acid
ECM1	*Extracellular Matrix Protein 1*
EIF1AX	*Eukaryotic translation initiation factor 1A*
EIF1B	*Eukaryotic translation initiation factor 1A X-Linked*
FDA	Food and Drug Administration
FEN1	*Flap structure-specific endonuclease 1*
FISH	fluorescence in situ hybridization
FXR1	*Fragile X mental retardation syndrome-related protein 1*
GEP	Gene expression profiling
GNA11	*Guanine nucleotide-binding protein subunit alpha-11*
GNAQ	*Guanine nucleotide-binding protein G(q) subunit alpha*
HTR2B	*5-hydroxytryptamine receptor 2B*
HUS1	HUS1 Checkpoint clamp component
ID2	Inhibitor of DNA binding 2
JAMA	Journal of the American Medical Association
LBD	Largest basal diameter
LCAs	Local coverage articles
LCDs	Local coverage determinations
LDTs	Laboratory-developed Tests
LIG1	*DNA ligase 1*
LMCD1	*LIM and cysteine rich domains 1*
LTA4H	*Leukotriene A4 hydrolase*
MAPK	*Mitogen-Activated Protein Kinases*
MCM10	*Minichromosome maintenance 10 Replication Initiation Factor*
MCM2	*Minichromosome maintenance complex component 2*
MCM4	*Minichromosome maintenance complex component 4*
MCM5	*Minichromosome maintenance complex component 5*
MLH3	*MutL Homolog 3*
MLPA	Multiplex Ligation-Dependent Probe Amplification
mRNA	Messenger Ribonucleic Acid

MRPS21	*Mitochondrial Ribosomal Protein S21*
MSH6	*MutS homolog 6*
MTUS1	*Microtubule associated scaffold protein 1*

UM	Uveal melanoma

V. Scientific Background

Uveal melanoma (Diener-West et al.) is the most common primary cancer in the eye, with an incidence of more than 7,000 new cases each year (Scott & Gerstenblith, 2018). The mortality rate at 15 years of diagnosis of the primary tumor is approximately 50% (Kujala et al., 2003); despite enucleation or definitive radiotherapy of the primary lesion, approximately half will develop a metastasis, and the average survival after metastasis is only 9-12 months (Carvajal et al., 2014; COMS, 2001; Diener-West et al., 2005; Kath et al., 1993; Onken et al., 2012; Rietschel et al., 2005). Tebentafusp is a United States Food and Drug Administration approved treatment for adults with advanced unresectable or metastatic uveal melanoma who are HLA-1 positive. Tebentadusp is a bispecific T cell engager targeting glycoprotein 100. The drug improved one-year overall survival rates compared to immunotherapy or

chemotherapy. Currently there is no effective treatment in preventing deaths from metastatic UM (Carvajal, 2024). Novel and innovative therapeutic targets for uveal melanoma are currently being investigated. These include liver-directed therapies, immunotherapy, and targeted-therapy on single compounds or combinational therapies (Mallone et al., 2020).

Uveal melanoma typically presents with visual disturbance, but may be asymptomatic (Mahendraraj et al., 2016). The diagnosis of UM is based upon fundoscopic examination by an experienced clinician, which is followed by ultrasound and/or fluorescein angiography. Biopsy is generally not indicated as the clinical diagnosis of UM has an accuracy of 99 percent (Pereira et al., 2013); however, molecular characterization of the tumor can provide important information about the risk of recurrence.

The molecular pathogenesis of UM is not completely characterized. It is not associated with the frequent *BRAF* mutations of cutaneous melanoma. UM has been associated with activating mutations in *GNAQ* or *GNA11* in greater than 80 percent of primary UMs leading to activation of downstream signaling pathways, including the mitogen-activated protein kinases (*MAPK*) pathway (Onken et al., 2008; Shoushtari & Carvajal, 2014; Van Raamsdonk et al., 2009; Van Raamsdonk et al., 2010). Inactivating somatic mutations have been found in the *BRCA1*-associated protein 1 (*BAP1*) gene in 84 percent of metastasizing tumors, implicating loss of *BAP1* in the progression of UM (Harbour et al., 2010). Germline mutations of *BAP1* in approximately five percent of patients with UMs have been associated with larger tumors and involvement of the ciliary body (Gupta et al., 2015). Recurring mutations occurring at codon 625 of the *SF3B1* gene and eukaryotic translation initiation factor 1A (*EIF1AX*) were associated with good prognosis (Harbour et al., 2013; Harbour, 2022; Martin et al., 2013). Other mutations such as *PLCB4, CYSLTR2, SF3B1,* and more are often observed (Carvajal, 2024).

Metastasis is common in UM. Approximately 50% of cases will have distal recurrence with the liver and lungs as the most common sites of metastasis. As many as 30% of patients with UM will die of a systemic metastasis within five years of diagnosis. The National Comprehensive Cancer Network (NCCN) considers *BAP1, PRAME, SF3B1*, and *EIF1AX* mutations to be associated with varying amounts of metastasis risk (NCCN, 2023). Cytogenetic changes may also confer increased metastasis risk. The most common cytogenetic changes in UM are monosomy of chromosome 3 (possibly the single strongest factor in predicting UM metastasis) and amplification of chromosome 8q; both of which are associated with poor prognosis. Other common cytogenetic alterations include amplification of chromosome 6p and loss of 1p (Amaro et al., 2017). Caines et al. (2015) organized four cytogenetic classes of prognostic risk based on

multiplex ligation-dependent probe amplification (MLPA) results. From best to worst, those classes are: "(i) normal chromosomes 3 and 8q; (Larsen et al.) chromosome 3 deletion, normal chromosome 8q; (iii) normal chromosome 3, chromosome 8q gain; and (iv) chromosome 3 deletion, chromosome 8q gain" (Caines et al., 2015).

Genetic analysis of UM can provide prognostic information for the risk of developing metastatic disease (Spagnolo et al., 2012) and "currently represents the gold standard in molecular prognosis" for uveal melanoma as it has a technical failure rate of only three percent (Mallone et al., 2020). Genetic expression profiling (GEP) determines the expression of multiple genes in a tumor and has been proposed as an additional method to stratify patients into prognostic risk groups. Castle Biosciences offers a gene expression profile for UM, called "Decision-DX." This test evaluates the gene expression of 15 genes, 12 as indicator genes and 3 as controls. The three control genes are *MRPS21, RBM23*, and *SAP130*, and the 12 indicators are *HTR2B, ID2, MTUS1, ECM1, ROBO1, SATB1, LTA4H, EIF1B, FXR1, CDH1, LMCD1,* and *RAB31* (Onken et al., 2010). The gene expression is reported in three classes of risk; class 1A with two percent chance of the cancer metastasizing over the next five years, class 1B with a 21% chance of metastasis, and class 2 with a 72% chance. Although the test does not change the course of treatment, it may still provide prognostic value for the patient (DecisionDX, 2024c).

Additionally, Decision-DX offers multiple tests for prognostication of UM. DecisionDX-UM*Seq* is a seven gene panel intended to identify somatic mutations relevant to UM. The seven genes are as follows: *GNAQ, GNA11, CYSLTR2, PLCB4, SF3B1*, exons 1-2 of *EIF1AX*, and all coding exons of *BAP1*. *GNAQ, GNA11, CYSLTR2,* and *PLCB4* are involved in G-protein-coupled receptor signaling, *EIF1AX* is involved with translation, *SF3B1* regulates transcript usage, and *BAP1* is a tumor suppressor on chromosome 3. This test will report any somatic mutations found in these seven genes, as well as an overview of any mutation found (DecisionDX, 2024b). DecisionDX also offers a test focusing on the preferentially expressed antigen in melanoma (*PRAME)* gene (compared to three control genes). The test reports whether the user is positive or negative, along with an overview. However, DecisionDX notes that the "exact clinical implications of *PRAME* are still under investigation" (DecisionDX, 2024a).

Another prognostic test available for UM is Impact Genetics' multiplex ligation-dependent probe amplification (MLPA). This test performs a copy number assessment on chromosomes 1, 3, 6, and 8 to detect monosomy, disomy, and trisomy, a microsatellite analysis on chromosome 3 to detect chromosome copy loss and/or isodisomy, and sequence analysis of *GNAQ, GNA11, SF3B1,* and *EIF1AX* (Impact, 2019b). The test combines these results with clinical and histomorphological data and predicts survival percentage at 3, 5, and 10 years (Impact, 2019a).

Analytical Validity

Plasseraud et al. (2017) examined the "technical reliability and correlation of molecular class with pathologic characteristics" of DecisionDx. The authors identified samples from de-identified clinical reports over a six year period. They found the inter-assay concordance of 16 samples (run on three consecutive days) to be 100% with strongly correlated discriminant scores (r^2 = .9944), inter-assay concordance of 46 samples performed in a one-year period to be 100% with an r^2 of .9747 for discriminant scores, and the inter-assay concordance of 12 assays concurrently run in duplicates to be 100% with an r^2 of .9934. Concordance between two sites assessing the same tumor was 100% with r^2 of 0.9818. Finally, the "technical success" of 5516 samples was 96.3% (Plasseraud et al., 2017).

Cook et al. (2018) investigated the validity of the DecisionDx-Melanoma test using formalin-fixed paraffin-embedded tumor tissue to analyze 31 genes. The authors evaluated samples from de-identified data over a three year period. They found inter-assay concordance on 168 specimens was 99% with strongly correlated discriminant scores (r^2 = 0.96). Inter-instrument concordance was 95% with a strongly correlated r^2 of .99. Overall, in tests that met tumor sample requirements, the technical success rate of the test was 98% (Cook et al., 2018).

Clinical Utility and Validity

In 2010, Onken et al. (2010) developed and validated the PCR-based 15-gene GEP assay comprising 12 discriminating genes and three endogenous control genes, analyzed the technical performance of the assay. A total of 609 samples were taken, and the authors defined an "undetectable" gene as "if its transcript was undetectable (i.e., no Ct value) after 40 qPCR cycles." A sample was said to have failed "if one or more endogenous controls was undetectable." By this definition, only 32 samples (of the 609) were said to have failed (Onken et al., 2010).

Damato et al. (2010) performed a study using MLPA to assess the correlation of chromosome 1p, 3, 6p, 6q, 8p, and 8q abnormalities with other risk factors and/or death. The authors examined 452 patients, and the ten-year disease-specific mortality rates were as follows: "0% in 133 tumors with no chromosome 3 loss, 55% in tumors with chromosome 3 loss but no chromosome 8q gain, and 71% in 168 tumors showing combined chromosome 3 loss and 8q gain." Lack of chromosome 6p gain was also noted as a prognosticator of poor survival. The authors concluded that "these results support the use of MLPA for routine clinical prognostication" (Damato et al., 2010)

Onken et al. (2012) further evaluated the prognostic accuracy of their GEP. A total of 459 patients from 12 independent centers were examined, and tumors were as

classified as "class 1" or "class 2." The authors then compared this classification to the 7th Edition clinical Tumor-Node-Metastasis (TNM) classification and chromosome 3 status (chromosome 3 was analyzed in the first 260 samples). The GEP assay was found to have correctly classified 446 of 459 samples, with 276 in class 1 and 170 in class 2. The authors also identified metastasis in three class 1 patients and 44 class 2 patients. GEP class was also found to have a strong independent association with metastasis than any other prognostic factor. The authors concluded that "the GEP assay had a high technical success rate and was the most accurate prognostic marker among all of the factors analyzed. The GEP provided a highly significant improvement in prognostic accuracy over clinical TNM classification and chromosome 3 status. Chromosome 3 status did not provide prognostic information that was independent of GEP" (Onken et al., 2012).

Larsen et al. (2014) evaluated the prognostic factors of the MLPA test and their associations with metastasis and survival. MLPA was used to identify cytogenetic changes in 36 patients. After adjusting for factors such as gender and age, chromosome 3 loss and 8q gain were identified to be "significant prognosticators" for poor survival. Chromosome 1p loss was also associated with metastatic death. Chromosome 6p gain and chromosome 6q loss did not show any associations with survival or metastasis, but the authors speculated this to be because of low occurrence (four each) (Larsen et al., 2014).

Correa and Augsburger (2016) conducted a prospective case series study of 299 patients to evaluate if any conventional clinical prognostic factors for metastasis from UM have prognostic value. The researchers found that GEP class was the strongest prognostic factor for metastatic death in this series. Using a two-term model including GEP class and "largest basal diameter" (LBD) led to strong, independent significance of each factor studied. The authors concluded that "both GEP and LBD of the tumor are independent prognostic factors for metastasis and metastatic death in multivariate analysis" (Correa & Augsburger, 2016).

Plasseraud et al. (2016) conducted a prospective, multicenter study "to document patient management differences and clinical outcomes associated with low-risk Class 1 and high-risk Class 2 results indicated by DecisionDx-UM testing." The initial results of the study indicated a low risk of metastasis for Class 1 patients (n = 37) compared to Class 2 patients (n = 33) (5% versus 36%, respectively). The authors found that the Class 1 patients (as determined by DecisionDx) had a 100% three year metastasis-free survival compared to 63% for Class 2 patients and that Class 2 patients received "significantly higher-intensity monitoring and more oncology/clinical trial referrals compared to Class 1 patients" (Plasseraud et al., 2016).

Aaberg et al. (2014) conducted a medical record review and cross-sectional survey of ophthalmologists to assess current clinical practices for UM and the impact of molecular prognostic testing on treatment decisions. The medical records for 191 Medicare patients was evaluated, with 88 (46%) patients having documented medical treatment actions or institutional policies related to surveillance plans. Of these 88, all GEP Class 1 UM patients were treated with low-intensity surveillance, while GEP Class 2 UM patients were treated with high-intensity surveillance. Patients with high metastatic risk (monosomy 3 or GEP Class 2) underwent more frequent surveillance with hepatic imaging and liver function testing every three to six months. High-risk patients were considered more suitable for adjuvant treatment protocols. The authors concluded that "the majority of ophthalmologists treating UM have adopted molecular diagnostic tests for the purpose of designing risk-appropriate treatment strategies" (Aaberg et al., 2014).

Worley et al. (2007) compared the gene expression-based classifier to the standard genetic prognostic marker, monosomy 3, for predicting metastasis in 67 primary UMs. The sensitivity and specificity for the molecular classifier (84.6% and 92.9%, respectively) were superior to monosomy 3 detected by aCGH (58.3% and 85.7%, respectively) and FISH (50.0% and 72.7%, respectively). The researchers concluded that "molecular classification based on gene expression profiling of the primary tumor was superior to monosomy 3 and clinicopathologic prognostic factors for predicting metastasis in UM" (Worley et al., 2007).

Recent studies have shown that even after controlling for gene expression profile, tumor size (≥ 12 mm) is an independent predictor of metastasis at five years (Walter et al., 2017; Weis et al., 2016). Weis et al. (2016) also noted that no published studies indicate that patients at high risk for future metastasis (GEP class 2) benefit from adjuvant therapy in reducing metastasis rates (Nathan et al., 2015).

Cai et al. (2018) compared the prognostic accuracy of gene expression profiling (GEP, Class 1 or 2) with *PRAME* status and Tumor-Node-Metastasis (TNM) staging in patients with uveal melanoma. A total of 128 patients were labeled Class 1 by the GEP, and 112 patients were labeled Class 2. *PRAME* status was negative in 157 cases and positive in 83 cases. TNM was stage I in 26 cases, IIA in 67 cases, IIB in 50 cases, IIIA in 59 cases and IIIB in 38 cases. Metastatic disease was detected in 59 cases after median follow-up of 29 months. GEP class was found to be associated with metastasis (Cai et al., 2018).

Kucherlapati (2018) examined groups of genes to identify gene correlations in UM survival. Genes with significant alteration include *MCM2, MCM4, MCM5, CDC45, MCM10, CIZ1, PCNA, FEN1, LIG1, POLD1, POLE, HUS1, CHECK1, ATRIP, MLH3,* and

MSH6. Exon 4 skipping in *CIZ1* was previously identified as an early serum biomarker in lung cancer. *MLH3* was found to have splicing variations with deletions to both Exon 5 and Exon 7 (Kucherlapati, 2018).

Szalai et al. (2018) evaluated the deterministic properties of UM, including mutation rate and metastatic rate. The metastatic rate was based on patients with three mutations: *BAP1, SF3B1,* and *EIF1AX*. The authors found that tumors with smaller thicknesses had a higher mutation rate and that tumors with only an *EIF1AX* mutation did not metastasize. Further, the authors identified a small peak in metastatic rate at one year and a large peak at 3.5 years post-treatment for *BAP1* mutations, and peaks at two to three years and seven years post-treatment for *SF3B1* mutations (Szalai et al., 2018).

Decatur et al. (2016) evaluated the associations between GEP classification, driver mutations, and patient outcomes in UM. A total of 81 patients treated by enucleation were examined. The GEP classified 35 patients as class 1 and 42 as class 2 (four were unknown). The authors then performed a multiple regression analysis. *BAP1* mutations were associated with class 2 GEP and older patients, *EIF1AX* mutations were associated with class 1 GEP, and *GNA11* mutations were not associated with any analyzed features. Class 2 GEP was identified as the prognostic factor most related to metastasis and melanoma-specific mortality, with relative risks (RRs) of 9.4 and 15.7 respectively. *BAP1* mutations were also strongly related to metastasis, with RRs of 10.6 and 9.0 respectively (Decatur et al., 2016).

Schefler et al. (2019) examined the relationship between *PRAME* expression, GEP class, and clinical features in UM cases. This retrospective, multicenter chart review study included 148 patients with UM. All patients underwent GEP and *PRAME* mRNA expression testing. The Tumor, Node, Metastasis (TNM) staging system was used to separate patients; a total of 51 patients were stage I, 33 patients were stage IIA, 34 patients were stage IIB, 20 patients were stage IIIA, and 10 patients were stage IIIB. The authors note, "There was no association between higher TNM stage and positive *PRAME* status ($p = 0.129$). *PRAME* expression was found to be independent of gender, patient age, and tumor thickness. *PRAME* expression was statistically associated with LBD [largest basal diameter] and tumor volume. Higher GEP class was associated with higher TNM staging" (Schefler et al., 2019). Additional research is needed to clarify these results.

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN notes that gene expression profiling of a biopsy specimen may provide prognostic information that can assist with eligibility of clinical trials or affect management. Specifically, the guidelines state, "Biopsy of the primary tumor may provide prognostic information that can help inform frequency of follow-up and may be needed for eligibility for clinical trials. If biopsy is performed, molecular/chromosomal is preferred over cytology alone" (NCCN, 2023).

The NCCN divides the "risk of distant metastasis" into three risk groups, low, medium, and high.

- The following markers are considered **low risk**: Class 1A, disomy of chromosome 3, gain of chromosome 6p, *EIF1AX* mutations, tumor stage T1 (AJCC).
- The following markers are considered **medium risk**: Class 1B, *SF3B1* mutations, tumor stage T2 and tumor stage T3 (AJCC).
- The following markers are considered **high risk**: Class 2, monosomy of chromosome 3, gain of chromosome 8q, *BAP1* mutations, *PRAME* mutations, tumor stage T4 (AJCC)(NCCN, 2023).

Regarding extraocular recurrence or metastasis, the NCCN states that results "should be confirmed histologically whenever possible or if clinically indicated. Biopsy techniques may include FNA or core. Obtain tissue for genetic analysis (screening for mutations that may be potential targets for treatment or determine eligibility for a clinical trial from either biopsy of the metastasis (preferred) or archival material if the patient is being considered for targeted therapy. Consider broader genomic profiling if the test results might guide future decisions or eligibility for participation in a clinical trial" (NCCN, 2023).

American Joint Committee on Cancer (AJCC)

The 7th edition of the American Joint Committee on Cancer (AJCC) classification system recommends using tumor size to predict survival and has been validated internationally. The guidelines from the AJCC Ophthalmic Oncology Task Force (OOTF) note that "the OOTF recognizes that future modifications of the AJCC staging system are inevitable. Future modifications are likely to involve incorporation of a patient's genetic and molecular UM characteristics" (AJCC, 2015).

The AJCC 8th edition updates and corrections document notes that "only minor adjustments are introduced in the AJCC Cancer Staging Manual, 8th Edition" regarding UM (AJCC, 2018). The document also states, "Prognostic biopsies of conservatively treated uveal melanomas that allow analysis of their cytogenic, gene expression, and molecular genetic features are increasingly common. However, evidence for a long-term association between these characteristics and survival according to the anatomic extent of the tumor is still incomplete" (AJCC, 2018).

United Kingdom (Van Raamsdonk et al.) Uveal Melanoma Guideline Development Group

United Kingdom (Van Raamsdonk et al.) uveal melanoma guideline development group published guidelines which were accredited by the National Institute for Health and Care Excellence (NICE). These guidelines state that: "Prognostic factors of UM are multi-factorial and include clinical, morphological, immunohistochemical and genetic features. There are several different cytogenetic and molecular techniques for evaluating genetic changes in UM but there is insufficient comparative data. No evidence was found that demonstrated one technique was superior to another" (Nathan et al., 2015).

Consensus-Based Provincial Clinical Practice Guideline

In 2016, a consensus-based guideline on the management of UM was published by a group of content experts from medical, radiation, and surgical oncology fields. These guidelines state, "Two genetic tests more precisely identify patients with worse prognosis: testing for monosomy 3 and gene-expression profiling (GEP)" (Weis et al., 2016).

National Institute of Health - National Cancer Institute Guideline (NIH-NCI)

The 2023 guidelines from the NIH specifies molecular features as key prognostic indicators. These are in addition to staging algorithms from the AJCC, which they acknowledge as the current classification system to define melanoma of the uveal tract. Key prognostic indicators from the NIH guideline specifically include:

"Molecular Features

1. Chromosomal alterations
   a. Chromosome 3 status (loss or no loss; complete or partial).
   b. Chromosome 6p status (gain or no gain).
   c. Chromosome 8q status (gain or no gain).

   Indicate:
   - Technique used for assessing chromosome status may include the following:
     - Karyotyping.
     - Fluorescence in situ hybridization.
     - Comparative genomic hybridization.
     - Loss of heterozygosity using DNA polymorphism analysis (e.g. single nucleotide polymorphism, microsatellite).
     - Other.
   - How specimen was obtained may include the following:
     - Enucleation.

- Local resection.
- Biopsy.
- Fine-needle aspiration biopsy.

- For needle biopsies, whether cytopathologic evaluation was performed to confirm the presence of tumor cells.

2. Gene-expression profile: class 1 or class 2
   Indicate:
   - Technique used for gene-expression profiling (e.g., microarray, pathologic complete response).
   - How specimen was obtained (e.g., enucleation, local resection, biopsy, fine-needle aspiration biopsy).
   - For needle biopsies, whether cytopathologic evaluation was performed to confirm the presence of tumor cells" (NIH, 2023).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81347	SF3B1 (splicing factor [3b] subunit B1) (eg, myelodysplastic syndrome/acute myeloid leukemia) gene analysis, common variants (eg, A672T, E622D, L833F, R625C, R625L)

CPT	Code Description
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat) **Gene:** *PRAME (preferentially expressed antigen in melanoma) (eg, melanoma), expression analysis*
81479	Unlisted molecular pathology procedure
81552	Oncology (uveal melanoma), mRNA, gene expression profiling by real-time RT-PCR of 15 genes (12 content and 3 housekeeping), utilizing fine needle aspirate or formalin-fixed paraffin-embedded tissue, algorithm reported as risk of metastasis
81599	Unlisted multianalyte assay with algorithmic analysis

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Alpha- and Beta- Thalassemia

Policy Number: AHS – M2131 – Genetic Testing for Alpha- and Beta-Thalassemia	Prior Policy Name and Number, as applicable: • AHS-M2131 Genetic Testing for Alpha Thalassemia
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Alpha-thalassemia is characterized by an impaired production of the alpha globin chains of hemoglobin, leading to a relative excess of gamma globin chains (fetus and newborn), or excess beta globin chains (children and adults) mainly due to deletion or mutation of the alpha globin genes. There are four alpha thalassemia syndromes, reflecting the loss of function of one, two, three, or all four of these alpha chain genes varying in severity from non-symptomatic to incompatibility with extrauterine life (Benz Jr & Angelucci, 2024; Martin & Thompson, 2013).

Beta-thalassemia is similarly characterized by impaired production of hemoglobin components but affects the beta chains instead of the alpha chains. This creates excess alpha globin chains, leading to hemolytic anemia, impaired iron handling, and other clinical symptoms (Benz Jr, 2023).

When pursuing genetic testing for alpha- or beta-thalassemia, genetic counseling is strongly recommended.

For guidance on prenatal screening and preconception screening for alpha- or beta-thalassemia, please see AHS-M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title

AHS-M2170	Red Blood Cell Molecular Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic testing to confirm an alpha- or beta-thalassemia diagnosis **MEETS COVERAGE CRITERIA** in **any** of the following situations:
   a) For individuals for whom one parent is a known carrier of alpha- or beta-thalassemia.
   b) For individuals for whom other testing to diagnose the cause of microcytic anemia has been inconclusive.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For all other situations not described above, genetic testing for alpha- or beta-thalassemia **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics and Genomics
ACOG	American College of Obstetrics and Gynecology
APHL	The Association of Public Health Laboratories
BCL11A	*B-cell CLL/lymphoma 11a*
BSH	British Society for Haematology
CCMG	Canadian College of Medical Geneticists
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers for Medicare and Medicaid
CRISPR/Cas9	Clustered Regularly Interspaced Short Palindromic Repeated/CRISPR-associated protein 9
DNA	Deoxyribonucleic acid
FDA	Food And Drug Administration
Hb	Hemoglobin
HBA1	*Alpha Globin 1*
HBA2	*Alpha Globin 2*

HBB	Hemoglobin, subunit beta
HbF	Hemoglobin F
HE	Electrophoresis
HHPLC	Hb high performance liquid chromatography
HLA	Human leukocyte antigens
LDTs	Laboratory-developed tests
MCH	Mean cell hemoglobin
MCV	Mean corpuscular volume
MDA	Multiple displacement amplification
NGS	Next-generation sequencing
NHS	National Health Service
PCR	Polymerase chain reaction
PGT	Preimplantation genetic testing
PHE	Public Health England
SCT	Sickle cell and thalassemia
SNP	Single nucleotide polymorphism
SOGC	Society of Obstetricians and Gynaecologists of Canada
β+	Reduced expression
β0	Absent expression

V. Scientific Background

Thalassemias result from deficiencies in hemoglobin biosynthesis due to mutations in or near the two globin gene clusters which encode the globin polypeptide subunits of hemoglobin (Benz Jr & Angelucci, 2024). Normal hemoglobin is a heterotetramer of two alpha globin chains and two beta globin chains (hemoglobin A) or two gamma globin chains (hemoglobin F). Well over 100 mutations have been documented to affect the biosynthesis or post-translational stability of the globin subunits needed for successful production of the large amounts of Hb needed for normal red cell homeostasis. Globin chain synthesis is very tightly controlled, such that the ratio of production of alpha to non-alpha chains is almost exactly 1:1 (Benz Jr, 2024b).

Alpha thalassemia refers to thalassemias that result from impaired or absent production of alpha globin, leading to a relative excess of gamma globin (fetus and newborn), or excess beta globin (children and adults). Excess beta globin chains can form soluble homotetramers, but they are nonfunctional and unstable. This may lead to increased hemolysis and a variety of clinical manifestations, such as anemia, thrombosis, and skeletal changes. A diagnosis of alpha thalassemia is often confirmed by genetic testing, as assessment of the hemoglobin gene is inexpensive and convenient (Benz Jr, 2024b).

The clinical severity is directly attributable to the net deficit of alpha globin synthesis but is complicated by the number of alpha globin genes affected, which of the two alpha globin loci is affected, and the degree to which the mutation blocks gene expression. In addition, combinations of defects in both alpha and beta globulins can balance each other out. Thus, understanding the broad spectrum of clinical severity in alpha thalassemia requires a detailed knowledge of the underlying genetic defect and the impact of these defects on the overall levels and balance of globin chain synthesis (Benz Jr, 2023).

The majority of cases of alpha thalassemia are attributable to deletion of alpha globin alleles, especially in Asia and Africa (Steinberg, 1999). However, more detailed analysis of globin gene sequences suggests that some fairly common forms of alpha thalassemia that appear to arise from a deletion of one copy of an alpha globin gene are actually due to unequal crossover and recombination events that fuse the two alpha globin genes together into one (Benz Jr, 2024b). Additionally, non-deletion alleles are also common, especially in the Mediterranean area, which contain mutations producing highly unstable alpha globin variants unable to produce intact hemoglobin (Benz Jr & Angelucci, 2024). Current research continues to identify novel mutations and improve thalassemia screening (He et al., 2018).

Beta-thalassemia is similar to alpha-thalassemia, with the beta chains of hemoglobin affected instead of the alpha chains. However, excess alpha globin chains do not form soluble homotetramers, causing them to aggregate when they accumulate in erythroid precursors. This causes clinical symptoms to be more severe, although the symptoms themselves are similar to alpha-thalassemia (anemia, iron overload, and so on) (Benz Jr, 2023; Benz Jr & Angelucci, 2024). There are two beta globin genes compared to four for the alpha chain. As with alpha-thalassemia, the severity of clinical presentation depends on the genotype of the beta globin genes (i.e. the ratio of beta to alpha globin chains). Mutations may result in a reduced expression (β^{+}) or absent expression (β^{0}). β^{0} phenotypes are generally transfusion-dependent as they produce very little (if any) adult hemoglobin (Benz Jr, 2023).

Due to the frequency of thalassemias worldwide, carrier screening may be useful, particularly in areas such as Southeast Asia, Africa, and the Indian subcontinent. Both primary thalassemias are autosomal recessive genetic disorders so parents who are heterozygous carriers would have a 25% chance to have an affected child despite being asymptomatic themselves. Identification of an affected fetus could alter decisions during the pregnancy (Yates, 2023).

Below is a table summarizing the clinical genotypes and phenotypes of both thalassemia syndromes (Benz Jr, 2024a; Benz Jr & Angelucci, 2024; Steinberg, 2024) (figure from Benz Jr).

Severity	Genotype	Anemia	Hemoglobin Analysis
Alpha Thalassemias			
Silent carrier	α α / α -	None	Normal, <3% Hb Barts (gamma globin tetramer) at birth
Minor	α α / - - or α - / α -	Mild Microcytic	Normal, 3 to 8% Hb Barts at birth
Hb H disease	α - / - -	Moderate Microcytic	up to 30% HbH (beta globin tetramer), present in adults, up to 4% HbA_2 (alpha and delta globin)
Major (fetal hydrops)	- - / - -	Severe Microcytic, usually fatal	Hb Barts, Hb Portland (zeta and gamma globin), and HbH present, HbA, HbF, and HbA_2 absent
Beta Thalassemias			
Minor (trait or carrier)	β / $β^0$ or β / β+	Mild Microcytic	HbA_2 (4% or more); HbF (up to 5%)
Intermedia (non-transfusion-dependent)	β+ / β+	Moderate Microcytic	HbA_2 (4% or more); HbF (up to 50%)
Major (transfusion-dependent)	$β^0$ / $β^0$ or $β^0$ / β+	Severe microcytic with target cells (typical Hb 3 to 4 g/dL)	HbA_2 (5% or more); HbF (up to 95%); no HbA

Analytical Validity

He et al. (2017) examined a next-generation sequencing (NGS) panel's utility for thalassemia screening in Southwestern China. A total of 951 individuals were tested, and the NGS screen found 471 carriers (49.5%) of thalassemia. In comparison, traditional methods (defined as "red cell indexes and hemoglobin electrophoresis, then

DNA sequencing") identified only 209 carriers (22%) of thalassemia, missing 217 alpha-thalassemia carriers and 47 beta-thalassemia carriers (He et al., 2017). In a separate study by Zhang et al. (2019), because of studying 3,973 subjects that underwent hematological examinations and additional NGS and Gap-PCR due to being suspected thalassemia carriers, the researchers found that "approximately 2.88% thalassemia carriers would be missed by traditional genetic analysis. In addition, four novel thalassemia mutations and one novel abnormal hemoglobin mutation were identified." This research further corroborated the increased effectiveness of using NGS in screening thalassemia in an area of high disease prevalence (Zhang et al., 2019).

Shook et al. (2020) evaluated the accuracy of a specific pattern in hemoglobin separation tests. The authors desired to find if an "FSA" pattern corresponded to a final diagnosis of the sickle cell trait (HbAS), or a final diagnosis of sickle beta-thalassemia ($HbS\beta^+$). Traditionally, the FSA pattern has indicated a diagnosis of $HbS\beta^+$; however, the authors hypothesized that the FSA pattern truly indicates a diagnosis of HbAS instead. 31 newborns with an initial screening result of the FSA pattern (a suspected diagnosis of $HbS\beta^+$) were included. 30 of these newborns underwent protein-base confirmatory testing and 17 underwent confirmatory genetic testing. Of the newborns undergoing protein confirmatory testing, 23 had an "FSA" pattern, establishing a diagnosis of HbAS. Of the 8 remaining newborns with an FSA pattern, 7 underwent genetic testing which identified HbAS as well. Genetic testing also confirmed positive HbAS results in 10 newborns that tested initially positive by protein testing. The authors concluded that genetic testing had utility in newborn screening for hemoglobinopathies (Shook et al., 2020).

Chen et al. (2021) established an effective NGS protocol for four-factor preimplantation genetic testing (PGT) to diagnose α- and β-thalassemia. Three couples, in whom both partners were α- and β-double thalassemia carriers, underwent PGT and a total of 35 biopsied trophectoderm samples underwent multiple displacement amplification (MDA). Using NGS-based single-nucleotide polymorphism (SNP) haplotyping, these samples were analyzed. "51.5% (17/33) of the embryos were diagnosed as unaffected non-carriers or carriers. Of the 17 unaffected embryos, nine (52.9%) were tested further and identified as euploid via NGS-based aneuploid screening, in which five had HLA types matching affected children." The authors conclude that NGS-SNP was effective in performing PGT for multipurpose detection (Chen et al., 2021).

Clinical Utility and Validity

Nosheen et al. (2015) evaluated a preliminary screening program for beta-thalassemia. The screening program focused on families of beta-thalassemia major children. 98

samples were taken, and 57 were found to have a beta-thalassemia trait with elevated hemoglobin alpha 2. The mean hemoglobin alpha 2 level of the carriers was 5.2±0.56% compared to 2.34±0.57% in normal subjects. The authors suggested that screening programs and counseling for carriers could decrease incidence of beta-thalassemia major (Nosheen et al., 2015).

Satirapod et al. (2019) evaluated the clinical outcomes of using preimplantation genetic testing (PGT) in couples at risk of passing on beta thalassemia. Two components of PGT were used, PGT for monogenic disease (used for diagnosis) and PGT for aneuploidy (intended to identify chromosomal aberrations) A total of 15 couples were included and a total of 106 embryos were tested. After preimplantation testing, 12 of 15 individuals were able to obtain satisfactory genetic testing results (defined as non-disease affected embryos without chromosomal aberration and transfer within first two cycles). Of these, nine individuals had successful implantations and eight individuals had successful pregnancies with live births (deemed a 53.33% success rate). PGT assessment of genetic status was confirmed by pre- and post-natal genetic testing. Overall, the authors concluded that combined PGT-A and PGT-M was a useful technology to prevent beta-thalassemia in the offspring of recessive carriers. To increase the diagnostic efficiency of PGT-M, multiple displacement amplification (MDA) may be utilized as the first step. This conclusion was drawn by Fu et al. (2019), who found in a retrospective cohort study, that from 2,315 embryos tested, MDA yielded a 96.99% diagnostic efficiency, versus a PCR group, which only yielded 88.15%. MDA also enabled statistically significantly more embryos to be available for transfer as well when compared to the PCR group (74.28% vs 64.28%, respectively, $P < 0.001$) (Fu et al., 2019).

Chen et al. (2020) also conducted a similar study that evaluated "the efficacy of preimplantation genetic testing (PGT) for α- and β-double thalassemia combined with aneuploidy screening using next-generation sequencing (NGS)." From 12 couples that each carried both α- and β- thalassemia mutations, the researchers were able to facilitate 11 healthy live births from examining 112 embryos. This NGS-based SNP (single nucleotide polymorphism) haplotyping was demonstrated to "reduce misdiagnosis by linkage analyses with multiple SNP loci" and increase the number of diagnosis results, including those from detecting aneuploidy and identified mutation sites, in a single PGT cycle. It was also found that NGS-based SNP haplotyping could be performed "through directly detecting mutation sites with NGS and using affected embryos or gametes as probands." This procedure benefits in eliminating multiple biopsies as well (Chen et al., 2020).

Dan et al. (2023) conducted a literature mini-review of the current state of beta-thalessemia management. Currently, beta-thalessemia requires lifelong management

strategies that include regular blood transfusions and iron chelation therapy for severe cases. The review discussed the limitations of current therapies and advocates for continued research into hematopoietic stem cell transplantation and gene therapy as new treatment approaches. Several novel therapeutic methods are being explored for clinical utility. For example, Luspatercept is a recently FDA-approved therapy that works by inhibiting the Smad2/3 signaling pathway, which is involved in erythropoiesis (the process of producing red blood cells). By modifying this pathway, Luspatercept helps to reduce the ineffective erythropoiesis that is a hallmark of beta-thalessemia. It is particularly useful for patients who are transfusion-dependent and has purported promise in improving iron balance and reducing the frequency of blood transfusions; however, the cost of Luspatercept is $170,000 annually per patient. Hydroxyurea is a drug that is well-known in the treatment of blood disorders, such as sickle cell disease, but could also have potential benefits in treating beta-thalessemia. Gene therapy focuses on strategies to increase the production of gamma globin chains, thereby increasing HbF levels. This approach could potentially correct the underlying genetic defects causing thalassemia. Gene therapy techniques include: (1) CRISPR/Cas9 gene editing (involves editing the BCL11A gene, a key regulator of hemoglobin production, to enhance HbF synthesis) and (2) Lentiviral Gene Transfer (therapies that involve a lentiviral vector to insert a functional copy of the beta-globin gene into the patients' hematopoietic stem cells). One example of lentiviral gene transfer is Zynteglo gene therapy, the first FDA-approved genetic treatment for beta-thalessemia (Dan et al., 2023).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG)

In 2021, ACMG released an updated guideline for screening for autosomal recessive and X-linked conditions during pregnancy and preconception. Their practice resource aims to recommend "a consistent and equitable approach for offering carrier screening to all individuals during pregnancy and preconception" and replaces any earlier ACMG position statements on prenatal/preconception expanded carrier screening.

The ACMG provides carrier screening recommendations during pregnancy that are split into three tiers. Tier 1 includes recommended screenings for all couples considering pregnancy or pregnant women. The tier 1 recommendations include disorders that have significant health impacts, for which prenatal diagnosis and potential interventions might be available; this tier includes screenings relevant to this policy, such as sickle cell disease, alpha-thalassemia, and beta-thalassemia. Tier 2 includes additional screenings that may be offered based on the family history or ancestry that suggest higher risk of specific genetic conditions. In some cases,

expanded carrier screening can be considered, which may test for less common hemoglobinopathies. Tier 3 screenings are "optional" and can be considered based on individual or family history factors. These screenings may include rare genetic disorders or less common variants of hemoglobinopathies. The ACMG provides the following specific recommendations:

- "Carrier screening enables those screened to consider their reproductive risks, reproductive options, and to make informed decisions."
- "The phrase "expanded carrier screening" be replaced by "carrier screening."
- "Adopting a more precise tiered system based on carrier frequency:
    - Tier 4: <1/200 carrier frequency (includes Tier 3) genes/condition will vary by lab
    - Tier 3: ≥ 1/200 carrier frequency (includes Tier 2) includes X-linked conditions
    - Tier 2: ≥1/100 carrier frequency (includes Tier 1)
    - Tier 1: *CF* [Cystic Fibrosis] + *SMA* [spinal muscular atrophy] + Risk Based Screening
        - "Tier 1 screening conveys the recommendations previously adopted by ACMG and ACOG" and "adopts an ethnic and population neutral approach when screening for cystic fibrosis and spinal muscular atrophy. Beyond these two conditions, additional carrier screening is determined after risk assessment, which incorporates personal medical and family history as well as laboratory and imaging information where appropriate"
        - "Tier 2 carrier screening stems from an ACOG recommendation for conditions that have a severe or moderate phenotype and a carrier frequency of at least 1/100." However, "data demonstrate that carrier screening for two common conditions using a carrier frequency threshold of 1/100 may not be equitable across diverse populations. Others have shown that limiting the carrier frequency to ≥1/100 creates missed opportunities to identify couples at risk for serious conditions."
        - "We define Tier 3 screening as carrier screening for conditions with a carrier frequency ≥1/200 . . . Tier 2 and Tier 3 screening prioritize carrier frequency as a way to think about conditions most appropriate for screening in the general population. However, when ACOG proposed this level, they did not specify whether it was thinking about carrier frequency in terms of the global population or subpopulations. We use "carrier frequency" to mean in any ethnic group with reasonable representation in the United States."
        - "Tier 4 includes genes less common than those in Tier 3 and can identify additional at-risk couples. Tier 4 has no lower limit carrier screening frequency and can greatly extend the number of conditions screened . . .

the clinical validity at this level of carrier screening may be less compelling, therefore we suggest reserving this level of screening for consanguineous pregnancies (second cousins or closer) and in couples where family or medical history suggests Tier 4 screening might be beneficial . . . Importantly, patients should understand that their chance of being a carrier for one or more conditions increases as the number of conditions screened is increased."

- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening.
- Tier 4 screening should be considered:
  - When a pregnancy stems from a known or possible consanguineous relationship (second cousins or closer);
  - When a family or personal medical history warrants.
- ACMG does NOT recommend:
  - Offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups.
  - Routine offering of Tier 4 panels.
- "Carrier screening paradigms should be ethnic and population neutral and more inclusive of diverse populations to promote equity and inclusion."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening for autosomal recessive [Table 1 & 5] . . . conditions."
- "Reproductive partners of pregnant patients and those planning a pregnancy may be offered Tier 3 carrier screening for autosomal recessive conditions [Table 1 & 5] when carrier screening is performed simultaneously with their partner."
- "When Tier 1 or Tier 2 carrier screening was performed in a prior pregnancy, Tier 3 screening should be offered" (Gregg et al., 2021).

ACMG American College of Medical Genetics and Genomics, *ACOG* American College of Obstetricians and Gynecologists, *AJ* Ashkenazi Jewish (≥2% of the US population), *OMIM* Online Mendelian Inheritance in Man,[55] *PR* Puerto Rican, *SEA* South East Asian.
[a]Carrier frequency of a sequence variant is <1/200, if reported in gnomAD.[50]
[b]Diagnostic laboratory data was not used for carrier frequency data.
[c]Specific data for general US population not available; however, recognized as common among many US immigrant populations.[62]
[d]This term is no longer used by the journal but is used in the original article to which these studies refer. We have therefore not changed the term but recognize it does not accurately describe the ancestry of the populations originally studied.[46]

(Gregg et al., 2021)

Canadian College of Medical Geneticists (CCMG) and Society of Obstetricians and Gynaecologists of Canada (SOGC)

The CCMG and SOGC published a joint guideline titled "Carrier Screening for Thalassemia and Hemoglobinopathies in Canada" in 2008. Their recommendations addressing thalassemia's/hemoglobinopathies are listed below:

1. "Carrier screening for thalassemia and hemoglobinopathies should be offered to a woman if she and/or her partner are identified as belonging to an ethnic population whose members are at higher risk of being carriers. Ideally, this screening should be done pre-conceptionally or as early as possible in the pregnancy. (II-2A)
2. Screening should consist of a complete blood count, as well as hemoglobin electrophoresis or hemoglobin high performance liquid chromatography. This investigation should include quantitation of HbA2 and HbF. In addition, if there is microcytosis (mean cellular volume < 80 fL) and/or hypochromia (mean cellular hemoglobin < 27 pg) in the presence of a normal hemoglobin electrophoresis or high-performance liquid chromatography the patient should be investigated with a brilliant cresyl blue stained blood smear to identify H bodies. A serum ferritin (to exclude iron deficiency anemia) should be performed simultaneously. (III-A)
3. If a woman's initial screening is abnormal (e.g., showing microcytosis or hypochromia with or without an elevated HbA2, or a variant Hb on electrophoresis or high-performance liquid chromatography) then screening of the partner should be performed. This would include a complete blood count as well as hemoglobin electrophoresis or HPLC, HbA2 and HbF quantitation, and H body staining. (III-A)
4. If both partners are found to be carriers of thalassemia or an Hb variant, or of a combination of thalassemia and a hemoglobin variant, they should be referred for genetic counselling. Ideally, this should be prior to conception, or as early as possible in the pregnancy. Additional molecular studies may be required to clarify the carrier status of the parents and thus the risk to the fetus. (II-3A)
5. Prenatal diagnosis should be offered to the pregnant woman/couple at risk for having a fetus affected with a clinically significant thalassemia or hemoglobinopathy. Prenatal diagnosis should be performed with the patient's informed consent. If prenatal diagnosis is declined, testing of the child should be done to allow early diagnosis and referral to a pediatric hematology centre, if indicated. (II-3A)
6. Prenatal diagnosis by DNA analysis can be performed using cells obtained by chorionic villus sampling or amniocentesis. Alternatively, for those who decline

invasive testing and are at risk of hemoglobin Bart's hydrops fetalis (four-gene deletion α-thalassemia), serial detailed fetal ultrasound for assessment of the fetal cardiothoracic ratio (normal < 0.5) should be done in a centre that has experience conducting these assessments for early identification of an affected fetus. If an abnormality is detected, a referral to a tertiary care centre is recommended for further assessment and counselling. Confirmatory studies by DNA analysis of amniocytes should be done if a termination of pregnancy is being considered. (II-3A)

7. The finding of hydrops fetalis on ultrasound in the second or third trimester in [individuals] with an ethnic background that has an increased risk of α-thalassemia should prompt immediate investigation of the pregnant patient and her partner to determine their carrier status for α-thalassemia. (III-A)" (Langlois et al., 2008).

The Thalassemia Longitudinal Cohort

The report on the Thalassemia Longitudinal Cohort recommends: "Obtaining genotyping to confirm the diagnosis and HLA typing for transplant evaluation for all patients who require chronic transfusion is strongly recommended. For pediatric patients, annual comprehensive follow up should include assessment of the availability of a related donor as well as a recommendation to bank cord blood and obtain HLA typing on all subsequently born full siblings" (Tubman et al., 2015).

American College of Obstetrics and Gynecology (ACOG)

The ACOG Committee Opinion #691 ("Carrier Screening for Genetic Conditions") states that: "Couples at risk of having a child with a hemoglobinopathy may benefit from genetic counseling to review their risk, the natural history of these disorders, prospects for treatment and cure, availability of prenatal genetic testing, and reproductive options. Prenatal diagnostic testing for the mutation responsible for sickle cell disease is widely available. Testing for α-thalassemia and β-thalassemia is possible if the mutations and deletions have been previously identified in both parents. These DNA-based tests can be performed using chorionic villi obtained by chorionic villus sampling or using cultured amniotic fluid cells obtained by amniocentesis. For some couples, preimplantation genetic diagnosis in combination with in vitro fertilization may be a desirable alternative to avoid termination of an affected pregnancy. Preimplantation genetic diagnosis has been successfully performed for sickle cell disease and most types of β-thalassemia" (ACOG, 2017). This was reaffirmed in 2020.

In 2022, ACOG put out a new practice bulletin regarding hemoglobinopathies in pregnancy (originally published in 2007) and reaffirmed this in 2023 with a few additions (ACOG, 2022).

- ACOG "recommends offering universal hemoglobinopathy testing to persons planning pregnancy or at the initial prenatal visit if no prior testing results are available for interpretation."
- "Hemoglobinopathy testing may be performed using hemoglobin electrophoresis or molecular genetic testing (eg, expanded carrier screening that includes sickle cell disease [SCD] and other hemoglobinopathies)."
- "The use of noninvasive prenatal diagnosis for SCD with cell-free fetal DNA is still experimental and currently not recommended" (ACOG, 2022).
-

National Health Service (NHS)

The NHS released standards for antenatal laboratories working with the NHS sickle cell and thalassaemia (SCT) screening program (NHS, 2021). The referral guidelines for antenatal screening specimens are as follows:

Biological mother carrier state	Biological father carrier state	Further studies by DNA analysis
No abnormalities detected	Testing of baby's biological father not required	None required
Any abnormal Hb or thalassaemia	No abnormality detected	None required
HbS	HbS or HbC	None required until PND
HbS	HbO^{Arab}, D^{Punjab}, E, Lepore, β thalassaemia or δβ thalassaemia	If PND is being considered send bloods for mutation confirmation, provided it does not limit options available
HbS	HPFH	Send bloods for mutation confirmation. PND is not usually indicated when HPFH has been confirmed
HbS + α thalassaemia	Assess risk as per HbS alone, unless family origins indicate a high risk of α^0 thalassaemia	Assess risk as per HbS alone, unless family origins indicate a high risk of a^0 thalassaemia
HbC	HbS	None required until PND
HbD	HbS	If PND is being considered send bloods for mutation confirmation, provided it does not limit options available
HbO^{Arab}	HbS, β thalassaemia or δβ thalassaemia	If PND is being considered send bloods for mutation confirmation, provided it does not limit options available
Hb Lepore	HbS, E, O^{Arab}, Lepore, β thalassaemia or δβ thalassaemia	If PND is being considered send bloods for mutation confirmation, provided it does not limit options available.
HbE	β thalassaemia, Hb Lepore, δβ thalassaemia, HbS	If PND is being considered send bloods for mutation confirmation, provided it does not limit options available
HbE	α thalassaemia (MCH < 25pg)	Send bloods for mutation confirmation if high risk family origins for α^0 thalassaemia, consider impact on options available
β or δβ thalassaemia	HbS, E, O^{Arab}, Lepore, β thalassaemia or δβ thalassaemia	If PND is being considered send bloods for mutation confirmation, provided it does not limit options available
β or δβ thalassaemia	α thalassaemia (high risk family origins)	Send bloods for mutation confirmation if high risk family origins for α^0 thalassaemia, consider impact on options available
HPFH	HbS, E, O^{Arab}, Lepore, β or δβ thalassaemia	Send bloods for mutation confirmation. PND is not usually indicated when HPFH has been confirmed
α thalassaemia (MCH < 27pg but ≥ 25pg)	Testing of baby's biological father not required	None required
α thalassaemia (MCH < 25pg)		
1. Low risk α^0 thal family origins in either biological parent	Testing of baby's biological father not required	None required
2. High risk α^0 thal family origins in both biological parents or unknown	Test baby's biological father and if MCH < 25pg irrespective of any other phenotype detected	Send maternal and paternal bloods for mutation confirmation, consider impact on options available.

The Association of Public Health Laboratories (APHL)

The Association of Public Health Laboratories (APHL) states that "Molecular testing can be added to resolve cases when the newborn has been transfused with packed red blood cells. Since the newborn's phenotype is masked by the donor, DNA testing can be used to identify any abnormal hemoglobins" (APHL, 2015).

Public Health England (PHE)

The PHE highlights the importance of antenatal screening. If the baby's mother is identified as a carrier, the biological father should also be tested. Both prenatal diagnosis and genetic counselling are recommended by the PHE (PHE, 2022).

British Society for Haematology (BSH)

The BSH provides the following recommendations:

- "Antenatal screening/testing of pregnant [individuals] should be carried out according to the guidelines of the NHS Sickle Cell and Thalassaemia Screening programme.
- Laboratories performing antenatal screening should utilize methods capable of detecting significant variants and be capable of quantitating haemoglobins A_2 and F at the cut-off points required by the national antenatal screening program" (Ryan et al., 2010).

Genetic counseling is also permitted for prospective parents.

The Thalassemia International Foundation (TIF)

The TIF provided recommendations for the management of transfusion dependent Thalassemia. The following recommendations were made (TIF, 2021):

- "Molecular genetic testing is available in clinical laboratories and may be useful for predicting the clinical phenotype in some cases as well as enabling presymptomatic diagnosis of at-risk family members and prenatal diagnosis.
- Molecular analysis is not required to confirm the diagnosis of a β carrier, but it is necessary to confirm the α thalassemia carrier status (grade A)
- Since the prevalent pathogenic variants of the β globin gene are limited in each at-risk population, a PCR method designed to detect the common specific mutation simultaneously should be used initially (grade B)

- β globin gene sequence analysis may be considered first if the affected individual is not of an ancestry at high risk or if targeted analysis reveals only one or no pathogenic variant (grade B)
- α thalassemias are mainly due to deletions of different length and they can be detected preferentially by reverse dot blot and Gap-PCR (grade B)
- Methods that may be used to detect rare or unknown deletions include: Southern blotting (now fallen into abeyance), quantitative PCR, long-range PCR and, above all, MLPA (grade B)" (TIF, 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81257	HBA1/HBA2 (alpha globin 1 and alpha globin 2) (eg, alpha thalassemia, Hb Bart hydrops fetalis syndrome, HbH disease), gene analysis; common deletions or variant (eg, Southeast Asian, Thai, Filipino, Mediterranean, alpha3.7, alpha4.2, alpha20.5, Constant Spring)
81258	HBA1/HBA2 (alpha globin 1 and alpha globin 2) (eg, alpha thalassemia, Hb Bart hydrops fetalis syndrome, HbH disease), gene analysis; known familial variant

CPT	Code Description
81259	HBA1/HBA2 (alpha globin 1 and alpha globin 2) (eg, alpha thalassemia, Hb Bart hydrops fetalis syndrome, HbH disease), gene analysis; full gene sequence
81269	HBA1/HBA2 (alpha globin 1 and alpha globin 2) (eg, alpha thalassemia, Hb Bart hydrops fetalis syndrome, HbH disease), gene analysis; duplication/deletion variants
81361	HBB (hemoglobin, subunit beta) (eg, sickle cell anemia, beta thalassemia, hemoglobinopathy); common variant(s) (eg, HbS, HbC, HbE)
81362	HBB (hemoglobin, subunit beta) (eg, sickle cell anemia, beta thalassemia, hemoglobinopathy); known familial variant(s)
81363	HBB (hemoglobin, subunit beta) (eg, sickle cell anemia, beta thalassemia, hemoglobinopathy); duplication/deletion variant(s)
81364	HBB (hemoglobin, subunit beta) (eg, sickle cell anemia, beta thalassemia, hemoglobinopathy); full gene sequence
S3845	Genetic testing for alpha-thalassemia
S3846	Genetic testing for hemoglobin E beta-thalassemia
96040	Medical genetics and genetic counseling services, each 30 minutes face-to-face with patient/family
S0265	Genetic counseling, under physician supervision, each 15 minutes

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate Cancers

Policy Number: AHS – M2003 – Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate Cancers	Prior Policy Name and Number, as applicable: AHS – M2003 – *BRCA*
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

BRCA1 and *BRCA2* are two distinct tumor suppressor genes involved in a common DNA repair process (Roy et al., 2012). Germline mutations of *BRCA* genes are associated with an increased risk of breast and ovarian cancer, as well as other cancer types, including pancreatic and prostate cancer to a lesser extent (Paul & Paul, 2014).

"Prior to 2020, the NCCN Guidelines for Genetic/Familial High-Risk Assessment: Breast and Ovarian (Breast, Ovarian, and Pancreatic as of 2020) focused largely on testing criteria for BRCA1/2 and appropriate risk management for carriers of a BRCA1 or BRCA2 P/LP variant. Sections on LFS and Cowden syndrome/PTEN hamartoma tumor syndrome (PHTS) were also included. Based on strong evidence that genes beyond *BRCA1/2*, *TP53*, and *PTEN* confer markedly increased risk of breast and/or ovarian cancers, these Guidelines have been expanded" (NCCN, 2024b) to include *BRCA1, BRCA2, CDH1, PALB2, PTEN*, and *TP53* as high-penetrance breast cancer susceptibility genes, as well as some moderate-penetrance susceptibility genes. These susceptibility genes are often found on multi-gene panels, in addition to *BRCA1/2*.

AHS-M2020	Molecular Diagnostics for Breast Cancer Prognosis
AHS-M2081	Genetic Testing for Li-Fraumeni Syndrome
AHS-M2087	Genetic Testing for PTEN Hamartoma Tumor Syndrome

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following coverage criteria are designed from National Comprehensive Cancer Network (NCCN) guidelines. "NCCN recommendations have been developed to be inclusive of individuals of all sexual and gender identities to the greatest extent possible. In this [policy], the terms males and females refer to sex assigned at birth."

Consideration of both maternal and paternal family histories is necessary in the evaluation of an individual's for risk of carrying a mutation in the BRCA1 or BRCA2 gene; each lineage must be considered separately.

1) For individuals without a diagnosis of a *BRCA*-related cancer who are at least 18 years of age, who have received genetic counseling, and who are in a family with a pathogenic familial gene mutation associated with breast cancer, the following testing **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial mutation.
   b) Comprehensive genetic testing, including muti-gene panel testing, when the specific familial mutation is unknown.

2) For individuals who have received genetic counseling, multi-gene panel testing (see Note 1, Note 2) for gene mutations associated with breast, ovarian, pancreatic, or prostate cancer **MEETS COVERAGE CRITERIA** when **one** of the following conditions are met:
   a) The individual has been diagnosed with breast cancer **and** meets at least one of the following conditions:
      i) Was diagnosed before 51 years of age.
      ii) Was diagnosed at any age with at least one of the following conditions:
         (a) High-risk (see Note 3), HER2-negative breast cancer.
         (b) Lobular breast cancer with a personal or family history of diffuse gastric cancer.
         (c) Metastatic breast cancer.
         (d) Triple negative breast cancer.
         (e) Two or more primary breast cancer diagnoses.
         (f) Male breast cancer.

(g) Has at least one close blood relative (see Note 4) with **any** of the following:

(i) Breast cancer before 51 years of age.

(ii) Breast cancer at any age in a male.

(iii) Ovarian cancer at any age.

(iv) Pancreatic cancer at any age.

(v) Prostate cancer that is metastatic or a high- or very-high risk group prostate cancer (see Note 5) at any age.

(h) Has a combined total of at least three diagnosed cancers (breast or prostate) in a single lineage of close blood relatives (see Note 4) (including the individual).

iii) Is of Ashkenazi Jewish ancestry

b) The individual has been diagnosed at any age with ovarian cancer (including fallopian tube cancer or peritoneal cancer).

c) The individual has been diagnosed at any age with pancreatic cancer.

d) The individual has been diagnosed at any age with prostate cancer with at least **one** of the following conditions:

i) Has metastatic cancer, the tumor has intraductal/cribriform histology, or a high- or very-high risk group (see Note 5).

ii) Has **any** of the following family history:

(a) Ashkenazi Jewish ancestry.

(b) At least one close blood relative (See Note 4) with **any** of the following:

(i) Breast cancer before 51 years of age.

(ii) Ovarian cancer at any age.

(iii) Pancreatic cancer at any age.

(iv) Prostate cancer that is metastatic, tumor with intraductal/cribriform histology, or a high- or very-high risk group (see Note 5) at any age.

(c) Two or more close blood relatives (See Note 4) with either breast or prostate cancer (any grade) at any age.

e) The individual has a gene mutation associated with breast, ovarian, pancreatic, or prostate cancer that was detected by tumor genomic profiling in the absence of germline mutation testing.

f) The individual meets testing criteria for Li-Fraumeni syndrome (LFS), Lynch syndrome, or Cowden syndrome/PTEN hamartoma tumor syndrome.

3) For individuals with a known family history of *BRCA*-related cancer who have received genetic counseling and are at least 18 years of age, multi-gene panel testing (see Note 1, Note 2) for gene mutations associated with breast, ovarian, pancreatic, or prostate cancer **MEETS COVERAGE CRITERIA** only if the family mutation is unknown (i.e., family member is unavailable for testing or testing results are unavailable) **and** at least one of the following conditions are met:

   a) The individual has at least one first- or second-degree blood relative (see Note 4) meeting any of the above criteria for an individual with cancer, **except as noted below**:

      i) Only first-degree relatives of an individual affected with pancreatic cancer should be offered testing.

   b) The individual has a family member with breast, ovarian, tubal, or peritoneal cancer with positive screening results (5-year probability of 5% or greater) from a tool (see Note 6) designed to identify a family history that may be associated with an increased risk for potentially harmful mutations in breast cancer susceptibility genes (*BRCA1* or *BRCA2*).

4) For individuals 18 years of age or older who are of Ashkenazi Jewish ancestry and who do not meet any of the above criteria, testing for the three known founder mutations (185delAG and 5385insC in *BRCA1*; 6174delT in *BRCA2*) **MEETS COVERAGE CRITERIA.**

5) Testing for gene mutations associated with breast, ovarian, pancreatic, or prostate cancer **DOES NOT MEET COVERAGE CRITERIA** for **any** of the following:

   a) General population screening.

   b) Women diagnosed with breast cancer who are over 65 years of age and who have no close blood relative (see Note 4) with breast, ovarian, pancreatic, or prostate cancer, as there is a low probability that testing will have findings of documented clinical utility.

   c) Individuals diagnosed with localized prostate cancer with Gleason Score <7 and who have no close blood relative (see Note 4) with breast, ovarian, pancreatic, or prostate cancer, as there is a low probability that testing will have findings of documented clinical utility.

   d) In all other situations not specified above.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

6) Testing family members for a variant of uncertain significance **DOES NOT MEET COVERAGE CRITERIA**.

7) For all other purposes, including, but not limited to, testing of the general population, genetic testing for susceptibility to breast, ovarian, pancreatic, or prostate cancer **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

Note 2: When germline multigene panel testing is performed in individuals with breast, ovarian, pancreatic, or prostate cancer, the panel should at minimum include the following high-penetrance breast, ovarian, pancreatic, and prostate cancer susceptibility genes: *ATM, BRCA1, BRCA2, BRIP1, CDH1, CDKN2A, CHEK2, EPCAM, HOXB13, MLH1, MSH2, MSH6, PALB2, PTEN, RAD51C, RAD51D, STK11,* and *TP53*.

Note 3: High-risk disease includes the following:

- The individual has four or more positive lymph nodes.
- The individual has triple negative receptor status cancer.
- The individual has cancer that had an incomplete pathologic response to chemotherapy.

Note 4: Close blood relatives include 1st-degree relatives (e.g., parents, siblings, and children), 2nd-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings), and 3rd-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins), all of whom are on the same side of the family.

Note 5: Risk groups are defined in NCCN Guidelines for Prostate Cancer https://www.nccn.org/professionals/physician_gls/pdf/prostate.pdf

Note 6: According to the USPSTF recommendation in 2019, the risk tools evaluated by the USPSTF include the Ontario Family History Assessment Tool, Manchester Scoring System, Referral Screening Tool, Pedigree Assessment Tool, 7-Question Family History Screening Tool, International Breast Cancer Intervention Study instrument (Tyrer-Cuzick),

and brief versions of BRCAPRO. They do not specifically state the preference of one tool over any of the others listed. According to the USPSTF, "these tools should be used to guide referrals to genetic counseling" (USPSTF, 2019).

IV. Table of Terminology

Term	Definition
AA	African American
ACOG	The American College of Obstetricians and Gynecologists
AJ	Ashkenazi Jewish
ASBS	The American Society of Breast Surgeons
ASCO	American Society of Clinical Oncology
ATM	Ataxia telangiectasia mutated
BRCA	*Breast cancer gene*
BRCA1	*Breast cancer gene 1*
BRCA2	*Breast cancer gene 2*
CDH1	*cadherin 1*
CDRH	Center for Devices and Radiological Health
CHEK2	*Checkpoint kinase 2*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CRPC	Castrate-resistant prostate cancer
dMMR	Mismatch despair deficiency
DNA	Deoxyribonucleic acid
EDTA	Ethylenediamine tetraacetic acid
ER	Estrogen receptor
FANCC	FA complementation group c
FDA	Food and Drug Administration
FFPE	Formalin-fixed paraffin-embedded
FGFR2	Fibroblast growth factor receptor 2
GIS	Genomic instability score
HBOC	Hereditary Breast and Ovarian Cancer
HER-2	*Human epidermal growth factor 2*
LDTs	Laboratory-developed tests
LFS	Li-Fraumeni syndrome
MSH2	*Muts homolog 2*
MSI	Microsatellite instability
NBN	*Nibrin*

NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
NICE	National Institute for Health and Care Excellence
OCCR	Ovarian cancer cluster region
PALB2	*Partner and localizer of brca2*
PARP	*Poly ADP-ribose polymerase*
PCR	Polymerase chain reaction
PMS2	Pms1 homolog 2, mismatch repair system component
PR	Progesterone receptor
PTEN	*Phosphatase and tensin homolog*
RAD51C	*Rad51 paralog c*
RAD51D	*RAD51 homolog C*
RECQL	*RecQ Like Helicase*
RET	*Ret proto-oncogene*
SMARCA4	*Swi/snf related, matrix associated, actin dependent regulator of chromatin, subfamily a, member 4*
TMB	Tumor mutational burden
TP53	*Tumor protein p53*
USPSTF	The U.S. Preventive Services Task Force

V. Scientific Background

BRCA1 and *BRCA2* are critical genes in the process of homologous recombination repair of double-strand DNA breaks (Walsh, 2015). Both genes are very large (occupying about 70 kb) and encode a combined total of 49 exons. They are considered tumor suppressor genes and a loss of function on either gene increases the cancer risk (Pan & Xie, 2017). *BRCA1* is thought to regulate c-Abl kinase activity (as loss of *BRCA1* results in a constitutively activated c-Abl kinase) whereas *BRCA2* is thought to regulate Rad51, which repairs DNA damage such as chromosomal breaks (Yoshida & Miki, 2004).

Different regions of mutation may confer different types of risk. For example, *BRCA2* has an area called the ovarian cancer cluster region (OCCR) in which mutations predispose the patient for ovarian cancer. Mutations outside the OCCR are more likely to result in breast cancer compared to mutations in the OCCR. On *BRCA1*, mutations closer to the 3' end of the gene may result in higher risk than mutations closer to the 5' end (Meric-Bernstam et al., 2013). Other gene defects that affect homologous recombination include hypermethylation of *RAD51C* or *ATR* mutation. However, these are considered to have a phenotype of "BRCAness" and behave like *BRCA*-deficient genes even if the *BRCA* gene itself is normal (Walsh, 2015).

Although the probability of cancer development in carriers is variable, estimates of penetrance in individuals with a pathogenic variant in *BRCA1* or *BRCA2* range from 46% to 87% lifetime risk for breast cancer, and 16.5% to 63% lifetime risk for ovarian cancer (Petrucelli et al., 2016). *BRCA1* and *BRCA2* mutations account for about 5 – 10% of breast cancers and 10 – 18% of ovarian cancers (Walsh, 2015). *BRCA* mutations are inherited in an autosomal dominant fashion and are highly penetrant (Isaacs & Peshkin, 2024).

It is clinically important to recognize these carriers to guide management of cancer and identify unaffected women with a *BRCA* mutation who will benefit from enhanced surveillance; in addition, recognizing carriers helps physicians tailor care to improve outcomes and more efficiently use health-care resources. Adherence to guidelines for managing cancer risk has the potential to have a significant individual and population health impact on morbidity and mortality (Buchanan et al., 2017). For example, *BRCA* deficient cancers are often targeted for a certain class of drugs called poly(ADP-ribose) polymerase (PARP) inhibitors. These inhibitors target enzymes responsible for the base excision repair pathway. A cell can survive with the loss of either the base excision repair pathway or the homologous recombination mechanism, but not both. Since *BRCA*-deficient cells already have a faulty homologous recombination mechanism, the *BRCA*-deficient cell dies when the PARP inhibitor shuts down the base excision repair pathway. *BRCA*-deficient cells have been shown to be affected 1000 times more by these PARP inhibitors than wild-type cells (Walsh, 2015).

Numerous proprietary tests exist for the assessment of *BRCA* or its related genes such as *RAD51*. For example, gene panels such as Ambry Genetics' panel include 25 genes such as *BRCA1*, *BRCA2*, *CHEK2*, *ATM*, *RAD51C*, and *BRIP1*. This test is performed by next generation sequencing or Sanger sequencing (except for *EPCAM*) with a turnaround time of 2-3 weeks. Ambry has several proprietary tests such BRCAplus and BreastNext (Ambry, 2023). Another gene panel that has been developed to identify genetic mutations associated with inherited breast and ovarian cancers is the AmpliSeq for Illumina *BRCA* Plus, Extended Hereditary Breast and Ovarian Research Panel. This panel assesses germline variants in 11 genes known to harbor mutations related to breast and ovarian cancer:
ATM, *BRCA1*, *BRCA2*, *CHEK2*, *PALB2*, *RAD51C*, *RAD51D*, *NBN*, *CDH1*, *SMARCA4*, and *TP53*. However, though these community panels boasts the convenience of being made-to-order, Illumina warns that they do not have associated performance metrics (Illumina, 2021). myChoice CDx by Myriad Genetics, Inc. is a tumor test that determines homologous recombination deficiency status by detecting *BRCA1* and *BRCA2* (sequencing and large rearrangement) variants. This next generation sequencing-based *in vitro* diagnostic assay focuses on assessing genomic instability by using loss of heterozygosity, telomeric allelic imbalance and large-scale state transitions from

tumor tissue specimens. The results can then be used to guide treatment and therapy for ovarian cancer patients with positive homologous recombination deficiency, which is defined by the presence of *BRCA1/2* mutations and/or positive Genomic Instability Score (Myriad Genetics, 2024).

Clinical Utility and Validity

A study performed by Kuchenbaecker et al. (2017) assessed the cumulative risk of breast and ovarian cancer based on mutation position. A sample of 9856 patients was analyzed, with 6036 patients carrying a *BRCA1* mutation and 3820 with a *BRCA2* mutation. 5046 patients were unaffected by either type of cancer and 4810 had breast cancer, ovarian cancer, or both at baseline. The breast cancer assessment was based on 3886 carriers, and the ovarian cancer assessment was based on 5066 women. The authors evaluated the cumulative risk of breast cancer to 80 years to be 72% for *BRCA1* mutation carriers and 69% for *BRCA2* carriers. Cumulative risk for ovarian cancer to 80 years was found to be 44% for *BRCA1* carriers and 17% for *BRCA2* carriers. *BRCA2* mutations outside the OCCR were found to have a higher risk of breast cancer than mutations inside it (hazard ratio: 1.93 for OCCR ranges 5′ to c.2830, c.2831 to c.6401, c.6402 to 3) but no difference in overall ovarian cancer risk. Mutations closer to the 3′ or 5′ ends of *BRCA1* were found to have a higher risk of breast cancer compared to the middle third of the gene and the third closest to the 3′ end had the highest hazard ratio of 1.51 compared to the third closest to the 5′ end (1.43) (Kuchenbaecker et al., 2017).

A meta-analysis of 44 articles was performed to assess the difference in risk factors between *BRCA1* and *BRCA2* carriers. Factors such as breastfeeding, coffee, infertility, and more were examined between both genotypes, and the only risk factor that revealed an association of any kind was age at first live birth for *BRCA1* carriers. Breast cancer risk was found to decrease for *BRCA1* women over 30 compared to women under 30, and the same was found for women from 25-29 compared to women under 25. However, the authors stressed that more research was required (Friebel et al., 2014).

However, the importance of *BRCA* testing has not only been explored for lifestyle choices or transient states; factors such as ethnicity can also play a role in the predisposition of patients to breast cancer. Palmer et al. (2020) delved into the risks of breast cancer in African American (AA) women associated with inherited mutations in breast cancer predisposition genes. Using germline DNA samples and drawing from 10 epidemiologic studies encompassing 5054 affected African American women and 4993 unaffected African American women, Palmer et al. (2020) sequenced mutations in 23 cancer predisposition genes using a QIAseq multiplex amplicon panel and found that

pathogenic mutations could be identified in 10.3% of women with estrogen receptor (ER)-negative breast cancer, 5.2% of women with ER-positive breast cancer, and 2.3% of unaffected women. Mutations in *BRCA1*, *BRCA2*, and *PALB2* were associated with an overall increased risk for breast cancer, while *RAD51D* mutations were observed specifically to be linked to higher risk of ER-negative disease. Other mutations the researchers found to be of interest were in *CHEK2*, *ATM*, *ERCC3*, *FANCC,* and *RECQL*. Thus, it was concluded that the study corroborated the use and "validity of current breast cancer testing panels for use in AA women" (Palmer et al., 2020).

A study using next generation sequencing (NGS) to identify *BRCA* mutations was performed by Lang et al. 4034 patients were screened (2991 breast cancer patients, 1043 healthy controls). *BRCA* mutations were found in 247 of the breast cancer patients or 8.3%. 13.9% (16/115) of the *BRCA1* mutations were of the "c.5470_5477del" variation, and several clinical characteristics such as high KI67 index and high tumor grade were related to *BRCA* mutations, *BRCA2* carriers were also found to have poorer disease-free survival among HER2 positive patients (Lang et al., 2017).

Tomao et al. (2019) investigated the ability of *BRCA* mutational status on predicting hematologic toxicity with platinum-based chemotherapy. 176 patients were included, with 58 *BRCA* mutation carriers (40 *BRCA1,* 18 *BRCA2*, 118 controls). The authors identified several differences in hematologic toxicity between the two groups; the *BRCA* positive group was observed to have significantly higher frequency in "thrombocytopenia (24% vs 5%), anemia (21% vs 7%; p = 0.006) and neutropenia (62% vs 27%)". The authors also noted that granulocyte-colony stimulating growth factors injection (12% versus 1%,) and dose delay (19% versus 27%) were more likely in the *BRCA* positive group (odds ratio = 2.567 for granulocyte-colony stimulating growth factors injection and 3.860 for dose delay). Overall, the authors concluded that "germline *BRCA* ½ mutations are associated with a higher hematologic toxicity in patients with ovarian cancer who underwent platinum-based chemotherapy" (Tomao et al., 2019).

Yoo et al. (2020) conducted *BRCA1/NGS* for 262 hereditary breast and ovarian cancer (HBOC) syndrome patients, and the results were confirmed by using multiplex ligation-dependent probe amplification and direct Sanger sequencing. A multigene panel test was also performed on 120 patients who did not possess *BRCA1/2* pathogenic variants but who met NCCN criteria for testing. The researchers reported that pathogenic variants in *BRCA1/2* were detected in 30 HBOC patients (11.5%), and four out of the 120 patients possessed pathogenic variants of *MSH2 PMS2, CHEK2* and *PALB2*, which were also detectable by multigene panel testing. The results suggested to the authors that "Multi-gene panel testing could be a significant screening tool for HBOC patients, especially for those with a family history of cancer" (Yoo et al., 2020).

BRCA testing has been demonstrated to be potentially beneficial, even when the testing is unselected and is population-based. Manchanda et al. (2020) examined the North London Ashkenazi-Jewish (AJ) population in a randomized controlled trial consisting of 1034 AJ women and men across two arms—one, a population-screening approach, and a second, a family history/clinical-criteria-based *BRCA* testing—to determine subsequent effects on psychological health and quality of life after providing genetic testing for three Jewish *BRCA* founder-mutations. Based on the results of the study, the researchers drew the conclusion that "Population-based AJ *BRCA* testing does not adversely affect long-term psychological wellbeing or quality-of-life, decreases anxiety and could identify up to 150% additional *BRCA* carriers" (Manchanda et al., 2020). However, these results on the anxiety and health-anxiety of this population may be contested, for validated questionnaires were used to measure the psychological wellbeing of the participants at baseline/1-year/2-year/3-year follow-ups. Moreover, the participants were recruited through self-referral, which may affect the internal validity of the trials.

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

NCCN guidelines titled *Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic Version 3.2024* address general hereditary cancer testing. Note that NCCN recommendations have been developed to be inclusive of individuals of all sexual and gender identities to the greatest extent possible. In this guideline, the terms males and females refer to sex assigned at birth. The NCCN list the following scenarios as "clinically indicated" for genetic testing:

1. "Individual with any blood relative with a known pathogenic/likely pathogen variant in a cancer susceptibility gene" [including *BRCA1/2*]
2. "Individuals meeting the criteria below but tested negative with previous limited testing, (eg, single gene and/or absent deletion duplication analysis) and are interested in pursuing multi-gene testing"
3. "A pathogenic/likely pathogenic variant identified on tumor genomic testing that has clinical implications if also identified in the germline"
4. "To aid in systemic therapy and surgical decision-making"
5. "Individual who meets Li-Fraumeni syndrome (LFS) testing criteria or Cowden syndrome/PTEN hamartoma tumor syndrome testing criteria or Lynch syndrome"
6. *Personal or family history of cancer*
    a. **Testing for high-penetrance breast cancer susceptibility genes** (Specifically *BRCA1, BRCA2, CDH1, PALB2, PTEN, STK11* and *TP53*)**:**

i. Personal history of breast cancer with specific features:
   a. By Age of diagnosis and family history
      (a) Diagnosed at age ≤50y
      (b) Diagnosed at any age:
         - Treatment indications:
            (i) To aid in systematic treatment decisions using PARP inhibitors for breast cancer in the metastatic setting
            (ii) To aid in adjuvant treatment decisions with Olaparib for high-risk, HER-2 negative breast cancer
         - Pathology/histology:
            (iii) Triple-negative breast cancer
            (iv) Multiple primary breast cancers (synchronous or metasynchronous)
            (v) Lobular breast cancer with personal or family history of diffuse gastric cancer
         - Family history:
            (vi) ≥1 close blood relative with ANY:
               - Breast cancer at age ≤50y
               - Male breast cancer
               - Ovarian cancer
               - Pancreatic cancer
               - Prostate cancer with metastatic or high- or very-high-risk group
            (vii) ≥3 total diagnoses of breast and/or prostate cancer (any grade) on the same side of the family including the patient with breast cancer.
         - Ancestry:
            (viii) Ashkenazi Jewish Ancestry
         - Male breast cancer
ii. Family history of cancer only
   a. Individuals affected with breast cancer (not meeting testing criteria listed above) or individual unaffected with breast cancer with a first- or second-degree blood relative meeting any of the criteria listed above (except unaffected individuals whose relatives meet criteria only for systemic therapy decision-making).
   b. Individuals affected or unaffected with breast cancer who otherwise do not meet the criteria above but have a probability >5% of a BRCA1/2 P/LP variant based on prior probability models (eg, Tyrer-Cuzick, BRCAPro,

CanRisk)

b. **Testing for ovarian cancer susceptibility genes**
   i. Personal history of epithelial ovarian cancer (including fallopian tube cancer or peritoneal cancer) at any age
   ii. Family history of cancer only
      a. An individual unaffected with ovarian cancer with a first- or second-degree blood relative with epithelial ovarian cancer (including fallopian tube cancer or peritoneal cancer) at any age
      b. An individual unaffected with ovarian cancer who otherwise does not meet the criteria above but has a probability >5% of a BRCA1/2 pathogenic variant based on prior probability models (eg, Tyrer-Cuzick, BRCAPro, CanRisk)

c. **Testing for pancreatic cancer susceptibility genes**
   i. Exocrine pancreatic cancer
      a. All individuals diagnosed with exocrine pancreatic cancer
      b. First-degree relatives of individuals diagnosed with exocrine pancreatic cancer

d. **Testing for high-penetrance prostate cancer susceptibility genes**
   i. Personal history of prostate cancer with specific features:
      a. By tumor characteristics (any age)
         (a) Metastatic
         (b) Histology
            (i) High- or very-high-risk group
      b. By family history and ancestry
         (a) ≥1 close blood relative with:
            (i) breast cancer at age ≤50 y
            (ii) triple-negative breast cancer at any age
            (iii) male breast cancer at any age
            (iv) ovarian cancer any age
            (v) pancreatic cancer any age
            (vi) metastatic, or high- or very-high risk group at any age
         (b) ≥3 close blood relatives with prostate cancer (any grade) and/or breast cancer on the same side of the family including the patient with prostate cancer
         (c) Ashkenazi Jewish ancestry
      c. Family history of cancer only

(a) An affected (not meeting testing criteria listed above) or unaffected individual with a first-degree blood relative meeting any of the criteria listed above (except unaffected individuals whose relatives meet criteria only for systemic therapy decision-making)

e. **Testing for Li-Fraumeni Syndrome**
   i. Individual from a family with a known TP53 pathogenic/likely pathogenic variant
   ii. Classic Li-Fraumeni syndrome (LFS) criteria:
      a. Combination of an individual diagnosed at age <45 years with a sarcoma AND
      b. A first-degree relative diagnosed at age <45 years with cancer AND
      c. An additional first- or second-degree relative in the same lineage with cancer diagnosed at age <45 years, or a sarcoma at any age
   iii. Chompret criteria:
      a. Individual with a tumor from LFS tumor spectrum (eg, soft tissue sarcoma, osteosarcoma, CNS tumor, breast cancer, adrenocortical carcinoma), before 46 years of age, AND at least one first- or second-degree relative with any of the aforementioned cancers (other than breast cancer if the proband has breast cancer) before the age of 56 years or with multiple primaries at any age OR
      b. Individual with multiple tumors (except multiple breast tumors), two of which belong to LFS tumor spectrum with the initial cancer occurring before the age of 46 years OR
      c. Individual with adrenocortical carcinoma, or choroid plexus carcinoma or rhabdomyosarcoma of embryonal anaplastic subtype, at any age of onset, regardless of family history OR
      d. Breast cancer before 31 years of age
   iv. Personal or family history of pediatric hypodiploid acute lymphoblastic leukemia
   v. In individuals with cancer with a pathogenic/likely pathogenic *TP53* variant identified on tumor-only genomic testing, germline testing should be considered for: (1) Those meeting one or more of the other LFS testing criterion above after reevaluation of personal and family history (2) those diagnosed age <30 years with any cancer (3) those with clinical scenario not meeting these criteria but warranting germline evaluation per clinician discretion.

f. **Testing for Cowden Syndrome (CS)/PTEN Hamartoma Tumor Syndrome (PHTS):**
   i. Individual from a family with a known PTEN pathogenic/likely pathogenic variant
   ii. Individual with a personal history of Bannayan-Riley-Ruvalcaba syndrome (BRRS)
   iii. Individual meeting clinical diagnostic criteria for CS/PHTS
   iv. Individual not meeting clinical diagnostic criteria for CS/PHTS with a personal history of:
      a. Adult Lhermitte-Duclos disease (cerebellar tumors); or
      b. Autism spectrum disorder and macrocephaly; or
      c. Two or more biopsy-proven trichilemmomas; or
      d. Two or more major criteria (one must be macrocephaly); or
      e. Three major criteria, without macrocephaly; or
      f. One major and ≥3 minor criteria; or
      g. ≥4 minor criteria
   v. Individual with a relative with a clinical diagnosis of CS/PHTS or BRRS for whom testing has not been performed
      a. The individual must have the following:
         (a) Any one major criterion or
            (i) Breast cancer
            (ii) Endometrial cancer
            (iii) Follicular thyroid cancer
            (iv) Multiple GI hamartomas or ganglioneuromas
            (v) Macrocephaly (megalocephaly) (ie, ≥97%, 58 cm in adult female, 60 cm in adult male)
            (vi) Macular pigmentation of glans penis
            (vii) Mucocutaneous lesions
               1) One biopsy-proven trichilemmoma
               2) Multiple palmoplantar keratoses
               3) Multifocal or extensive oral mucosal papillomatosis
               4) Multiple cutaneous facial papules (often verrucous)
         (b) Two minor criteria
            (i) Autism spectrum disorder
            (ii) Colon cancer
            (iii) ≥3 esophageal glycogenic acanthoses
            (iv) Lipomas

(v) Intellectual disability (ie, IQ ≤75)
(vi) Papillary or follicular variant of papillary thyroid cancer
(vii) Thyroid structural lesions (eg, adenoma, nodule[s], goiter)
(viii) Renal cell carcinoma
(ix) Single GI hamartoma or ganglioneuroma
(x) Testicular lipomatosis
(xi) Vascular anomalies (including multiple intracranial developmental venous anomalies)

vi. PTEN pathogenic/likely pathogenic variant detected by tumor genomic testing on any tumor type in the absence of germline analysis

The NCCN states that general hereditary cancer testing may be considered in the following scenario (with appropriate pre-test education and access to post-test management):

- An individual of Ashkenazi Jewish ancestry without additional risk factors.
- Personal history of serious endometrial cancer.

The NCCN states that testing for high-penetrance breast cancer susceptibility genes may be considered in the following scenarios (with appropriate pre-test education and access to post-test management):

1. Personal history of breast cancer < 60 y not meeting any of the above criteria may approach a 2.5% probability of having a pathogenic/likely pathogenic variant, based on recent data. It is cautioned that many of those PVs will be in moderate penetrance genes, which are over-represented in older affected individuals. Access to an experienced genetic counseling team to discuss management options is particularly important in this setting.
2. Personal history of breast cancer diagnosed at any age with ≥1 close blood relative with intermediate-risk prostate cancer with intraductal/cribriform histology.
3. Individuals affected or unaffected with breast cancer who otherwise do not meet any of the above criteria but with a 2.5%-5% probability of *BRCA 1/2* pathogenic variant/likely pathogenic variant based on prior probability models (e.g. Tyrer-Cuzick, BRCAPro, CanRisk).

The NCCN states that when testing for high-penetrance breast cancer susceptibility genes, there is "a low probability (<2.5%) that testing will have findings of documented high-penetrance genes in the following scenarios:

1. Female diagnosed with breast cancer at age >60 y, with no close relative with breast, ovarian, pancreatic, or prostate cancer
2. Diagnosed with localized prostate cancer with Gleason Score <7 and no close relative with breast, ovarian, pancreatic, or prostate cancer" (NCCN, 2024b).

The NCCN suggests that prior to genetic testing,

- "The probability of pathogenic or likely pathogenic variant detection associated with these criteria will vary based on family structure, which includes size of the family, age of the family members, early death, adoption, and number of male and female relatives. Individuals with unknown or limited family history/structure, such as fewer than 2 female first- or second-degree relatives having lived beyond age 45 in either lineage, may have an underestimated probability of familial P/LP variant detection. The estimated likelihood of P/LP variant detection may be low in families with many unaffected and/or male relatives.
- Patients who have received an allogeneic bone marrow transplant or with active or recent hematologic malignancies should not have molecular genetic testing via blood, saliva, or buccal samples (due to unreliable test results from contamination by donor DNA) until other technologies are available. If available, DNA should be extracted from a fibroblast culture. If this source of DNA is not possible, buccal samples can be considered, subject to the risk of donor DNA contamination or malignant cells from the hematologic malignancy.
- If more than one family member is affected with cancers highly associated with a particular inherited cancer susceptibility syndrome, consider initial testing of a family member with youngest age at diagnosis, bilateral disease, multiple primary cancers, or other cancers associated with the syndrome, or most closely related to the proband/patient. If there are no available family members with cancer that is a cardinal feature of the syndrome in question, consider testing first- or second-degree family members affected with other cancers thought to be related to the gene in question (eg, prostate or pancreas with *BRCA1/2*).
- Testing for unaffected family members when no affected member is available should be considered. Significant limitations of interpreting test results should be discussed.
- In children <18 y, genetic testing is generally not recommended when results would not impact medical management.
- Likely pathogenic variants are usually clinically managed similarly to pathogenic variants, while patients with variants of uncertain significance (VUS) and likely

benign variants should be managed based on the cancers present in the family.
- Choice of multi-gene testing" (NCCN, 2024b).

Furthermore, in the situation where the presence of a pathogenic or likely pathogenic variant is unknown, the NCCN recommends that "the testing of the unaffected individual (or of unaffected family members) should only be considered when no affected family member is available for testing. In such cases, the unaffected individual or unaffected close relative with the highest likelihood of testing positive for the pathogenic or likely pathogenic variant should be tested," though "A negative test result in such cases, however, is considered indeterminate and does not provide the same level of information as when there is known pathogenic or likely pathogenic variant in the family." The NCCN also remarks that "testing multiple family members may be indicated" when testing unaffected individuals "(in the absence of having tested affected family members)" to aid in interpreting results (NCCN, 2024b).

The NCCN also recommends assessing *BRCA1/2* in all patients with recurrent or metastatic breast cancer to identify candidates for PARP inhibitor therapy (NCCN, 2024a).

Regarding *BRCA* in ovarian cancer, the NCCN recommends testing for *BRCA1/2* mutations prior to initiating treatment for persistent/recurrent ovarian cancer since "germline and/or somatic *BRCA1/2* status informs maintenance therapy." The NCCN notes that *BRCA* testing may be done prior to this stage (NCCN, 2024c).

BRCA testing was also mentioned in guidelines for pancreatic adenocarcinoma. The NCCN recommends tumor/somatic gene profiling for those with "locally advanced/metastatic disease who are candidates for anti-cancer therapy to identify uncommon mutations, including testing for mutations in *BRAF, BRCA1/2, HER2, KRAS,* and *PALB2* genes, fusions in *ALK, NRG1, NTRK, ROS1, FGFR2, RET* genes, microsatellite instability (MSI), mismatch repair deficiency *(dMMR*) , or tumor mutational burden (TMB) via an FDA-approved and/or validated next-generation sequencing (NGS)-based assay" (NCCN, 2024d).

The NCCN also published guidelines regarding *BRCA* in prostate cancer. Germline genetic testing, which should include *BRCA1/2* among other genes, such as *ATM, PALB2,* and *CHEK2* was recommended for initial patients with prostate cancer and any of the following: "a positive family history; high-risk, very-high-risk, regional, or metastatic prostate cancer, regardless of family history; Ashkenazi Jewish ancestry; [and] a personal history of breast cancer." The NCCN also notes that "germline genetic testing should be considered in patients with a personal history of prostate cancer and 1) intermediate-risk prostate cancer and intraductal/cribriform histology or 2) a

personal history of exocrine pancreatic cancer, breast cancer, colorectal, gastric, melanoma, pancreatic cancer, upper tract urothelial cancer, glioblastoma, biliary tract cancer, and small intestinal cancer" Moreover, the NCCN asserts that germline testing should include "*MLH1, MSH2, MSH6, and PMS2* (for Lynch syndrome) and homologous recombination genes *BRCA1, BRCA2, ATM, PALB2, and CHEK2*", urging that cancer predisposition next-generation sequencing be considered (NCCN, 2024e).

Regarding somatic tumor testing in risk groups,

- "Tumor testing for somatic homologous recombination gene mutations (eg, *BRCA1, BRCA2, ATM, PALB2, FANCA, RAD51D, CHEK2, CDK12*) can be considered in patients with regional (N1) prostate cancer and is recommended for those with metastatic disease.
- Tumor testing for MSI or dMMR can be considered in patients with regional or metastatic castration-naïve prostate cancer and is recommended in the metastatic castrate-resistant prostate cancer (CRPC) setting.
- Tumor mutational burden (TMB) testing may be considered in patients with metastatic CRPC.
- Multigene molecular testing can be considered for patients with low-, intermediate-, and high-risk prostate cancer and life expectancy ≥10 years.
- The Decipher molecular assay is recommended to inform adjuvant treatment if adverse features are found post-radical prostatectomy and can be considered as part of counseling for risk stratification in patients with PSA resistance/recurrence after radical prostatectomy (category 2B)" (NCCN, 2024e).

The NCCN published information on *TP53* as a pathogenic/likely pathogenic variant, noting that testing for Li-Fraumeni syndrome should occur when the individual is from a family with a known *TP53* pathogenic/likely pathogenic variant. They specifically note that when this gene is "included as part of a multi-gene panel, an individual does not need to meet these testing criteria [for Li-Fraumeni syndrome]- if "testing criteria on other testing criteria pages are met" (NCCN, 2024b).

The U.S. Preventive Services Task Force (USPSTF)

In 2019, the USPSTF updated their 2014 recommendation (Moyer, 2014). In it, they state that "the USPSTF recommends that primary care clinicians assess women with a personal or family history of breast, ovarian, tubal, or peritoneal cancer or who have an ancestry associated with breast cancer susceptibility 1 and 2 (*BRCA1*/2) gene mutations with an appropriate brief familial risk assessment tool. Women with a positive result on the risk assessment tool should receive genetic counseling and, if indicated after counseling, genetic testing." This recommendation is intended for women with a "personal or family history of breast, ovarian, tubal, or peritoneal cancer or an ancestry

associated with *BRCA1*/2 gene mutation" (USPSTF, 2019).

Moreover, they do not recommend (i.e. issue a D recommendation) routine screening, genetic testing, or genetic counseling for women who have no family or personal history of breast cancer or whose ancestry or ethnicity is not associated with a higher risk for potentially pathogenic *BRCA1* or *BRCA2* gene mutations (USPSTF, 2019).

The American College of Obstetricians and Gynecologists (ACOG)

The ACOG released guidelines in 2019 for Hereditary Cancer Syndromes and Risk Assessments. The ACOG recommends:

- Evaluating a patient's risk of hereditary breast and ovarian cancer syndrome should be a routine part of obstetric and gynecologic practice. Initial risk evaluation should include a personal medical history and family history.
- Genetic testing is recommended when the results of a detailed risk assessment that is performed as part of genetic counseling suggest the presence of an inherited cancer syndrome for which specific genes have been identified and when the results of testing are likely to influence medical management.
- The two main genetic testing options for hereditary breast and ovarian cancer syndrome are *BRCA* mutation testing and multigene panel testing that includes both *BRCA* and other genetic mutations. Multigene panel testing may be useful when more than one gene may be associated with an inherited cancer syndrome or when a patient has a personal or family history that is consistent with an inherited cancer susceptibility, but single-gene testing has not identified a pathogenic variant (ACOG, 2019).

The American Society of Breast Surgeons (ASBS)

The American Society of Breast Surgeons have released guidelines on genetic testing for hereditary breast cancer. They are as follows:

1. "Breast surgeons, genetic counselors, and other medical professionals knowledgeable in genetic testing can provide patient education and counseling and make recommendations to their patients regarding genetic testing and arrange testing"
2. "Genetic testing should be made available to all patients with a personal history of breast cancer. Recent data support that genetic testing should be offered to each patient with breast cancer (newly diagnosed or with a personal history). If

genetic testing is performed, such testing should include *BRCA1*/*BRCA2* and *PALB2*, with other genes as appropriate for the clinical scenario and family history. For patients with newly diagnosed breast cancer, identification of a mutation may impact local treatment"

3. "Patients who had genetic testing previously may benefit from updated testing. Every patient being seen by a breast surgeon, who had genetic testing in the past and no pathogenic variant was identified, should be re-evaluated and updated testing considered. In particular, a patient who had negative germline *BRCA1* and 2 testing, who is from a family with no pathogenic variants, should be considered for additional testing.1 Genetic testing performed prior to 2014 most likely would not have had PALB2 or other potentially relevant genes included and may not have included testing for large genomic rearrangements in *BRCA1* or *BRCA2*"
4. "Genetic testing should be made available to patients without a history of breast cancer who meet NCCN guidelines. Unaffected patients should be informed that testing an affected relative first, whenever possible, is more informative than undergoing testing themselves. When it is not feasible to test the affected relative first, then the unaffected family member should be considered for testing if they are interested, with careful pre-test counseling to explain the limited value of "uninformative negative" results. It is also reasonable to order a multi-gene panel if the family history is incomplete (i.e., a case of adoption, patient is uncertain of exact type of cancer affecting family members, among others) or other cancers are found in the family history, as described above" (Manahan et al., 2019).

American Society of Clinical Oncology (ASCO)

ASCO recommends germline genetic testing for *BRCA1/2* for all women diagnosed with epithelial ovarian cancer. Somatic tumor testing for *BRCA1/2* should be performed in women that do not carry a germline pathogenic or likely pathogenic variant (Konstantinopoulos et al., 2020).

ASCO also published a guideline regarding PARP inhibitors for ovarian cancer. In recommendation 2.2, they recommend the use of "Myriad myChoice CDx" to determine *BRCA1/2* status for therapy decisions (Tew et al., 2020).

In 2024, ASCO published "Germline Testing in Patients With Breast Cancer: ASCO-Society of Surgical Oncology Guideline" with the following recommendations:

- "BRCA1/2 mutation testing should be offered to all newly diagnosed patients with breast cancer ≤65 years and select patients >65 years based on personal history, family history, ancestry, or eligibility for poly(ADP-ribose) polymerase (PARP) inhibitor therapy."
- "All patients with recurrent breast cancer who are candidates for PARP inhibitor therapy should be offered BRCA1/2 testing, regardless of family history. BRCA1/2 testing should be offered to women who develop a second primary cancer in the ipsilateral or contralateral breast."
- "For patients with prior history of breast cancer and without active disease, testing should be offered to patients diagnosed ≤65 years and selectively in patients diagnosed after 65 years, if it will inform personal and family risk."
- "Testing for high-penetrance cancer susceptibility genes beyond BRCA1/2 should be offered to those with supportive family histories; testing for moderate-penetrance genes may be offered if necessary to inform personal and family cancer risk."
- "Patients should be provided enough pretest information for informed consent; those with pathogenic variants should receive individualized post-test counseling. Variants of uncertain significance should not impact management, and patients with such variants should be followed for reclassification."
- "Referral to providers experienced in clinical cancer genetics may help facilitate patient selection and interpretation of expanded testing, and provide counseling of individuals without pathogenic germline variants but with significant family history" (Bedrosian et al., 2024).

National Institute for Health and Care Excellence (NICE)

NICE updated their guidelines on familial breast cancer in 2019. In it, they maintain their *BRCA*-related recommendations from 2013, which are as follows:

"Offer genetic testing in specialist genetic clinics to a relative with a personal history of breast and/or ovarian cancer if that relative has a combined *BRCA1* and *BRCA2* mutation carrier probability of 10% or more."

"Offer genetic testing in specialist genetic clinics to a person with no personal history of breast or ovarian cancer if their combined *BRCA1* and *BRCA2* mutation carrier probability is 10% or more and an affected relative is unavailable for testing."

"Offer genetic testing in specialist genetic clinics to a person with breast or ovarian

cancer if their combined *BRCA1* and *BRCA2* mutation carrier probability is 10% or more" (NICE, 2019).

European Expert Group

A group of 19 experts in *BRCA* testing were convened to publish this set of guidelines. These experts came from across Europe and Israel, and participants included clinical or medical geneticists (32%), oncologists (37%), and gynaecologists (26%).

The guidelines state that with the rise of next-generation sequencing, hotspot testing instead of complete sequencing is "not acceptable," albeit noting a possible exception of founder mutations representing >99% of pathogenic variants in a specific area.

A majority of experts (60%) voted that *BRCA* testing should be offered to all patients with metastatic breast cancer (Singer et al., 2019).

In 2021, the group published guidance on *BRCA* and HRR deficiency testing for recently diagnosed patients with ovarian cancer. Consensus statements pertaining to *BRCA1/2* include (not an all-inclusive list):

1. "Tumour *BRCA1/2* testing should be carried out at primary diagnosis.
2. Tumour *BRCA1/2* testing should be carried out at disease recurrence (if not carried out earlier)
3. Germline and/or tumour *BRCA* testing should be used (in either order) to determine *BRCA* status at primary diagnosis" (Vergote et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

The Center for Devices and Radiological Health of the Food and Drug Administration (FDA, 2018) granted premarket approval on January 12,2018 to BRACAnalysis CDx®,

an in vitro diagnostic device intended for the qualitative detection and classification of variants in the protein coding regions and intron/exon boundaries of the *BRCA1* and *BRCA2* genes using genomic DNA obtained from whole blood specimens collected in EDTA. Single nucleotide variants and small insertions and deletions (indels) are identified by polymerase chain reaction (PCR) and Sanger sequencing. Large deletions and duplications in *BRCA1* and *BRCA2* are detected using multiplex PCR. Another FDA-approved device is the "FoundationFocus CDxBRCA", which is a "is a next generation sequencing based in vitro diagnostic device for qualitative detection of *BRCA1* and *BRCA2* alterations in formalin-fixed paraffin-embedded (FFPE) ovarian tumor tissue." This test is intended to be used "as an aid in identifying ovarian cancer patients for whom treatment with Rubraca (rucaparib) is being considered" (FDA, 2016). A more recent FDA-approved device comes out of Myriad Genetics, Inc., the myChoice HRD CDx, which was approved on October 23, 2019. This test is a "next generation sequencing-based in vitro diagnostic test that assesses the qualitative detection and classification of single nucleotide variants, insertions and deletions, and large rearrangement variants in protein coding regions and intron/exon boundaries of the BRCA1 and BRCA2 genes and the determination of Genomic Instability Score (GIS)" based off tumor tissue specimens.

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81162	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (e.g., hereditary breast and ovarian cancer) gene analysis; full sequence analysis and full duplication/deletion analysis (i.e., detection of large gene rearrangements)
81163	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis
81164	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (e.g., hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (i.e., detection of large gene rearrangements)
81165	BRCA1 (BRCA1, DNA repair associated) (e.g., hereditary breast and ovarian cancer) gene analysis; full sequence analysis

CPT	Code Description
81166	BRCA1 (BRCA1, DNA repair associated) (e.g., hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (i.e., detection of large gene rearrangements)
81167	BRCA2 (BRCA2, DNA repair associated) (e.g., hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (i.e., detection of large gene rearrangements)
81212	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; 185delAG, 5385insC, 6174delT variants
81215	BRCA1 (BRCA1, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; known familial variant
81216	BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis
81217	BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; known familial variant
81432	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel, must include sequencing of at least 10 genes, always including BRCA1, BRCA2, CDH1, MLH1, MSH2, MSH6, PALB2, PTEN, STK11, and TP53
81433	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); duplication/deletion analysis panel, must include analyses for BRCA1, BRCA2, MLH1, MSH2, and STK11
81479	Unlisted molecular pathology procedure
0102U	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA, and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated (17 genes [sequencing and deletion/duplication]) Proprietary test: BreastNext® Lab/Manufacturer: Ambry Genetics®
0103U	Hereditary ovarian cancer (eg, hereditary ovarian cancer, hereditary endometrial cancer), genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA, and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated (24 genes [sequencing and deletion/duplication], EPCAM [deletion/duplication only]) Proprietary test: OvaNext® Lab/Manufacturer: Ambry Genetics®

CPT	Code Description
0129U	Hereditary breast cancer–related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer), genomic sequence analysis and deletion/duplication analysis panel (ATM, BRCA1, BRCA2, CDH1, CHEK2, PALB2, PTEN, and TP53) Proprietary test: BRCAplus Lab/Manufacturer: Ambry Genetics
0172U	Oncology (solid tumor as indicated by the label), somatic mutation analysis of BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) and analysis of homologous recombination deficiency pathways, DNA, formalin-fixed paraffin-embedded tissue, algorithm quantifying tumor genomic instability score Proprietary test: myChoice® CDx Lab/Manufacturer: Myriad Genetics Laboratories, Inc
0474U	Hereditary pan-cancer (eg, hereditary sarcomas, hereditary endocrine tumors, hereditary neuroendocrine tumors, hereditary cutaneous melanoma), genomic sequence analysis panel of 88 genes with 20 duplications/deletions using nextgeneration sequencing (NGS), Sanger sequencing, blood or saliva, reported as positive or negative for germline variants, each gene Proprietary test: GeneticsNow® Comprehensive Germline Panel Lab/Manufacturer: GoPath Diagnostics, Inc
0475U	Hereditary prostate cancerrelated disorders, genomic sequence analysis panel using next-generation sequencing (NGS), Sanger sequencing, multiplex ligation-dependent probe amplification (MLPA), and array comparative genomic hybridization (CGH), evaluation of 23 genes and duplications/deletions when indicated, pathologic mutations reported with a genetic risk score for prostate cancer Proprietary test: ProstateNowTM Prostate Germline Panel Lab/Manufacturer: GoPath Diagnostics, Inc

Genetic Testing for CHARGE Syndrome

Policy Number: AHS – M2070 – Genetic Testing for CHARGE Syndrome	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

CHARGE (coloboma, heart defects, atresia choanae, growth retardation, genital abnormalities, and ear abnormalities) syndrome is a multiple congenital anomaly condition affected by mutations in the *CHD7* gene (Hsu et al., 2014). The majority of these mutations result in a wide range of congenital anomalies that include colobomas (congenital absence of pieces of tissue in eye structures that may cause defects in the iris, retina, or optic nerve); heart defects; choanal atresia (an obliteration or blockage of the posterior nasal aperture due to a persistent oronasal membrane that prevents joining of the nose and oropharynx); retarded growth and development; genital hypoplasia; ear anomalies; and deafness (Guercio & Martyn, 2007; Isaacson, 2022; Jongmans et al., 2006).

II. Related Policies

Policy Number	Policy Title
AHS-M2145	General Genetic Testing, Germline Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) To confirm a diagnosis in a patient with signs/symptoms of CHARGE (coloboma, heart defects, atresia choanae, growth retardation, genital abnormalities, and ear abnormalities) syndrome when a definitive diagnosis cannot be made with clinical criteria, genetic testing for the presence of *CHD7* variants **MEETS COVERAGE CRITERIA**.

2) For asymptomatic individuals who have a first-degree relative (see Note 1) diagnosed with CHARGE syndrome who have a known likely pathogenic or

pathogenic variant, genetic testing restricted to the known familial *CHD7* variant **MEETS COVERAGE CRITERIA**.

3) For individuals seeking prenatal or pre-implantation screening, genetic testing for the presence of *CHD7* variants **MEETS COVERAGE CRITERIA**.

4) For individuals with clinical features of CHARGE syndrome who have already tested negative for likely pathogenic or pathogenic variants in *CHD7*, screening for variants in *ZEB2, KMT2D* and *EFTUD2* **MEETS COVERAGE CRITERIA.**

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) For all other situations not discussed above, genetic testing for CHARGE syndrome **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: First-degree relatives include parents, full siblings, and children of the individual.

IV. Table of Terminology

Term	Definition
ATP	Adenosine triphosphate
CHARGE	Coloboma, heart defects, atresia choanae, growth retardation, genital abnormalities, and ear abnormalities
CHD7	*Chromodomain helicase deoxyribonucleic acid binding protein 7*
CHH	Congenital hypogonadotropic hypogonadism
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CN	Cranial nerve
CN I	Cranial nerve absent or reduced sense of smell
CN IX, X	Cranial nerve swallowing problem
CN V	Cranial nerve weak chewing/swallowing
CN VII	Cranial nerve facial palsy
CN VIII	Cranial nerve sensorineural hearing loss and balance/ vestibular problems
DNA	Deoxyribonucleic acid
EFTUD2	*Elongation factor Tu GTP binding domain containing 2*
ENT	Ear, nose, and throat

EP300	*E1A binding protein p300*
FDA	Food and Drug Administration
GI	Gastrointestinal
GnRH	*Gonadotropin-releasing hormone*
HH	Hypogonadotropic hypogonadism
KMT2D	*Lysine methyltransferase 2D*
LDTs	Laboratory-developed tests
MLPA	Multiplex ligation-dependent probe amplification
NGS	Next-generation sequencing
NIPT	Non-invasive prenatal test
NORD	National Organization for Rare Disorders
PUF60	*Poly(U) binding splicing factor 60*
RERE	*Arginine-glutamic acid dipeptide repeats*
SNP	Single nucleotide polymorphism
SWI-SNF	Switch/sucrose non-fermentable
TBX1	*T-box transcription factor 1*
ZEB2	*Zinc finger E-box binding homeobox 2*

V. Scientific Background

CHARGE (coloboma, heart defects, atresia choanae, growth retardation, genital abnormalities, and ear abnormalities) syndrome is a relatively common cause of congenital anomalies affecting approximately 1 in 8,500 to 10,000 births (Longman, 2018). First described by Hall (1979) and Hittner et al. (1979), CHARGE syndrome was diagnosed clinically (Blake et al., 1998; Pagon et al., 1981) until causative mutations were identified in the *CHD7* (Chromodomain-helicase-DNA-binding protein 7/ATP-dependent helicase CHD7) gene (Vissers et al., 2004). Due to the variability associated with *CHD7* mutations, genetic analysis may be helpful for genotypic diagnostics but will not necessarily assist in phenotypic predictions (Bergman et al., 2011). Most cases of CHARGE syndrome occur through spontaneous mutation of the *CHD7* gene; however, the disorder can also be passed from parent to offspring in an autosomal dominant fashion (Usman & Sur, 2024).

The *CHD7* gene contains 38 exons that encode for the 300-kDa CHD7 chromatin remodeler protein (Bilan et al., 2012). The CHD7 protein is a member of the SWI-SNF superfamily of ATP-dependent chromatin remodelers that bind to DNA and modulate gene expression (Asad et al., 2016; Marfella & Imbalzano, 2007). CHD7 has an important, dosage-dependent role in the development of several craniofacial tissues (Sperry et al., 2014) and has also been found to assist with orchestrating neural crest

and central nervous system development (Bajpai et al., 2010; He et al., 2016; Van Nostrand et al., 2014; Whittaker et al., 2017). Further, *CHD7* plays a role in additional gene expression programs and cellular interactions during embryogenesis; this likely occurs through the dysregulation of co-transcriptional alternative splicing (Belanger et al., 2018; Berube-Simard & Pilon, 2018; Schulz et al., 2014).

It is worth noting that the CHARGE syndrome acronym does not cover all disorders that may result from this disease; a diagnosis may include additional sensory deficits and birth defects, including cranial nerve dysfunction and feeding and gastrointestinal (GI) dysfunction (Blake & Hudson, 2017). It is notable that more than 90% of patients experience feeding and GI dysfunction; this is known to cause significant morbidity and mortality in the CHARGE syndrome patient population (Blake & Hudson, 2017; Hefner & Fassi, 2017). Further, many CHARGE syndrome patients exhibit clival pathology, such as coronal clefts; this is now considered a useful diagnostic criteria for patients (Mahdi & Whitehead, 2018). Nonetheless, the range of mutations in the *CHD7* gene results in a broad phenotype that may involve almost all organ and sensory systems in the body, therefore causing significant variabilities in severity and comorbidity (de Geus et al., 2017). Hence, no single feature is universally present or sufficient for the clinical diagnosis of CHARGE syndrome.

Clinical Validity

The initial clinical CHARGE syndrome diagnostic criteria (Blake et al., 1998) was first adapted to include supplemental clinical abnormalities (Verloes, 2005). More recently, the diagnostic criteria were updated to incorporate results of molecular testing (Hale et al., 2016a). Most individuals (90-95%) fulfilling the clinical criteria for a CHARGE syndrome diagnosis have a *CHD7* variant that is detectable by Sanger sequencing or next-generation sequencing (NGS) (Bergman et al., 2011; Janssen et al., 2012). However, since the inclusion of *CHD7*, variants have been described in 14-17% of mildly affected individuals who would not meet the clinical criteria for a CHARGE syndrome diagnosis (Bergman et al., 2011). This has resulted in the addition of *CHD7* to NGS gene panels for developmental delay, colobomata, heart defects (Corsten-Janssen et al., 2014), and other congenital malformations (van Ravenswaaij-Arts & Martin, 2017). The clinical validity of genetic testing that relies on identifying *CHD7* gene mutations may create issues in the future; van Ravenswaaij-Arts and Martin (2017) stated that individuals with a missense variant of the *CHD7* gene will less often fulfill clinical criteria for a CHARGE syndrome diagnosis, since there may be a decreased prevalence of congenital heart defects and choanal atresia with a missense variant. However, this type of variant is overrepresented in families with parent to child transmission of CHARGE syndrome (van Ravenswaaij-Arts & Martin, 2017).

Despite the availability of molecular diagnostic tools, "the cause of CHARGE syndrome remains unclear in approximately 5-10% of typical CHARGE patients and in 40-60% of suspected cases" (Janssen et al., 2012). Other genetic conditions such as 22q11.2 deletion (DiGeorge) syndrome, Kallmann syndrome, and Kabuki syndrome are known to have an overlapping phenotypic spectrum with CHARGE syndrome (Janssen et al., 2012), which may complicate diagnosis based strictly on clinical criteria. Additionally, it is challenging to distinguish younger patients with Kabuki syndrome from those with CHARGE syndrome since they lack the facial gestalt of Kabuki syndrome but show similar organ malformations to those of CHARGE syndrome patients (Pauli et al., 2017).

A more recent study utilized whole exome sequencing to genetically analyze 28 individuals exhibiting CHARGE syndrome features. Pathogenic variants in *CHD7*, other genes (*RERE, KMT2D, EP300, PUF60)*, and no pathogenic variants were found in 53.6%, 14.3%, and 28.6% of participants, respectively (Moccia et al., 2018). Based on these results, it was suggested that "the phenotypic features of CHARGE syndrome overlap with multiple other rare single-gene syndromes" (Moccia et al., 2018).

In a study by Gonçalves et al. (2019), mutations in the *CHD7* gene were observed in patients with isolated congenital hypogonadotropic hypogonadism (CHH), a condition that is characterized by the lack of normal pubertal development resulting from deficient gonadotropin-releasing hormone (GnRH). This demonstrates a limitation to clinical validity in *CHD7* genetic testing for CHARGE syndrome. The variable phenotypic expression is related to the type of mutation, as CHARGE syndrome patients seem to have "typically highly deleterious protein-truncating mutations, whereas *CHD7* mutations in isolated CHH are typically missense" (Gonçalves et al., 2019).

A study conducted by Qin et al. (2020) also found five neonatal patients to have drastically different clinical CHARGE syndrome phenotypes, with postnatal dyspnea as the most prominent symptom in the study cohort. The study found three novel genetic variants (c.2828_2829delAG, c.4667dupC, and c.7873C > T) and two reported variants (c.4667dupC and c.1480C > T) using whole exome sequencing that contributed to CHARGE syndrome clinical presentations. In accordance with this data, researchers concluded that though prenatal diagnosis of CHARGE syndrome may continue to be a challenge, "fetal *de novo* mutations screening by non-invasive prenatal test (NIPT) with maternal plasma is highly efficient for diagnosis. Detection of mutations in E1 and E38 may also provide clues for predicting severity of CHARGE syndrome by NIPT with maternal plasma" (Qin et al., 2020).

Another study was completed with data from 145 participants, all of whom were previously clinically diagnosed with CHARGE syndrome. Researchers surveyed these

participants to determine if they had completed genetic testing to confirm a CHARGE syndrome diagnosis. Of the total survey participants, 68% had never received genetic testing; of the 46 patients who did complete genetic testing, 74% tested positive for a *CHD7* mutation (Hartshorne et al., 2011).

Clinical Utility and Validity

Patients with CHARGE syndrome experience a wide spectrum of comorbidities, some more severe than others, and the complex management of these comorbidities can often lead to more issues. The clinical utility of making a definite diagnosis of CHARGE syndrome is high since a confirmed CHARGE diagnosis will lead to changes in clinical management, including well-defined clinical assessment and treatment recommendations (de Geus et al., 2017; Trider et al., 2017). No consensus on the utility of genetic testing in patients who present with a clear clinical diagnosis exists. However, testing may be useful in patients who do not have the classical CHARGE characteristics and may be at risk for the long-term complications of CHARGE syndrome (Blake et al., 2011). For instance, many patients with CHARGE syndrome will often have more than one dysfunctional cranial nerve (CN), which can manifest as an absent or reduced sense of smell (CN I), weak chewing/swallowing (CN V), facial palsy (CN VII), sensorineural hearing loss (CN VIII), balance/vestibular problems (CN VIII), and swallowing problems (CN IX, X) (Hudson et al., 2017). Testing is recommended in all suspected cases of CHARGE syndrome, especially in patients who partially meet the clinical criteria (Bergman et al., 2011; Hale et al., 2016a; Trider et al., 2017).

Hefner and Fassi (2017) state that a CHARGE syndrome diagnosis "should be considered in patients with any of the major diagnostic features: coloboma, choanal atresia, semicircular canal anomalies, or cranial nerve anomalies." These features are also common in 22q11.2 deletion (DiGeorge) and Kabuki syndromes, and genetic testing may be used to distinguish between these conditions; further, genetic counseling is an important step in a CHARGE syndrome diagnosis (Hefner & Fassi, 2017). This will prove to be critical in establishing a multidisciplinary care team for potential developmental concerns of a CHARGE syndrome child, such as combined deafness-blindness (Hudson et al., 2017). As CHARGE patients grow up, they may have feeding difficulties or orofacial anomalies that may need to be attended to by ENT specialists, cardiovascular malformations that may involve pediatric cardiologists, or concomitant hypogonadotropic hypogonadism (HH) that may require the help of pediatric endocrinologists, supporting the high clinical utility of *CHD7* testing of CHARGE syndrome (Dijk et al., 2019).

VI. Guidelines and Recommendations

The CHARGE Syndrome Foundation

The CHARGE Syndrome Foundation states that CHARGE syndrome is marked by key features such as coloboma, cranial nerve abnormalities, choanal atresia, heart defects, characteristic external ears, esophageal defects, small/absent semicircular canals, genitourinary abnormalities, and *CHD7* gene mutations, and that its "diagnosis should be made by a Medical Geneticist. Diagnosis is based on key features, ideally with DNA testing for *CHD7* mutations." Though "It does not usually run in families," the "Recurrence risk to unaffected parents is 1-2%" and "If a parent has CHARGE Syndrome, the risk to a baby is 50/50" (CHARGE Syndrome Foundation, 2024).

The National Organization for Rare Disorders (NORD)

NORD states that "Diagnosis can be confirmed by molecular genetic testing identifying the variants in the *CHD7* gene associated with the condition. If no disease-causing variants are found, a SNP chromosomal microarray should be done, because in a few patients, there has been a submicroscopic change in the chromosome 8q12.2 region. If both these tests are negative, whole genome exome sequencing should be done, since other genetic disorders share some clinical features with CHARGE syndrome, and new variants in the *ZEB2, KMT2D* and *EFTUD2* genes have been found in children previously diagnosed as having CHARGE syndrome" (National Organization for Rare Disorders, 2024).

Other Recommendations

Guidelines by professional societies and organizations about genetic testing for CHARGE syndrome are limited; however, recommendations by subject matter experts in the field are included below.

A comprehensive guideline and clinical checklist were developed by the Atlantic Canadian CHARGE syndrome team. This checklist includes diagnostic criteria such as clinical diagnoses and genetic testing; genetic consultation for *CHD7* analysis and array comparative genomic hybridization is also recommended. Further, the guideline notes that although "there is no consensus on genetic testing in the presence of a clear clinical diagnosis," multiple guidelines recommend genetic testing in "all suspected cases of CHARGE syndrome and especially for patients who partially meet the clinical criteria" (Trider et al., 2017).

According to guidelines published by researchers at The Children's Mercy Hospitals and Clinics in Kansas City, Missouri, a previously unknown missense mutation in exon 31 of *CHD7* can cause a diagnosis of CHARGE syndrome. This mutation can be inherited, showing that family history should be considered as a major diagnostic criterion for CHARGE syndrome (Hughes et al., 2014). Moreover, because orofacial

clefting is often observed with a diagnosis of CHARGE syndrome, it is also suggested that patients with this anomaly be tested for CHARGE syndrome (Hughes et al., 2014).

Guidelines published by de Geus et al. (2017) provide a comprehensive overview of all other published recommendations for CHARGE syndrome and introduce guidelines for cranial imaging. A summary of their recommendations is included in the table below (de Geus et al., 2017).

Recommendation	References
CHARGE is a clinical diagnosis	(Bergman et al., 2011; Blake et al., 1998; Harris et al., 1997; Issekutz et al., 2005; Verloes, 2005)
***CHD7* testing can confirm uncertain diagnosis in mildly affected patients**	(Bergman et al., 2011)
***CHD7* testing may be performed according to a flow diagram**	(Bergman et al., 2011)
A genome-wide array should be performed in patients with CHARGE syndrome but without a *CHD7* mutation	(Corsten-Janssen et al., 2013)
Clinical genetics consultation is indicated, including options for prenatal diagnosis	(Bergman et al., 2011; Lalani et al., 2012)
Patients diagnosed with hypogonadotropic hypogonadism and anosmia should be screened for clinical features consistent with CHARGE syndrome	(Jongmans et al., 2009)
Olfactory bulb hypoplasia and semicircular canal aplasia should be considered major signs for CHARGE syndrome	(Asakura et al., 2008; Sanlaville et al., 2006)
If a parent has any features of CHARGE syndrome, molecular genetic testing is appropriate if a *CHD7* pathogenic variant has been identified in the proband	(Jongmans et al., 2008)
***CHD7* analysis should be performed in patients with a 22q11.2 deletion**	(Corsten-Janssen et al., 2013)

phenotype without *TBX1* haploinsufficiency	
***CHD7* analysis should be performed in patients with Kallmann syndrome who have at least two additional CHARGE features or semicircular canal anomalies**	(Bergman et al., 2012; Costa-Barbosa et al., 2013; Jongmans et al., 2009)
***CHD7* should be included in massive parallel sequencing gene panels for diagnostics in syndromic heart defects**	(Corsten-Janssen et al., 2014)
***CHD7* analysis should not be performed routinely in patients with only atrial septal defect or conotruncal heart defects**	(Corsten-Janssen et al., 2014)
***CHD7* analysis should not be performed in septo-optic dysplasia patients without features of CHARGE**	(Gregory et al., 2013)
MLPA analysis is indicated if no causal *CHD7* is mutation is found	(Wincent et al., 2008; Wincent et al., 2009)
MLPA analysis is not indicated if no *CHD7* mutation is found	(Bergman et al., 2008)

Guidelines for clinical diagnosis have also been published by Hale et al. (2016a), which include the identification of a pathogenic *CHD7* variant as major criteria for a CHARGE syndrome diagnosis. In a response to comments received on their publication by (Blake et al., 2011), Hale and colleagues reaffirmed the appropriateness of *CHD7* testing under the right circumstances. They state "there are specific (and extremely useful) guidelines for when to test for *CHD7* sequence variants in individuals with CHARGE features (Bergman et al., 2011). Accurate and meaningful genetic information can lead to improved understanding of etiology, provide accurate recurrence risks, and help pave the way toward better clinical care. We advocate incorporating *CHD7* sequence variant information into the diagnostic algorithm, when it is available, since this information can improve understanding of disease causation, pathogenesis, and treatment options. In cases when *CHD7* variant testing is not available, the diagnosis can still be made based on appropriate clinical assessments" (Hale et al., 2016b).

Bergman et al. (2011) asserted that *CHD7* testing can confirm uncertain diagnoses in mildly affected patients. Moreover, a clinical genetics consultation is also indicated, including options for prenatal diagnosis.

Corsten-Janssen et al. (2014) published recommendations which state that:

- *CHD7* should be included in massive parallel sequencing gene panels for diagnostics in syndromic heart defects
- *CHD7* analysis should be performed in patients with a 22q11.2 deletion phenotype without *TBX1* haploinsufficiency
- Genome-wide array should be performed in patients with CHARGE syndrome but without a *CHD7* mutation

Jongmans et al. (2008) and Jongmans et al. (2009) recommended that:

- Patients diagnosed with hypogonadotropic hypogonadism and anosmia should be screened for clinical features consistent with CHARGE syndrome
- If a parent has any features of CHARGE syndrome, molecular genetic testing is appropriate if a *CHD7* pathogenic variant has been identified in the proband
- *CHD7* analysis should be performed in patients with Kallmann syndrome who have at least two additional CHARGE features or semicircular canal anomalies

Usman and Sur (2024) compiled guidelines for the diagnosis of CHARGE syndrome that state that the "only gene associated with CHARGE syndrome is *CHD7*, encrypting the chromodomain helicase DNA binding protein. This sequencing detects pathogenic variants in maximum individuals with typical CHARGE syndrome with the following criteria of having the three primary characteristics or four major and three minor characteristics." The major criteria are the 4C's: coloboma, cranial nerve abnormalities, choanal atresia, and typical CHARGE ear. The minor criteria are heart defects, cleft lip or palate, genital abnormalities, hypotonia, kidney abnormalities, esophageal atresia, poor growth, typical CHARGE face, and typical CHARGE hand. The authors summarize the outline of diagnosis as:

- "Clinical diagnosis: It is a combination of major and minor diagnostic characteristics, having the three primary features or four major and three minor characteristics."
- "Laboratory analysis: It includes having the blood workup done, such as complete blood count (CBC), serum electrolytes, renal function test, luteinizing hormone-releasing hormone, Human chorionic gonadotropin (hCG), blood urea nitrogen (BUN), creatinine, growth hormone levels, and immunologic studies."
- "Genetic analysis: Prenatal screening for *CHD7* variants is restricted to familial cases, via amniocentesis chorionic or villus sampling at 10–12 and 18–20 weeks' gestation."
- "Imaging studies: Involves a skeletal survey, abdominal ultrasound, barium swallow, echocardiography, chest x-ray, cranial ultrasound in neonates, and head computed tomography (CT) scan and magnetic resonance imaging (MRI)" (Usman & Sur, 2024).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81407	Molecular pathology procedure, level 8 (eg, analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)
81479	Unlisted molecular pathology procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Connective Tissue Disorders

Policy Number: AHS – M2144 – Genetic Testing for Connective Tissue Disorders	Prior Policy Name and Number, as applicable: • AHS-M2144 Marfan Syndrome
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

More than 200 heritable connective tissue disorders exist and include Marfan Syndrome (MFS), Ehlers-Danlos syndrome (EDS), Epidermolysis bullosa (EB), and Loeys-Dietz syndrome (LDS) (NIH, 2016). Every disorder impacts connective tissue differently, including several with vascular implications, and clinical severity varies within each disorder.

II. Related Policies

Policy Number	Policy Title
AHS-M2145	General Genetic Testing, Germline Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have consulted with a cardiology specialist prior to genetic testing, *FBN1* mutation testing for Marfan Syndrome **MEETS COVERAGE CRITERIA** in the following situations:
    a) When Marfan syndrome is suspected based on clinical features, but a definitive diagnosis cannot be made using established clinical diagnostic criteria (see Note 1).

b) For an asymptomatic individual who has an affected first-degree blood relative (i.e., parent, sibling, child) with a known mutation.

c) For the prenatal diagnosis or preimplantation genetic diagnosis (PGD) of Marfan syndrome in the offspring of patients with known disease-causing variants.

2) Genetic testing for Loeys-Dietz Syndrome (*TGFBR1* or *TGFBR2* mutation) **MEETS COVERAGE CRITERIA** in the following situations:

a) To confirm or establish a diagnosis of LDS in an individual with vascular characteristics of LDS (see Note 2).

b) For an asymptomatic individual who has an affected first-degree blood relative (i.e., parent, sibling, child) with a known mutation.

c) For individuals suspected of having Marfan Syndrome who have tested negative for *FBN1*.

3) For individuals with characteristics of vascular Ehlers-Danlos Syndrome (vEDS) (see Note 3), genetic panel testing for *COL3A1* and *COL1A1* mutations to confirm or establish a diagnosis of vEDS **MEETS COVERAGE CRITERIA.**

4) For individuals with characteristics of hypermobile Ehlers-Danlos syndrome (hEDS) (see Note 5), genetic testing to confirm or establish a diagnosis **DOES NOT MEET COVERAGE CRITERIA.**

5) All other gene testing for Marfan Syndrome or other connective tissue disorders, including Ehlers-Danlos Syndrome, **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Clinical Diagnostic Criteria for Marfan Syndrome is as follows:

Revised Ghent nosology — The 2010 revised Ghent nosology puts greater weight on aortic root dilatation/dissection and ectopia lentis as the cardinal clinical features of MFS and on testing for mutations in *FBN1* (Loeys et al., 2010; Wright & Connolly, 2023).

- In the absence of family history of MFS, the presence of one of any of the following criteria is diagnostic for MFS:
  - Aortic criterion (aortic diameter Z ≥2 or aortic root dissection) and ectopia lentis*
  - Aortic criterion (aortic diameter Z ≥2 or aortic root dissection) and a causal *FBN1* mutation
  - Aortic criterion (aortic diameter Z ≥2 or aortic root dissection) and a systemic score ≥7 points*

- Ectopia lentis and a causal *FBN1* mutation that has been identified in an individual with aortic aneurysm

- In the presence of family history of MFS (as defined by the above criteria), the presence of one of any of the following criteria is diagnostic for MFS:
  - Ectopia lentis
  - Systemic score ≥7 points*
  - Aortic criterion (aortic diameter Z ≥2 above 20 years old, Z ≥3 below 20 years, or aortic root dissection) *

For criteria with an asterisk (*), the diagnosis of MFS can be made only in the absence of discriminating features of Shprintzen-Goldberg syndrome, Loeys-Dietz syndrome, or vascular Ehlers-Danlos syndrome **and** after *TGFBR1/2*, collagen biochemistry, or *COL3A1* testing if indicated.

Systemic score — The revised Ghent nosology includes the following scoring system for systemic features (Loeys et al., 2010; Wright & Connolly, 2023):

- Wrist AND thumb sign: 3 points
- Wrist OR thumb sign: 1 point
- Pectus carinatum deformity: 2 points
- Pectus excavatum or chest asymmetry: 1 point
- Hindfoot deformity: 2 points
- Plain pes planus: 1 point
- Pneumothorax: 2 points
- Dural ectasia: 2 points
- Protrusio acetabuli: 2 points
- Reduced upper segment/lower segment ratio AND increased arm span/height AND no severe scoliosis: 1 point
- Scoliosis or thoracolumbar kyphosis: 1 point
- Reduced elbow extension (≤170 degrees with full extension): 1 point
- Facial features (at least three of the following five features: dolichocephaly, malar hypoplasia, enophthalmos, downslanting palpebral fissures, retrognathia): 1 point
- Skin striae: 1 point
- Myopia >3 diopters: 1 point
- Mitral valve prolapse: 1 point

Note 2: Clinical features of Loeys-Dietz Syndrome: aortic/arterial aneurysms/tortuosity, arachnodactyly, bicuspid aortic valve and patent ductus arteriosus, blue sclerae, camptodactyly, cerebral, thoracic or abdominal arterial aneurysms and/or dissections, cleft palate/bifid uvula, club feet, craniosynostosis, easy bruising, joint hypermobility, ocular hypertelorism, pectus carinatum or pectus

excavatum, scoliosis, talipes equinovarus, thin skin with atrophic scars, velvety and translucent skin, widely spaced eyes (Loeys & Dietz, 2018).

Note 3: Clinical features of Vascular EDS (vEDS) from The 2017 International Classification For The Ehlers-Danlos Syndromes (Malfait et al, 2017):

- Inheritance
  Autosomal dominant
- Major criteria
  1. Family history of vEDS with documented causative variant in *COL3A1*
  2. Arterial rupture at a young age
  3. Spontaneous sigmoid colon perforation in the absence of known diverticular disease or other bowel pathology
  4. Uterine rupture during the third trimester in the absence of previous C-section and/or severe peripartum perineum tears
  5. Carotid-cavernous sinus fistula (CCSF) formation in the absence of trauma
- Minor criteria
  6. Bruising unrelated to identified trauma and/or in unusual sites such as cheeks and back
  7. Thin, translucent skin with increased venous visibility
  8. Characteristic facial appearance
  9. Spontaneous pneumothorax
  10. Acrogeria
  11. Talipes equinovarus
  12. Congenital hip dislocation
  13. Hypermobility of small joints
  14. Tendon and muscle rupture
  15. Keratoconus
  16. Gingival recession and gingival fragility
  17. Early onset varicose veins (under age 30 and nulliparous if female)
- Minimal criteria suggestive for vEDS:
  A family history of the disorder, arterial rupture or dissection in individuals less than 40 years of age, unexplained sigmoid colon rupture, or spontaneous pneumothorax in the presence of other features consistent with vEDS should all lead to diagnostic studies to determine if the individual has vEDS. Testing for vEDS should also be considered in the presence of a combination of the other "minor" clinical features listed above.

Note 4: For 5 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

Note 5: Clinical features of Hypermobile EDS (hEDS) from The 2017 International Classification For The Ehlers-Danlos Syndromes (Malfait et al, 2017):

- Inheritance
  Autosomal dominant
- Molecular basis
  Unknown
- Clinical diagnosis

Clinical spectrum ranging from asymptomatic joint hypermobility, through "non-syndromic" hypermobility with secondary manifestations, to hEDS (*see "A Framework for the Classification of Joint Hypermobility and Related Conditions" by Castori et al., this issue*).

The clinical diagnosis of hEDS needs the simultaneous presence of criteria 1 AND 2 AND 3:

Criterion 1: Generalized Joint Hypermobility (GJH)

Criterion 2: Two or More Among the Following Features (A–C) MUST Be Present (for Example: A and B; A and C; B and C; A and B and C)

Feature A: systemic manifestations of a more generalized connective tissue disorder (a total of five must be present)

1. Unusually soft or velvety skin
2. Mild skin hyperextensibility
3. Unexplained striae such as striae distensae or rubrae at the back, groins, thighs, breasts and/or abdomen in adolescents, men or prepubertal women without a history of significant gain or loss of body fat or weight
4. Bilateral piezogenic papules of the heel
5. Recurrent or multiple abdominal hernia(s) (e.g., umbilical, inguinal, crural)
6. Atrophic scarring involving at least two sites and without the formation of truly papyraceous and/or hemosideric scars as seen in classical EDS
7. Pelvic floor, rectal, and/or uterine prolapse in children, men, or nulliparous women without a history of morbid obesity or other known predisposing medical condition
8. Dental crowding and high or narrow palate
9. Arachnodactyly, as defined in one or more of the following: (i) positive wrist sign (Steinberg sign) on both sides; (ii) positive thumb sign (Walker sign) on both sides
10. Arm span-to-height ≥1.05
11. Mitral valve prolapse (MVP) mild or greater based on strict echocardiographic criteria
12. Aortic root dilatation with Z-score > +2

Feature B: positive family history, with one or more first degree relatives independently meeting the current diagnostic criteria for hEDS.

Feature C: musculoskeletal complications (must have at least one)

1. 1.Musculoskeletal pain in two or more limbs, recurring daily for at least 3 months
2. 2.Chronic, widespread pain for ≥3 months
3. Recurrent joint dislocations or frank joint instability, in the absence of trauma (a or b)
   a. Three or more atraumatic dislocations in the same joint or two or more atraumatic dislocations in two different joints occurring at different times
   b. Medical confirmation of joint instability at two or more sites not related to trauma

Criterion 3: All the Following Prerequisites MUST Be Met

1. Absence of unusual skin fragility, which should prompt consideration of other types of EDS
2. Exclusion of other heritable and acquired connective tissue disorders, including autoimmune rheumatologic conditions. In patients with an acquired connective tissue disorder (e.g., lupus, rheumatoid arthritis, etc.), additional diagnosis of hEDS requires meeting both Features A and B of Criterion 2. Feature C of Criterion 2 (chronic pain and/or instability) cannot be counted towards a diagnosis of hEDS in this situation.
3. Exclusion of alternative diagnoses that may also include joint hypermobility by means of hypotonia and/or connective tissue laxity. Alternative diagnoses and diagnostic categories include, but are not limited to, neuromuscular disorders (e.g., myopathic EDS, Bethlem myopathy), other HCTD (e.g., other types of EDS, Loeys–Dietz syndrome, Marfan syndrome), and skeletal dysplasias (e.g., OI). Exclusion of these considerations may be based upon history, physical examination, and/or molecular genetic testing, as indicated.

IV. Table of Terminology

Term	Definition
AAP	American Academy of Pediatrics
AATS	American Association for Thoracic Surgery
ACC	American College of Cardiology
ACCF	American College of Cardiology Foundation
ACMG	American College of Medical Genetics
ACR	American College of Radiology
ACTA2	*Actin alpha 2, smooth muscle gene*
AD	Autosomal dominant

ADAMTS2	*ADAM metallopeptidase with thrombospondin type 1 motif 2 gene*
aEDS	Arthrochalasia Ehlers-Danlos syndrome
AHA	American Heart Association
AngII	Angiotensin II
AR	Autosomal recessive
ARBs	Angiotensin receptor blockers
ASA	American Stroke Association
ATR1	Angiotensin II receptor type 1
B3GALT6	*Beta-1,3-galactosyltransferase 6* gene
B4GALT7	*Beta-1,4-galactosyltransferase 7* gene
BAV	Bicuspid aortic valve
BCS	Brittle cornea syndrome
C	Carboxy
C1R	Complement C1r
C1S	Complement C1s
CCS	Canadian Cardiovascular Society
CCSF	Carotid-cavernous sinus fistula
cEDS	Classical Ehlers-Danlos syndrome
CHST14	*Carbohydrate sulfotransferase 14* gene
clEDS	Classical-like Ehlers-Danlos syndrome
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid Services
CNV	Copy number variant
COL12A1	*Collagen type XII alpha 1 chain* gene
COL1A1	*Collagen type I alpha 1 chain* gene
COL1A2	*Collagen type I alpha 2 chain* gene
COL1A2 NMD	*Collagen type I alpha 2* gene nonsense-mediated mRNA decay
COL3A1	*Collagen type III alpha 1 chain* gene
CPD	Clinical provisional diagnosis
CT	Computerized tomography
cvEDS	Cardiac-valvular Ehlers-Danlos syndrome
CVS	Chorionic villus sampling
D4ST1	Dermatan 4-sulfotransferase-1 protein
dEDS	Dermatosparaxis Ehlers-Danlos syndrome
DNA	Deoxyribonucleic acid
DSE	*Dermatan sulfate epimerase* gene
EB	Epidermolysis bullosa
EDS	Ehlers-Danlos syndrome

EFEMP2	*EGF containing fibulin extracellular matrix protein 2* gene
EGF	*Epidermal growth factor*
ELN	*Elastin gene*
EM	Electron microscopy
FBN1	*Fibrillin-1* gene
FBN2	*Fibrillin-2* gene
FDA	Food and Drug Administration
FKBP14	*FKBP (FK506 binding protein) prolyl isomerase 14* gene
FKBP22	*FKBP (FK506 binding protein) prolyl isomerase 22* gene
FLNA	*Filamin A* gene
GAG	Glycosaminoglycan
GJH	Generalized joint hypermobility
HCTD	Heritable connective tissue disorders
hEDS	Hypermobile Ehlers-Danlos syndrome
HP	Hydroxylysyl-pyridinoline
HPLC	High-performance liquid chromatography
IFM	Immunofluorescence mapping
kEDS	Kyphoscoliotic
KRT14	*Keratin 14* gene
KRT5	*Keratin 5* gene
LDS	Loeys-Dietz syndrome
LDTs	Laboratory-developed tests
LH1	Lysyl hydroxylase 1
LOX	Lysyl oxidase gene
LP	Lysyl-pyridinoline
MCC	Meets coverage criteria
mcEDS	Musculocontractural Ehlers-Danlos syndrome
mEDS	Myopathic Ehlers-Danlos syndrome
MFS	Marfan syndrome
MLPA	Multiplex ligation-dependent probe amplification
MRI	Magnetic resonance imaging
MVP	Mitral valve prolapse
MYH11	*Myosin heavy chain 11* gene
MYLK	*Myosin light chain kinase* gene
NGS	Next-generation sequencing
NORD	National Organization for Rare Disorders
OI	Osteogenesis imperfecta
PCR	Polymerase chain reaction

pEDS	Periodontal Ehlers-Danlos syndrome
PGD	Preimplantation genetic diagnosis
PGT-M	Preimplantation genetic testing for monogenic diseases
PLEC	*Plectin gene*
PLOD1	*Procollagen-Lysine,2-Oxoglutarate 5-Dioxygenase 1* gene
PRDM5	*PR/SET Domain 5* gene
PRKG1	*Protein kinase cGMP-dependent 1* gene
RCT	Randomized controlled trial
RNA	Ribonucleic acid
SCA	Society of Cardiovascular Anesthesiologists
SCAI	Society for Cardiovascular Angiography and Interventions
SDS-PAGE	Sodium dodecyl sulphate–polyacrylamide gel electrophoresis
SIR	Society of Interventional Radiology
SKI	SKI proto-oncogene
SLC2A10	*Solute Carrier Family 2 Member 10* gene
SLC39A13	*Solute Carrier Family 39 Member 13* gene
SMAD3	*Mothers against decapentaplegic homolog 3* gene
SMAD4	*Mothers against decapentaplegic homolog 4* gene
SMC	Smooth muscle cell
spEDS	Spondylodysplastic Ehlers-Danlos syndrome
STS	Society of Thoracic Surgeons
SVM	Society for Vascular Medicine
TAD	Thoracic aortic disease
TAAD	Thoracic aortic aneurysm and dissection
TEM	Transmission electron microscopy
TGFB	*Transforming growth factor beta gene*
TGFB2	*Transforming Growth Factor B 2 Ligand* gene
TGFB3	*Transforming Growth Factor B 3 Ligand* gene
TGFBR	*Transforming growth factor beta receptor* gene
TGFBR1	*Transforming Growth Factor B Receptor I* gene
TGFBR2	*Transforming Growth Factor B Receptor II* gene
TGF-β	Transforming Growth Factor-B
TNXA	*Tenascin XA* (Pseudogene)
TNXB	*Tenascin XB* gene
vEDS	Vascular Ehlers-Danlos Syndrome
VUS	Variant of unknown significance
WES	Whole exome sequencing
WGS	Whole genome sequencing
ZIP13	Zrt- and Irt-like protein 13

ZNF469	*Zinc finger protein 469* gene

V. Scientific Background

Connective tissue helps to bind and support other types of tissue in the body. Unfortunately, many types of connective tissue afflictions exist, including more than 200 heritable connective tissue disorders (NIH, 2016) such as Marfan Syndrome (MFS), Ehlers-Danlos syndrome (EDS), Epidermolysis bullosa (EB), and Loeys-Dietz syndrome (LDS). Each disorder affects connective tissue in a different manner. Symptoms may include joint issues, bone growth problems, blood vessel damage, cranial structural problems, skin problems, and height issues (NIH, 2016).

Marfan Syndrome (MFS) was first described more than 100 years ago by a Parisian professor of pediatrics, Antoine-Bernard Marfan. He was the first to report the association of long slender digits with other skeletal abnormalities in a 5-year-old girl (Radke & Baumgartner, 2014). MFS is a fairly common condition with an incidence of about 1 in 3000 to 5000 individuals. MFS is a systemic disorder of connective tissue with significant clinical variability across a broad phenotypic continuum, ranging from mild isolated features to severe and rapidly progressive neonatal multiorgan disease (Faivre et al., 2007). Ocular findings include myopia, ectopia lentis, and an increased risk for retinal detachment, glaucoma, and early cataracts. Skeletal system symptoms include "bone overgrowth and joint laxity, disproportionately long extremities for the size of the trunk, overgrowth of the ribs, and scoliosis." The major cause of death in MFS results from cardiovascular system problems, including aortic root dilatation and rupture, mitral or tricuspid valve prolapse, and enlargement of the proximal pulmonary artery. Severe and prolonged regurgitation of the mitral or aortic valve can lead to left ventricular dysfunction and heart failure. Patients presenting with one isolated symptom are rare. However, with careful management, life expectancy approximates that of the general population (Dietz, 2017; Pyeritz, 2017; Wright & Connolly, 2023).

MFS primarily affects connective tissue, particularly the fibrillin component of the extracellular matrix. Fibrillins are large glycoproteins that form extracellular microfibrils that provide elasticity and structural support to tissues, modulate elastic fiber biogenesis and homeostasis, and regulate the bioavailability and activity of different growth factors (Davis & Summers, 2012; Grewal & Gittenberger-de Groot, 2018). Fibrillin-1 is an important matrix component of both elastic and nonelastic tissues (Wright & Connolly, 2023). Mutations can lead to impaired fibrillin-1 protein function, causing extracellular matrix integrity to fail (Grewal & Gittenberger-de Groot, 2018). These fibrillin-1 problems also cause smooth muscle cell (SMC) contractile dysfunction and dysregulation of the tensile strength of aortic tissue, which is a common finding in many cardiovascular conditions (Nataatmadja et al., 2003). Recent studies indicate a

role for SMC phenotype in the pathogenesis of MFS. Early phenotypic switch resulting from *FBN1* mutation appears to be associated with initiation of important metabolic changes in SMCs that contribute to subsequent pathology (Dale et al., 2017). Mutation in *FBN1* has been shown to dysregulate the transforming growth factor-β (TGF-β) pathway, as matrix sequestration of cytokines is crucial to their regulated activation and signaling (Bin Mahmood et al., 2017; Neptune et al., 2003).

EDS is a term that encompasses several rare genetic connective tissue disorders. Each disorder is characterized by specific features, including "skin hyperextensibility, joint hypermobility, and tissue fragility," and affects approximately 1 in 5000 individuals (Pauker & Stoler, 2023). EDS hypermobile type (hEDS) is the most common type of EDS. Unfortunately, the genetic basis for hEDS is still unknown, meaning that a genetic test to confirm diagnosis is not available for this subtype. As of 2017, an international forum has classified EDS into 13 different subtypes. The table below has been modified from Malfait et al. (2017) and lists all EDS types:

Clinical EDS Subtype	**Abbreviation**	**Inheritance Pattern**	**Genetic Bases**	**Protein**
Classical EDS	cEDS	AD (autosomal dominant)	Major: *COL5A1, COL5A1* Rare: *COL1A1*	Type V collagen Type I collagen
Classical-like EDS	clEDS	AR (autosomal recessive)	*TNXB*	Tenascin XB
Cardiac-valvula	cvEDS	AR	*COL1A2* (biallelic mutations that lead to *COL1A2* NMD and absence of pro α2(I) collagen chains)	Type I collagen
Vascular EDS	vEDS	AD	Major: *COL3A1* Rare: *COL1A1*	Type III collagen Type I collagen
Hypermobile EDS	hEDS	AD	Unknown	Unknown

Arthrochalasia EDS	aEDS	AD	*COL1A1, COL1A2*	Type I collagen
Dermatosparaxis EDS	dEDS	AR	*ADAMTS2*	ADAMTS-2
Kyphoscoliotic EDS	kEDS	AR	*PLOD1* *FKBP14*	LH1 FKBP22
Brittle Cornea syndrome	BCS	AR	*ZNF469* *PRDM5*	ZNF469 PRDM5
Spondylodysplastic EDS	spEDS	AR	*B4GALT7* *B3GALT6* *SLC39A13*	β4GalT7 β3GalT6 ZIP13
Musculocontractural EDS	mcEDS	AR	*CHST14* *DSE*	D4ST1 DSE
Myopathic EDS	mEDS	AD or AR	*COL12A1*	Type XII collagen
Periodontal EDS	pEDS	AD	*C1R* *C1S*	C1r C1s

This naming convention has also been adopted by The Ehlers Danlos Society (EDS, 2017), who previously used Villefranche nosology to classify EDS types. Unfortunately, no cure for EDS currently exists, and treatments may include physical therapy, braces, counseling, and pain medication (Pauker & Stoler, 2023).

Vascular EDS (vEDS) is characterized by "arterial aneurysm, dissection and rupture, bowel rupture, and rupture of the gravid uterus" and affects 1 in 50,000 to 200,000 individuals (Byers et al., 2017). These arterial aneurysms may be life threatening. As noted in the table above, this disorder is due to mutations in the *COL3A1* or *COL1A1* genes, with a sequence analysis of *COL3A1* thought to identify approximately 98% of vEDS cases (Malfait et al., 2017). A diagnosis depends on clinical features, including family history. Aneurysms occur in other types of EDS, including classical EDS (cEDS), due to vascular fragility (Malfait, 2018). Johansen et al. (2020) published a recent cross-sectional study with data collected from 18 patients with genetically verified vEDS and 34 patients with genetically verified LDS. The median age at diagnosis was 34 years. "Most respondents (87%) had cardiovascular surveillance visits, 58% yearly or more often, and still 29% had no antihypertensive medications (Johansen et al., 2020)."

LDS was first described in 2005 and is now considered an autosomal dominant connective tissue disorder characterized by "aortic aneurysms and generalized arterial tortuosity, hypertelorism, and bifid/broad uvula or cleft palate" (MacCarrick et al., 2014). LDS was initially characterized by mutations in the transforming growth factor β receptor I (*TGFBR1*) and transforming growth factor β receptor II (*TGFBR2*) genes;

however, additional genes have been identified, including the mothers against decapentaplegic homolog 3 (*SMAD3*) gene, the transforming growth factor β 2 ligand (*TGFB2*) gene, and the transforming growth factor β 3 ligand (*TGFB3*) gene (MacCarrick et al., 2014; Wright & Connolly, 2023). If a mutation is identified in all three genes, transforming growth factor-β (TGF-β) signaling is affected and patients typically exhibit similar craniofacial, cutaneous, cardiovascular, and skeletal features. Vascular involvement in LDS has recently been studied by Jud and Hafner (2019) who published a case study which followed a woman with a history of ectasias of the aortic arch, abdominal aorta, carotid bulbs, and common femoral arteries, as well as an asymptomatic aneurysm in superior mesenteric artery. In comparing surgical outcomes between those with LDS versus MFS, it was found that LDS patients had a greater likelihood of reoperation for aortic arch aneurysms than MFS patients, and that those with mutations in *TGFBR1* had higher rates of reoperation than those with *TGFBR2* mutations (Seike et al., 2020).

Epidermolysis bullosa (EB) is a group of hereditary diseases characterized by mucosa and skin fragility due to mutations that affect skin structural proteins, causing the skin to easily blister. Four major types of EB have been identified and include EB simplex, junctional EB, dystrophic EB, and Kindler syndrome (Murrell, 2024). Unfortunately, there is currently no effective therapeutic option for this disorder, and treatment largely focuses on wound management. All of the major EB types may result from mutations in the keratin 5 (*KRT5*) or keratin 14 (*KRT14*) gene (Coulombe et al., 1991; NIH, 2020). These two genes work together to encourage strength in the epidermis. Mutations prevent the keratin from assembling in necessary networks, leading to fragility. Further, a rare type of EB, known as Ogna, has been associated with mutations in the *PLEC* gene, leading to issues in the attachment of the epidermis to other layers of the skin (NIH, 2020). Ryan et al. (2016) note that ventricular dysfunction and aortic dilation have been identified in patients with recessive dystrophic EB.

Clinical Utility and Validity

More than 90% of patients with the typical Marfan phenotype have mutations involving the gene encoding the connective tissue protein fibrillin-1 (*FBN1*). Out of a sample of 93 patients with MFS, 85 (91%) were found to have a *FBN1* mutation. The eight remaining patients did not display any drastically different clinical features or family history, and the authors suggest that *FBN1* mutations that go undetected are due to technical limitations (Loeys et al., 2004). Most patients have a family history of MFS, but up to 25% have a mutation *de novo*. Mutations are in one of five categories: nonsense, frameshift (deletion, insertion), splicing errors, a missense mutation that substitutes or creates cysteine residues, or a missense mutation affecting a conserved *EGF* sequence. Although the phenotypic variability is wide, mutations involving exon

skipping tend to result in more severe disease. Genetic findings have importance in the diagnosis, risk stratification, and clinical management of patients, as well as identifying potentially affected relatives (Wright & Connolly, 2023).

Becerra-Munoz et al. (2018) conducted a prospective cohort study to summarize variants in *FBN1* and establish a genotype-phenotype correlation. Genotype-phenotype correlations have identified that patients with MFS and truncating variants in *FBN1* presented a higher proportion of aortic events compared to a more benign course in patients with missense mutations. A total of 84 patients fulfilled the Ghent diagnostic criteria, and of these 84, 44 had missense mutations and 35 had truncating mutations. However, of the 44 with missense mutations, only six had suffered an aortic event (such as aortic aneurysm) whereas 20 of the 35 with a truncating mutation had suffered an aortic event (Becerra-Munoz et al., 2018). Up to 10% of patients with the Marfan phenotype have no identifiable mutation in the *FBN1* gene. Rather, mutations are identified in TGF-beta receptor 1 (*TGFBR1*) and *TGFBR2* genes. It has been proposed that patients with the Marfan phenotype and *TGFBR1* or *TGFBR2* mutations be classified as having LDS to properly address the potential for more aggressive vascular disease than seen in MFS (Wright & Connolly, 2023).

The diagnosis of MFS is now established by an *FBN1* pathogenic variant known to be associated with Marfan syndrome AND one of the following: aortic root enlargement (Z-score ≥2.0), ectopia lentis, demonstration of aortic root enlargement (Z-score ≥2.0) and ectopia lentis OR a defined combination of features throughout the body yielding a systemic score ≥7 (Dietz, 2017). These features are summarized in the 2010 Ghent nosology, which is slightly altered for patients under 20 years old (Wright & Connolly, 2023). Due to the identification of *FBN1* as the genetic basis for MFS and its subsequent effects, the understanding of MFS as a structural disorder has become one of a developmental abnormality with broad effects on the morphogenesis and function of multiple organ systems. Importantly, this also introduced new biological targets for treatment strategies in MFS (Dietz et al., 2005; Jensen & Handford, 2016).

Current clinical studies have elucidated a medical regimen for patients with MFS to help control the progression of cardiovascular manifestations and resulting mortality. The standard of care for medical management includes the use of β-blockers with supplementation or replacement by angiotensin receptor blockers (ARBs). However, the best course of treatment is a subject of ongoing research (Bin Mahmood et al., 2017; Hiratzka et al., 2010). However, a Cochrane review concluded, "Based on only one, low-quality RCT comparing long-term propranolol to no treatment in people with Marfan Syndrome, we could draw no definitive conclusions for clinical practice." The authors concluded that further, high-quality, randomized trials were needed to evaluate the long-term efficacy of beta-blocker treatment in people

with Marfan syndrome (Koo et al., 2017). Sellers et al. (2018) recently reported, "Despite promising preclinical and pilot clinical data, a recent large-scale study using antihypertensive angiotensin II (AngII) receptor type 1 (ATR1) blocker losartan has failed to meet expectations at preventing MFS-associated aortic root dilation, casting doubts about optimal therapy." Their mouse study suggested that "increased protective endothelial function, rather than ATR1 inhibition or blood pressure lowering, might be of therapeutic significance in preventing aortic root disease in MFS (Sellers et al., 2018)."

Johansen et al. (2020); Ritelli et al. (2020); Shalhub et al. (2020) analyzed vEDS data from 11 institutions between the year 2000 and 2015. Data used for this study included family history, clinical features, diagnostic criteria, demographics, and molecular testing results. A total of 173 individuals were identified for the purposes of this study, with 11 excluded because pathogenic *COL3A1* variants were not identified. Of the remaining individuals, 86 had been diagnosed with a pathogenic *COL3A1* variants, and 76 were diagnosed with only clinical criteria. "Compared with the cohort with pathogenic *COL3A1* variants, the clinical diagnosis only cohort had a higher number of females (80.3% vs 52.3%; P < .001), mitral valve prolapse (10.5% vs 1.2%; P = .009), and joint hypermobility (68.4% vs 40.7%; P < .001). Additionally, they had a lower frequency of easy bruising (23.7% vs 64%; P < .001), thin translucent skin (17.1% vs 48.8%; P < .001), intestinal perforation (3.9% vs 16.3%; P = .01), spontaneous pneumothorax/hemothorax (3.9% vs 14%, P.03), and arterial rupture (9.2% vs 17.4%; P = .13) (Shalhub et al., 2020)." This study highlights the importance of genetic testing for a vEDS diagnosis as the symptoms of vEDS overlap with many other disorders and a correct diagnosis is necessary for efficient disease treatment. Further, not all *COL3A1* variants are pathogenic, meaning that genetic results must be interpreted by a trained professional.

Using a next-generation sequencing (NGS) multigene panel, Mariath et al. (2019) identified 11 disease-causing variants of EB in a Brazilian population with an efficiency of 94.3%. Other studies that they have included have calculated efficiencies of 83.5% for a panel with 21 genes, 90% with 49 genes, and 97.7% in 21 genes, where all identified mutations were only in five genes. This conveys the clinical utility of gene variants in EB that could be translated to other connective tissue disorder mutations. In a study done with children with inherited EB, the accuracy of several diagnostic techniques, which included electron microscopy (EM), immunofluorescence mapping (IFM), and clinical provisional diagnosis (CPD) was evaluated. It was found that IFM, EM, and CPD yielded an accuracy of 75%, 75%, and 81.5%, respectively (Saunderson et al., 2019). All genetic components, tissue specimen, and clinical history are all necessary for a confirmed EB diagnosis.

Li et al. (2021) conducted a study in northwestern China to determine the genotype-phenotype correlation for thoracic aortic aneurysm and dissection via NGS. They screened 15 genes from 212 patients to find that 67 (31.60%) patients in this cohort had a (likely) pathogenic variant, "42 (19.81%) had a variant of uncertain significance (VUS), and 103 (48.58%) had no variant (likely benign/benign/negative)," with 135 reportable variants. With *FBN1*, a gene implicated in MFS, they found that "patients with truncating and splicing mutations are more prone to developing severe aortic dissection than those with missense mutations, especially frameshift mutations (82.76% vs. 42.86%)," and "the positive rate of genetic testing was higher in TAAD [thoracic aortic aneurysm and dissection] patients with family history than in those without (76.74% vs. 18.94%)".

Chen et al. (2021) investigated how genetic testing could aid in avoiding the occurrence of MFS among Chinese families. Using data from 11 families, as well as variant classification and interpretation through pedigree analysis, the researchers were able to support two families who agreed to pre-implantation genetic testing for monogenic diseases (PGT-M) as part of the *in vitro* fertilization process. They were able to identify 11 potential-disease causing *FBN1* variants and found that "nine variants were classified as likely pathogenic/pathogenic variants. Among 11 variants, eight variants were missense and seven of them were located in the Ca-binding *EGF*-like motifs. Moreover, half of them substituted conserved Cysteine residues." They also found one splice site variant, one frameshift variant, one synonymous variant, and two *de novo* variants. All variants were detected by polymerase chain reaction (PCR). Ultimately, the two MFS families were able to give birth to a baby without the *FBN1* mutation, as the healthy embryo was selected using haplotype analysis "to deduce the embryo's genotype by using single nucleotide polymorphisms." This demonstrated the tangible benefits of genetic testing for eliminating MFS and the development of comorbid conditions among future generations.

Damseh et al. (2022) conducted a retrospective study using the 2017 EDS classification criteria on 72 pediatric patients who were referred for evaluation of EDS. From this initial cohort, 18 patients met the clinical criteria for an EDS subtype diagnosis, and 15 were confirmed molecularly. 75% (n=54) of the patients also had clinical features that belonged to EDS and other joint hypermobility syndromes, but not a complete qualification of EDS clinical criteria. From those 54 patients, it was discovered that 12 patients (22%) had a molecular genetic diagnosis of EDS. An EDS genetic panel, microarray, whole exome sequencing, single gene sequencing, familial variant testing, and other genetic panels were utilized to confirm genetic based diagnoses of EDS. Of the 15 patients who met clinical criteria and had a positive molecular diagnosis and 12 that did not meet clinical criteria but had a positive molecular diagnosis, 41% had classical EDS, 26% had arthrochalasia EDS, 11% had kyphoscoliotic EDS, and 22% had

vascular EDS. The researchers ultimately "observed a correlation between generalized joint hypermobility, poor healing, easy bruising, atrophic scars, skin hyperextensibility, and developmental dysplasia of the hip with a positive molecular result." This study aided in expanding the scope of the 2017 EDS classifications into the pediatric population and effecting changes to clinical decision making and treatment.

Veatch et al. (2022) utilized clinical exam data and genetic testing results to understand the phenotypic and genotypic correlation for hereditary connective tissue diseases from 2016-2020. From a cohort of 100 unrelated individuals, the researchers isolated six likely pathogenic, and 35 classified "potentially pathogenic variants of unknown clinical significance." They found that those with potentially pathogenic variants and pathogenic/likely pathogenic variants of the same genes exhibited similar symptoms, as those with "connective tissue symptoms had suggestive evidence of increased odds of having skin (odds ratio 2.18, 95% confidence interval 1.12 to 4.24) and eye symptoms (odds ratio 1.89, 95% confidence interval 0.98 to 3.66) requiring further studies." Ultimately, the symptoms were broken up into classes of minimal skeletal symptoms (e.g., limb asymmetry, scoliosis, pes planus), more skeletal than connective tissue (e.g., joint hypermobility, dental defects, repeated ligament and cartilage disease), nervous, or gastrointestinal (e.g., irritable bowel syndrome, food intolerance) symptoms, and more nervous system (e.g., migraines, neuropathy) symptoms. Comprehending the spectrum of phenotypic heterogeneity could guide consequential clinical decision making for surveilling and counseling patients with hereditary connective tissue disorders and their current and future families (Veatch et al., 2022).

VI. Guidelines and Recommendations

American College of Cardiology (ACC)

The ACC released guidelines on thoracic aortic disease jointly with the American Association for Thoracic Surgery, American College of Radiology, American Stroke Association, Society of Cardiovascular Anesthesiologists, Society for Cardiovascular Angiography and Interventions, Society of Interventional Radiology, Society of Thoracic Surgeons, and Society for Vascular Medicine. The MFS-specific guidelines are listed below:

- An echocardiogram is recommended at the time of diagnosis of Marfan syndrome to determine the aortic root and ascending aortic diameters and six months thereafter to determine the rate of enlargement of the aorta.
- Annual imaging is recommended for patients with Marfan syndrome if stability of the aortic diameter is documented. If the maximal aortic diameter is 4.5 cm or greater, or if the aortic diameter shows significant growth from baseline, more frequent imaging should be considered.

- If a mutant gene (*FBN1*, *TGFBR1*, *TGFBR2*, *COL3A1*, *ACTA2*, *MYH11*) associated with aortic aneurysm and/or dissection is identified in a patient, first-degree relatives should undergo counseling and testing.
- Sequencing of other genes known to cause familial thoracic aortic aneurysms and/or dissection (*TGFBR1*, *TGFBR2*, *MYH11*) may be considered in patients with a family history and clinical features associated with mutations in these genes (Hiratzka et al., 2010).
- Aortic imaging is recommended in patients with LDS or a who have a confirmed genetic mutation known to predispose an individual to aortic aneurysms and aortic dissections (*TGFBR1, TGFBR2, FBN1, ACTA2*, or *MYH11*)

American Heart Association (Malfait et al.)

The AHA published a guideline regarding genetic testing for inherited cardiovascular diseases. The AHA notes that genetic testing plays a major role in diagnosing both Loeys-Dietz Syndrome and Marfan Syndrome, as well as confirming diagnoses of familial thoracic aortic aneurysm and dissection. A confirmed diagnosis may then affect timing of treatment or extent of screening for family members of the proband.

The AHA cites an ACMG list of "Genes Associated With Cardiovascular Disorders in Which Secondary/Incidental Findings Are Reportable". *COL3A1* is listed for Ehlers-Danlos Syndrome and *FBN1, TGFBR1, TGFBR2, SMAD3, ACTA2, MYH11* are listed for Marfan syndrome, Loeys-Dietz syndromes, and familial thoracic aortic aneurysms and dissections.

The AHA then lists another ACMG list of "Lists of Genes to Be Considered for Testing From Guidelines and Statements". Regarding heritable thoracic aortic aneurysm(s) or dissection(s), the genes *ACTA2, COL3A1, FBN1, MYH11, SMAD3, TGFB2, TGFBR1, TGFBR2, MYLK, LOX, PRKG1* are listed as having "definitive or strong evidence", and the genes *EFEMP2, ELN, FBN2, FLNA, NOTCH1, SLC2A10, SMAD4, SKI*, are considered as "potentially diagnostic" (Musunuru et al., 2020).

American College of Medical Genetics (ACMG)

The ACMG recommends the following diagnostic evaluations for a MFS diagnosis: a physical exam, family history, echocardiogram, dilated eye exam, CT or MRI, and the consideration of *FBN1* gene sequencing (Pyeritz, 2012). The ACMG notes that, since *FBN1* mutations may cause conditions other than MFS (such as EDS and LDS), clinical features must be used to diagnose MFS properly. The ACMG further notes *SMAD3*, *ACTA2*, and *MYH11* as potential genes of interest in identifying MFS, in addition to *FBN1*, *TGFBR1*, and *TGFBR2* (Pyeritz, 2012).

Regarding LDS, the ACMG notes that "LDS strongly resembles the vascular form of Ehlers–Danlos syndrome, especially in terms of thin skin" (Pyeritz, 2012). Further, a diagnostic evaluation of LDS includes the following: a "physical exam, family history, echocardiogram, dilated eye exam (to exclude MFS), magnetic resonance angiography of the head, neck thorax, abdomen and pelvis, and TGFBR1 and *TGFBR2* gene sequencing (Pyeritz, 2012)." Specifically, the ACMG states that "In a patient found to have consistent facial features, bifid uvula, and arterial tortuosity, the diagnosis [of LDS] can be confirmed with *TGFBR* testing (Pyeritz, 2012)."

Regarding EDS hypermobile type, the ACMG recommends the following diagnostic evaluation: a physical exam, family history, echocardiogram and dilated eye exam (to exclude MFS). The guidelines also specifically state that "Diagnosis is based on clinical evaluation and family history. A small subset of individuals with the hypermobile form of EDS have an insertion or deletion in the *TNXB* gene" (Pyeritz, 2012).

ACMG also published a statement titled "Recommendations for reporting of secondary findings in clinical exome and genome sequencing". In it, *COL3A1* is listed for Ehlers-Danlos Syndrome, vascular type, and *FBN1, TGFBR1, TGFBR2, SMAD3, ACTA2,* and *MYH11* were listed as relevant genes for aortopathies (Miller et al., 2022; Miller et al., 2021).

American Academy of Pediatrics (AAP)

The AAP has released guidelines on the management of supervision of children with MFS. However, they allude to genetic testing of *FBN1*, stating it is "best reserved" for patients with "strong clinical suspicion" of MFS. The AAP states that younger patients (18 and under) should be evaluated periodically instead of undergoing genetic testing (Tinkle & Saal, 2013).

The Marfan Foundation

The Marfan Foundation has released recommendations on certain aspects of testing for MFS. The Foundation mentions several situations in which genetic testing may be useful, such as patients with features of multiple disorders, patients with a clinical symptom characteristic of MFS (such as ectopia lentis), children of parents affected by MFS, or adults with MFS that are considering having children. Prenatal testing may be performed, either a chorionic villus sampling (CVS) at 10-11 weeks or amniocentesis at 16-18 weeks. However, the parent's mutation must be confirmed before proceeding with either prenatal test (Foundation, 2024).

Screening of first-degree relatives of patients with MFS is also warranted. Aortic imaging may be performed if the mutation has not been identified (Foundation, 2015).

The Ehlers Danlos Society and the International Consortium on the Ehlers-Danlos Syndromes

These guidelines state that Ehlers-Danlos syndrome "Molecular diagnostic strategies should rely on NGS technologies, which offer the potential for parallel sequencing of multiple genes. Targeted resequencing of a panel of genes, for example, *COL5A1*, *COL5A2*, *COL1A1* and *COL1A2*, is a time- and cost-effective approach for the molecular diagnosis of the genetically heterogeneous EDS. When no mutation (or in case of an autosomal recessive condition only one mutation) is identified, this approach should be complemented with a copy number variant (CNV) detection strategy to identify large deletions or duplications, for example Multiplex Ligation-dependent Probe Amplification (MLPA), qPCR, or targeted array analysis. Alternatively, or in a second phase, whole exome sequencing (Nataatmadja et al.) or whole genome sequencing (WGS) and RNA sequencing techniques can be used, with data-analysis initially focusing on the genes of interest for a given EDS subtype. In absence of the identification of a causal mutation, this approach allows to expand the analysis to other genes within the genome. This is particularly interesting in view of the clinical overlap between EDS subtypes and with other HCTDs, and the observation that in an important proportion of EDS-patients, no pathogenic variants are identified in any of the known EDS-associated genes (Malfait et al., 2017)."

For cEDS, the following guidelines were given:

- "Molecular screening by means of targeted resequencing of a gene panel that includes at least the *COL5A1, COL5A2, COL1A1*, and *COL1A2* genes, or by WES or WGS, is indicated. When no mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications.
  Absence of these confirmatory findings does not exclude the diagnosis, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques; however, alternative diagnoses should be considered in the absence of (a) *COL5A1, COL5A2, COL1A1*, or *COL1A2* mutation(s)" (Malfait et al., 2017).

For classical-like EDS (clEDS), the following guidelines were given:

- "Molecular analysis of the *TNXB* gene should be used as the standard confirmatory test. Difficulties in DNA testing are related to the presence of a pseudogene (*TNXA*), which is more than 97% identical to the 3′ end of *TNXB* (exons 32–44). With the only exception of exon 35, which partially shows a TNXB-specific sequence, exon and intron sequences in this region are identical or

almost identical in both the gene and the pseudogene. This has implications both for sequencing and deletion/duplication analysis.

- For sequence analysis of *TNXB*, two approaches are recommended.
  - Sanger sequencing of the entire *TNXB* gene.
  - Next-generation sequencing of *TNXB* + Sanger sequencing of the pseudogene region."
- If no or only one causative mutation is identified by classic sequencing, additional methods that allow detection of large deletions/duplications should be added. So far no method is able to specifically detect TNXB CNVs in the highly homologous exons 32–34 and 36–44. CNV analysis of exon 35 is currently used to detect deletions in this region, including the 30 kb deletion
- Absence of these confirmatory findings does not exclude the diagnosis, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques; however, alternative diagnoses should be considered in the absence of a TNXB mutation (Malfait et al., 2017)."

For cardiac-valvular EDS (cvEDS), the following recommendations were given:

- "Molecular screening by Sanger sequencing of *COL1A2*, or targeted resequencing of a gene panel that includes *COL1A2* is indicated. When no mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications.
- In case of unavailability of genetic testing, SDS PAGE demonstrates total absence of (pro-) α2(I) collagen chains.
- Whereas absence of these confirmatory biochemical findings allows to exclude the diagnosis of cvEDS, absence of these confirmatory genetic findings does not exclude the diagnosis, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques (Malfait et al., 2017)."

For vEDS, the following guidelines were given:

- "Molecular screening by Sanger sequencing of *COL3A1*, or targeted resequencing of a gene panel that includes *COL3A1* and *COL1A1* (the latter to identify the above-listed arginine-to-cysteine substitution mutations) is indicated. When no mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications.
- Absence of these confirmatory findings does not exclude the diagnosis, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques; however, alternative diagnoses should

be considered in the absence of a *COL3A1* or *COL1A1* mutation (Malfait et al., 2017)."

For hypermobile EDS (hEDS), the following guidelines were given:

- "The diagnosis of hEDS remains clinical as there is yet no reliable or appreciable genetic etiology to test for in the vast majority of patients (Malfait et al., 2017)."

For arthrochalasia EDS (aEDS), the following guideline were given:

- "Molecular screening by Sanger sequencing of *COL1A1* and *COL1A2*, or targeted resequencing of a gene panel that includes these genes, is indicated. When no mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications.
- In case of unavailability of genetic testing, SDS PAGE of the pepsin-digested collagen in the medium or cell layer of cultured dermal fibroblasts demonstrates the presence of a mutant pNα1(I) or pNα2(I) chain (precursor procollagen chains in which the carboxy (C)-but not the amino (N)-propetide is cleaved off).
- TEM of skin specimens shows loosely and randomly organized collagen fibrils with a smaller and more variable diameter, and an irregular outline. These findings may support the diagnosis, but cannot confirm it.
- Absence of a causative mutation in *COL1A1* or *COL1A2* that leads to complete or partial deletion of the exon 6 of either gene excludes the diagnosis of aEDS (Malfait et al., 2017)."

For dermatosparaxis EDS (dEDS), the following guidelines were given:

- "Molecular screening by Sanger sequencing of targeted resequencing of a gene panel that includes *ADAMTS2* is indicated. When no, or only one, causative mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications.
- In case of unavailability of genetic testing, SDS, PAGE demonstrates presence of pNα1(I) and pNα2(I) chains of type I procollagen extracted from dermis in the presence of protease inhibitors or detected in fibroblast cultures.
- TEM shows collagen fibrils in affected skin specimens with a hieroglyphic pattern. These ultrastructural findings are usually typical but may be almost indistinguishable from those observed in aEDS. As such, they are not sufficient to confirm the diagnosis.
- Absence of these confirmatory findings does not exclude the diagnosis of dEDS, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques; however, alternative diagnoses

should be considered in the absence of ADAMTS2 mutations (Malfait et al., 2017)."

For kyphoscoliotic (kEDS), the following recommendations were given:

- Laboratory confirmation of kEDS should start with the quantification of deoxypyridinoline (Dpyr or LP for lysyl-pyridinoline) and pyridinoline (Pyr or HP for hydroxylysyl-pyridinoline) cross-links in urine quantitated by means of high-performance liquid chromatography (HPLC). An increased Dpyr/Pyr ratio is a highly sensitive and specific test for kEDS caused by biallelic PLOD1 mutations (kEDS-PLOD1), but is normal for biallelic FKBP14 mutations (kEDS-FKBP14).
- The normal ratio of Dpyr/Pyr cross-links is approximately 0.2, whereas in kEDS-PLOD1 the ratio is significantly increased (approximately 10–40 times increase, range 2–9). This method is fast and cost-effective and it can also be used to determine the pathogenic status of a VUS in PLOD1.
- SDS–PAGE may detect faster migration of underhydroxylated collagen chains and their derivatives in kEDS-*PLOD1* but not in kEDS-*FKBP14*. However, abnormalities in migration can be subtle.
- Molecular analysis for kEDS-*PLOD1* may start with MLPA analysis of *PLOD1*, for the evaluation of the common intragenic duplication in PLOD1 caused by an Alu-Alu recombination between introns 9 and 16 (the most common mutant allele) [Hautala et al., 1993].
- Molecular screening by means of targeted resequencing of a gene panel that includes *PLOD1* and *FKBP14*, is indicated when MLPA of *PLOD1* fails to identify the common duplication. Such a gene panel my also include other genes associated with phenotypes that clinically overlap with kEDS, such as *ZNF469, PRDM5, B4GALT7, B3GALT6, SLC39A13, CHST14* and *DSE*. Alternatively, WES may be performed. When no, or only one, causative mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications in these genes.
- TEM on skin specimens has shown variable diameters and abnormal contours of the collagen fibrils and irregular interfibrillar space, but these abnormalities are not unique to this condition. As such, whereas TEM on a skin biopsy can support diagnosis, it cannot confirm it.
- Whereas absence of an abnormal urinary LP/HP ratio excludes the diagnosis of kEDS-PLOD1, absence of the confirmatory genetic findings does not exclude the diagnosis of kEDS, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques and/or other, yet to be discovered, genes, may be associated with this phenotype; however, alternative diagnoses should be considered in the absence of *PLOD1* or *FKBP14* mutations (Malfait et al., 2017)."

For brittle cornea syndrome (BCS), the following guidelines were given:

- "Molecular screening by means of targeted resequencing of a gene panel that includes ZNF469 and PRDM5 is indicated. Such a gene panel my also include other genes associated with phenotypes that clinically overlap with BCS, such as *PLOD1, FKBP14, B4GALT7, B3GALT6, SLC39A13, CHST14*, and *DSE*. Alternatively, WES may be performed. When no, or only one, causative mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications in these genes.
- Absence of these confirmatory findings does not exclude the diagnosis, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques, and other, yet unknown genes, might be associated with BCS (Malfait et al., 2017)."

For spondylodysplastic EDS (spEDS), the following guidelines were given:

- Molecular screening by means of targeted resequencing of a gene panel that includes *B4GALT7, B3GALT6*, and *SLC39A13* is indicated. Such a gene panel my also include other genes associated with phenotypes that clinically overlap with spEDS, such as *PLOD1, FKBP14, ZNF469, PRDM5, CHST14,* and *DSE*. Alternatively, WES may be performed. When no, or only one, causative mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications in these genes.
- For definite proof of GAG deficiency (*B4GALT7* and *B3GALT6* mutations), biochemical methods to assess GAG synthesis in patients' cultured fibroblasts are currently available in many specialized laboratories.
- The laboratory measurement of urinary pyridinolines, lysyl-pyridinoline (LP) and hydroxylysyl-pyridinoline (HP) quantitated by HPLC allows the detection of an increased ratio LP/HP to approximately 1, (compared to a normal value of approximately 0.2) in patients with mutations in *SLC39A13*. This fast and cost-effective method can also be used to determine the pathogenic status of a VUS (see also "verification of diagnosis" in kEDS-PLOD1).
- Absence of confirmatory genetic findings does not exclude the diagnosis of spEDS, as specific types of mutations (eg deep intronic mutations) may go undetected by standard diagnostic molecular techniques, and still other, yet to be discovered, genes may be associated with these phenotypes. In case no *B4GALT7*, *B3GALT6*, or *SCL39A13* mutations are identified, alternative diagnoses should however be considered (Malfait et al., 2017)."

For musculocontractural EDS (mcEDS), the following guidelines were given:

- "Molecular screening by means of targeted resequencing of a gene panel that includes *CHST14* and *DSE* is indicated. Such a gene panel my also include other genes associated with phenotypes that clinically overlap with mcEDS, such as *PLOD1, FKBP14, ZNF469, PRDM5*, *B4GALT7, B3GALT6* and *SLC39A13*. Alternatively, WES may be performed. When no, or only one, causative mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications in these genes.
- Absence of these confirmatory genetic findings does not exclude the diagnosis of mcEDS, as specific types of mutations (e.g., deep intronic mutations) may go undetected by standard diagnostic molecular techniques. In case no CHST14 or DSE mutations are identified, alternative diagnoses should be considered (Malfait et al., 2017)."

For myopathic EDS (mEDS), the following guidelines were given:

- "Molecular screening by means of targeted resequencing of a gene panel that includes *COL12A1* is indicated. Such a gene panel my also include other genes associated with phenotypes that clinically overlap with mEDS, such as *COL6A1*, *COL6A2*, *COL6A3*. Alternatively, WES may be performed. When no, or only one, causative mutation is identified, this approach should be complemented with a CNV detection strategy to identify large deletions or duplications in these genes.
- Absence of these confirmatory findings does not exclude the diagnosis, as specific types of mutations (eg deep intronic mutations) may go undetected by standard diagnostic molecular techniques, and other, yet to be discovered, genes may be associated with this phenotype (Malfait et al., 2017)."

For periodontal EDS (pEDS), the following guidelines were given:

- "Identification of known or compatible mutations by sequence analysis of C1R and C1S. Large deletions or null mutations that completely remove C1r or C1s protein function do not cause pEDS.
- At present it cannot be stated whether absence of a C1R or C1S mutations excludes the diagnosis because the experience with the molecular diagnosis is limited (Malfait et al., 2017)."

Canadian Cardiovascular Society (CCS)

The CCS has published recommendations for MFS stating a strong recommendation for clinical and genetic screening for anyone with suspected MFS "to clarify the nature of the disease and provide a basis for individual genetic counseling" (Boodhwani et al., 2014).

The CCS also published recommendations for non-Marfan genetic forms of aortic disease such as thoracic aortic disease (TAD). These guidelines state that "We recommend screening for TAD-associated genes in non-BAV aortopathy index cases to clarify the origin of disease and improve clinical and genetic counselling (Boodhwani et al., 2014)." These guidelines also state that individuals with a known LDS mutation (such as *TGFBR1/2*, *TGFB*, *SMAD3*, *ACTA2*, or *MYH11*) should receive complete aortic imaging when diagnosed and 6 months after diagnosis.

International Group of Specialists with a Broad Aggregate Experience in the Care of Individuals with Vascular EDS

Recommendations made by this group of vEDS specialists recommend to "identify causative variants in *COL3A1* prior to [the] application of diagnosis" of vEDS (Byers et al., 2017).

National Organization for Rare Disorders (NORD)

NORD has posted recommendations on EB stating that "When EB is suspected, a skin biopsy should be obtained and sent to an appropriate laboratory to confirm the diagnosis with transmission electron microscopy (TEM) and/or immunofluorescent antibody/antigen mapping. Molecular genetic testing for mutations in most of the genes known to be associated with the various types of EB is clinically available" (NORD, 2024).

On the diagnosis of EDS, the NORD has stated that diagnosis is generally made using patient histories and clinical findings, and that genetic testing can help in the diagnosis of some subtypes. Electron microscopic analysis could also aid in revealing the collagen abnormalities seen in EDS. "The clinical evaluation of individuals with suspected or diagnosed EDS typically includes assessments to detect and determine the extent of skin and joint hyperextensibility." The NORD also posted recommendations of utilizing computerized tomography (Musunuru et al.) scanning, magnetic resonance imaging (MRI), and echocardiography to observe any mitral valve prolapse and aortic dilatation. On kEDS, NORD has written of confirmatory tests using "either a urine sample and extrapolated ratio of deoxypyridinoline to pyridinoline cross-links, or on a skin biopsy sample and measurement of lysyl hydroxylase enzyme activity from skin fibroblast cells" (NORD, 2021)

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state

coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81405	Molecular pathology procedure, Level 6 Genes: ***TGFBR1*** (transforming growth factor, beta receptor 1) (eg, Marfan syndrome), full gene sequence ***TGFBR2*** (transforming growth factor, beta receptor 2) (eg, Marfan syndrome), full gene sequence
81408	Molecular pathology procedure, Level 9 Genes: ***FBN1*** (fibrillin 1) (eg, Marfan syndrome), full gene sequence
81410	Aortic dysfunction or dilation (eg, Marfan syndrome, Loeys Dietz syndrome, Ehler Danlos syndrome type IV, arterial tortuosity syndrome); genomic sequence analysis panel, must include sequencing of at least 9 genes, including FBN1, TGFBR1, TGFBR2, COL3A1, MYH11, ACTA2, SLC2A10, SMAD3, and MYLK
81411	Aortic dysfunction or dilation (eg, Marfan syndrome, Loeys Dietz syndrome, Ehler Danlos syndrome type IV, arterial tortuosity syndrome); duplication/deletion analysis panel, must include analyses for TGFBR1, TGFBR2, MYH11, and COL3A1

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Cystic Fibrosis

Policy Number: AHS – M2017 – Genetic Testing for Cystic Fibrosis	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Cystic fibrosis (CF) is an autosomal recessive genetic disease in which dysfunctional epithelial chloride channels lead to excessively thick mucus affecting multiple organ systems. Common complications include mucous plugging of the airway, lung inflammation, chronic pulmonary infections, intestinal malabsorption, pancreatic insufficiency, and infertility (Pritchard, 2016).

When pursuing genetic testing for cystic fibrosis, genetic counseling is strongly recommended.

For guidance on pre-implantation genetic testing, please see AHS-M2039-Pre-Implantation Genetic Testing. For guidance on prenatal screening and preconception screening for cystic fibrosis, please see AHS-M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title
AHS-M2039	Pre-Implantation Genetic Testing
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Common variant testing (see Note 1) or comprehensive gene sequencing for mutations in the *CFTR* gene **MEETS COVERAGE CRITERIA** in **any** of the following situations:
   a) In a newborn after an abnormal newborn screening result using immunoreactive trypsinogen.
   b) For infants with meconium ileus.
   c) For individuals with congenital absence of the vas deferens (CAVD).
   d) For individuals with idiopathic pancreatitis or bronchiectasis.

2) As an adjunct to sweat testing in an individual presenting with symptoms of cystic fibrosis, common variant testing (see Note 1) or comprehensive gene sequencing for mutations in the *CFTR* gene **MEETS COVERAGE CRITERIA** in **any** of the following situations:
   a) When there are no known familial mutations.
   b) When there are known familial mutations; testing must include the familial mutations.
   c) When only one familial mutation is known; testing should include the known familial mutation.

3) For individuals with congenital bilateral absence of the vas deferens (CBAVD), common variant testing (see Note 1) or comprehensive gene sequencing for mutations in the *CFTR* gene, including testing for the *CFTR* IVS8 5T/7T/9T variant, **MEETS COVERAGE CRITERIA**.

4) When the *CFTR* R117H mutation is detected on carrier screening, reflex genetic testing for the *CFTR* IVS8 5T/7T/9T variant **MEETS COVERAGE CRITERIA**.

5) For individuals for whom common variant testing (see Note 1) identified no mutations or only one mutation, but for whom the clinical suspicion of cystic fibrosis still remains, comprehensive sequencing of the *CFTR* gene **MEETS COVERAGE CRITERIA** in **any** of the following situations:
   a) For individuals that presented with symptoms of cystic fibrosis and who received panel testing as an adjunct to sweat testing.
   b) When a diagnosis of cystic fibrosis related CBAVD remains a consideration in individuals with CBAVD.

6) For all other situations not described above, genetic testing for mutations in the *CFTR* gene **DOES NOT MEET COVERAGE CRITERIA**.

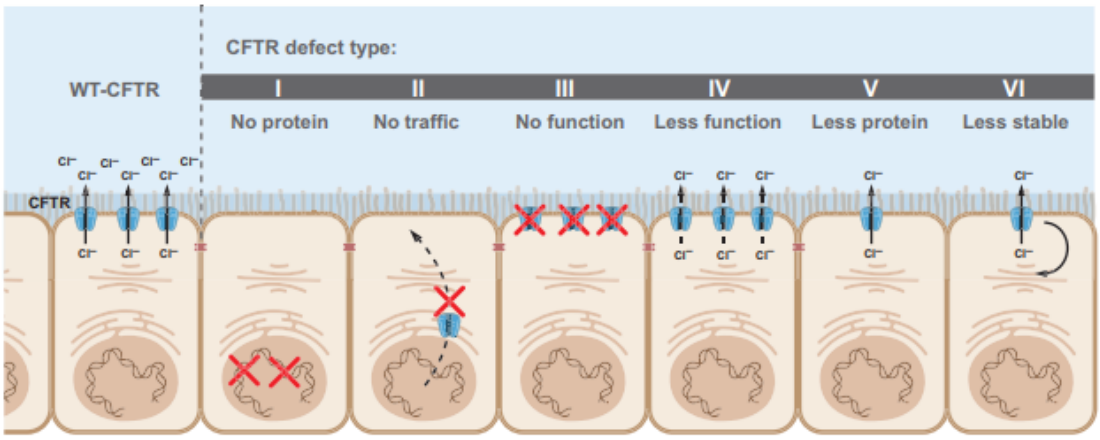
NOTES:

Note 1: Common variant testing for *CFTR* mutations must include the American College of Medical Genetics' (ACMG) *CFTR* carrier screening variant set (n=100). Please see the "Guidelines and Recommendations" section of this policy for a table of ACMG's *CFTR* minimum variant set.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics
ACOG	American College of Obstetrics and Gynecology
CAVD	Congenital absence of the vas deferens
CBAVD	Congenital bilateral absence of the vas deferens
CF	Cystic fibrosis
CFCD	Cystic fibrosis carrier detection
CFF	Cystic Fibrosis Foundation
CFSPID	Cystic fibrosis screen positive inconclusive diagnosis
CFTR	Cystic fibrosis transmembrane conductance regulator
CFTR2	Clinical and functional translation of CFTR
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CLSI	Clinical and Laboratory Standards Institute
CMS	Centers For Medicare and Medicaid
CPIC	Clinical Pharmacogenetics Implementation Consortium
CRMS	Customer relationship management system
CVS	Chorionic villus sampling
DNA	Deoxyribonucleic acid
ECFS	European Cystic Fibrosis Society
FDA	Food and Drug Administration
FEV1	Forced expiratory volume in 1 second

ICM	Intestinal current measurement
IRT	Immunoreactive trypsinogen
IVA	Ivacaftor
LDT	Laboratory-developed test
LUM	Lumacaftor
MMWR	Morbidity And Mortality Weekly Report
MVCC	Mutation of varying clinical consequence
NBS	Newborn screening
NGS	Next generation sequencing
NICE	National Institute for Health and Care Excellence
NPD	Nasal potential difference
NSGC	National Society of Genetic Counselors
PCR	Polymerase chain reaction
PCRM	Physicians Committee for Responsible Medicine
PCS	Cystic fibrosis carrier screening
QALY	Quality adjusted life year
RT-PCR	Reverse transcription polymerase chain reaction
TDAS	XTAG Data Analysis Software
TDN	Therapeutics Development Network
TOP	Termination of pregnancy
UNK	Uncharacterized mutation
VUS	Variant of uncertain significance



V. Scientific Background

Cystic fibrosis (CF) is a common life-limiting autosomal recessive genetic disorder caused by the mutation of a gene that encodes an epithelial chloride-conducting transmembrane channel called the cystic fibrosis transmembrane conductance regulator (CFTR). This gene regulates anion (negatively charged ion) transport and mucociliary clearance. Mucociliary clearance is the process by which particles and gases dissolved in the mucus are moved unidirectionally from the respiratory tract. The CFTR protein was first identified as a chloride channel but has been shown to facilitate or regulate the transport of other ions, such as sodium, thiocyanate, bicarbonate, as well as water absorption and excretion (Clancy & Jain, 2012; Cohen-Cymberknoh et al., 2011). The CFTR protein is present in the epithelia of various tissues, including that of the lungs, sweat glands, gastrointestinal tract, and pancreas (Barrett et al., 2012). CFTR

dysfunction mainly affects epithelial cells; although, there is evidence of a role in immune cells.

Mutations in the *CFTR* gene which impede protein production, stability, or activity result in less available functional protein (Clancy & Jain, 2012). Functional failure of CFTR results in defective mucociliary clearance, chronic infection, and abnormal inflammatory response leading to progressive, irreversible lung damage (Cohen-Cymberknoh et al., 2011). Other manifestations of dysfunctional CFTR include pancreatic insufficiency and meconium ileus (Barrett et al., 2012). The early identification and treatment of patients by multidisciplinary teams have resulted in improvements in both quality of life and clinical outcomes in patients with cystic fibrosis, with life expectancy reaching 50 or even 60 years (Clancy & Jain, 2012).

Most mutations of the *CFTR* gene are missense alterations, but other mutations, deletions and insertions have been described (Bell et al., 2015). Missense mutations occur when a single nucleotide is changed, resulting in a different amino acid which may affect the overall protein functionality. To date, over 2000 mutations have been identified in the *CFTR* gene (CF Foundation, 2023). *CFTR* mutations can be divided into six classes according to their effects on protein function as depicted in the figure below (Bell et al., 2015).

Mutation examples	G542X (a) W1282X (a) 1717-1G (b)	F508del N1303K A561E	G551D S549R G1349D	R117H R334W A455E	A455E 3272-26A>G 3849+10 kb C>T	c.120del23 rF508del
Corrective therapy	Rescue synthesis	Rescue traffic	Restore channel activity	Restore channel activity	Correct splicing	Promote stability
Drug	Read-through compounds	Correctors	Potentiators	Potentiators	AONs Correctors Potentiators	Stabilizers
Drug approved (Yes/No)	No	No	Yes	No	No	No

Class I, II, and III mutations are associated with no residual CFTR function and patients with these mutations have a severe phenotype, whereas individuals with class IV, V, and VI mutations have some residual function of CFTR protein and have a mild lung phenotype and pancreatic sufficiency (Bell et al., 2015; Wilschanski et al., 1995).

Due to the relatively high frequency in the U.S. population and studies demonstrating that early detection and care can improve outcomes, CF testing is included as part of the newborn screen in all states (Grosse et al., 2004). Newborn screening (NBS) for CF can include testing for immunoreactive trypsinogen (IRT), which is a pancreatic enzyme found at elevated levels in the blood of some individuals with CF, genetic testing for common CF mutations, or a combination of IRT and genetic testing. Positive newborn screens are typically followed by genetic testing (if not already done), and a sweat test, which measures the chloride concentration in sweat. The sweat test historically has been considered the "gold standard" for CF diagnosis. The presence of two disease-causing mutations also may be considered diagnostic of the disease, even in the absence of classic symptoms or in the case of a negative or inconclusive sweat test (Farrell et al., 2008).

In addition to NBS, CF carrier screening (PCS) has become commonplace in the U.S., particularly among pregnant individuals and couples planning a pregnancy. PCS has been found to markedly reduce CF birth rates with a shift towards milder mutations, but it was often avoided for cultural reasons necessitating the use of complementary PCS and NBS (Stafler et al., 2016).

A subset of 23 mutations accounts for most cystic fibrosis cases in the U.S. and were accepted by most guidelines as the primary genes to be screened for diagnosis of CF and carrier status. The most common CF-causing mutation is F508del, which is present in over 70% of known CF cases. The Clinical and Functional Translation of CFTR (CFTR2) project continually evaluates genotype and phenotype correlations and has confirmed many additional mutations as being causative of CF (CF Foundation, 2023). Information from over 88,000 patients with specific cystic fibrosis variants from the United States, Canada, and Europe was collected by the CFTR2 team from national CF Patient Registries and placed in the CFTR2 database and then compiled into the CFTR2 website that contains information about the 322 most common CFTR variants (CF Foundation, 2023).

Analysis of data from the CF Foundation Patient Registry found that patients of Hispanic, black, or Asian ancestry were less likely to have two identified *CFTR* variants and more likely to carry no mutations on the commonly used 23 mutation carrier screening panel (Schrijver et al., 2016). Analysis of the Exome Aggregation Consortium dataset also found that none of the current genetic screening panels or existing *CFTR* mutation databases covered most deleterious variants in any geographical population outside of Europe. Both clinical annotation and mutation coverage by commercially available targeted screening panels for CF are strongly biased toward detection of reproductive risk in persons of European descent (Lim et al., 2016). This research indicates the possible need for adjustment of this panel to facilitate equity in mutation detection between white and nonwhite or mixed-ethnicity CF patients, enabling an earlier diagnosis improving their quality of life.

Proprietary Testing

There are several cystic fibrosis genotyping assays approved by the FDA. eSensor Cystic Fibrosis Carrier Detection System detects 24 CFTR mutations (Coty, 2006), Tag-It™ Cystic Fibrosis Kit detects 39 mutations (FDA, 2006b), Cystic Fibrosis Genotyping Assay detects 30 mutations (FDA, 2007), InPlex™ CF Molecular Test detects 32 mutations (Hologic, 2008) , Verigene®CFTR and Verigene®CFTR PolyT Nucleic Acid Tests detect 26 mutations (FDA, 2009b), xTAG® Cystic Fibrosis 71 v2 Kit detects 71

mutations (Luminex, 2024) , and Illumina MiSeqDx™ Cystic Fibrosis 139-Variant Assay (Illumina, 2013).

Next generation sequencing (NGS) is also being integrated into CF diagnostic protocols. A diagnostic protocol in which a quick and relatively low-cost polymerase chain reaction (PCR)-based screening for the most common CF mutation, F508del, followed by full-gene next generation sequencing of *CFTR* was shown to improve genetic diagnosis and "holds promise to be a straightforward, convenient and rapid diagnostic protocol for CF patients" (Straniero et al., 2016). A study using NGS for NBS found that the NGS assay was 100% concordant with traditional methods. Retrospective analysis results indicate an IRT/NGS screening algorithm would enable high sensitivity, better specificity, and positive predictive value (Baker et al., 2016). Further, whole genome sequencing of the *CFTR* gene is also growing in popularity. This type of sequencing has revealed a high prevalence of the intronic variant c.3874-4522A>G in those affected by CF (Morris-Rosendahl et al., 2020).

Cystic fibrosis transmembrane conductance regulator (CFTR) modulators are a new class of medications targeting the underlying defect in CF by improving production, intracellular processing, and/or function of the defective CFTR protein. Ivacaftor (IVA), which improves chloride channel function, IVA combined with lumacaftor (LUM), which partially corrects the CFTR misfolding, and IVA combined with tezacaftor, which improves the intracellular processing and trafficking of CFTR, have been approved by the U.S. Food and Drug Administration for use in patients with CF. The indications and efficacy of these drugs depend upon the CFTR mutation in the individual patient. For example, ivacaftor has been FDA-approved and Clinical Pharmacogenetics Implementation Consortium (CPIC)-recommended only for CF patients with the *G551D* mutation. It is not recommended for any other CF mutation (Clancy et al., 2014).

Analytical Validity

Lyon et al. (2014) assessed clinical laboratories' proficiency at evaluating genetic alterations for CF. A total of 357 labs participated, performing approximately 120,000 tests monthly. Analytical sensitivity and specificity were 98.8% and 99.6%, respectively. Clinical interpretation matched intended response for zero, one, and two mutations. The authors concluded that laboratory testing for CF in the United States is of high quality (Lyon et al., 2014).

Sugunaraj et al. (2019) completed a cross-sectional study which included the analysis of *CFTR* variants in 50,778 exomes. Only 24 patients were identified to contain bi-allelic pathogenic *CFTR* variants; the authors identified 21 of these cases as true-positives and

three as potential false positives. Therefore, "genomic screening exhibited a positive predictive value of 87.5%, negative predictive value of 99.9%, sensitivity of 95.5%, and a specificity of 99.9%" (Sugunaraj et al., 2019). Overall, the presence and/or absence of *CFTR* variants was strongly related to a CF diagnosis.

Hendrix et al. (2020) assessed the performance of dried blood spot DNA extraction methods in NGS for cystic fibrosis. A total of 20 DNA samples were used in this study and sequenced using Illumina's MiSeqDx™ Cystic Fibrosis 139-Variant Assay and Swift Biosciences' Accel-Amplicon™ CFTR panel. The MiSeqDx CFTR Clinical Sequencing Assay identified 37 CF-causing variants in the 20 samples tested, for a total of 141 benign variants which were all confirmed with Sanger sequencing. The Swift Biosciences' Accel-Amplicon™ CFTR panel identified 39 CF-causing variants for a total of 123 benign variants which were all confirmed with Sanger sequencing. Illumina's MiSeqDx performed well with a very high average coverage per method (>3000×) despite most DNA extraction methods being low-concentration and relatively crude. Because of the higher input of samples on a single flow cell, the average coverage per target was lower in the Accel-Amplicon™ CFTR panel in comparison to the clinical sequencing assay, but still often had >1000× coverage. The authors conclude that "both these tests are appropriate DNA extraction methods that can be used with dried blood spots that will result in consistent, high-quality sequencing results" (Hendrix et al., 2020).

Sicko et al. (2021) validated the use of a custom NGS assay, Archer CF assay, for CF newborn screening. According to the New York State, CF NBS had high false positive rates. However, after the implementation of this three-tier IRT-DNA-SEQ approach using commercially available tests, the positive predictive value of CF NBS improved from 3.7% to 25.2%. The Archer CF assay involves full gene sequencing, analyzing a specific panel of 338 clinically relevant CFTR variants (second tier), followed by unblinding of all sequence variants and bioinformatic assessment of deletions/duplications (third tier). 227 infant samples were taken, and 190 of 227 carries one or more of the 338 panel variants. The second-tier panel variants were all called correctly, detecting 44 different variants with a 100% sensitivity and 100% specificity. All 227 samples also underwent third tier analysis which detected 62 additional unique SNV/indel variants (Sicko et al., 2021).

Clinical Utility and Validity

Sosnay et al. (2013) performed a comprehensive analysis of CF genotypes and phenotypes. The authors collected genotype and phenotype data from 39696 CF patients and found 159 variants with over 0.01% allele frequency, 127 of which met

both the clinical and functional criteria for CF. The phenotypic criterion used to define the pathogenic threshold was sweat chloride conductance of 10%. These 127 pathogenic genetic variants were estimated to represent 95.4% of CF alleles, leaving only 0.21% of CF patients without an identified pathological CFTR variant. The phenotypes of these variants vary (Sosnay et al., 2013).

Wainwright et al. (2015) evaluated the combination of IVA and LUM in CF patients homozygous for the *F508D* mutation (labeled Phe508del). A total of 1108 patients were examined. The mean baseline forced expiratory volume in one second "FEV1" was 61% of the predicted value. The absolute mean improvement in FEV1% was found to be 2.6-4%, which corresponded to a 4.3-6.7% relative treatment difference. The rate of pulmonary exacerbations was found to be 30-39% less in the treatment group compared to the placebo group. However, the rate of discontinuation due to an adverse event was 4.2% in the treatment group compared to the placebo group (Wainwright et al., 2015).

Sharma et al. (2018) performed a cost-effectiveness analysis of the FDA-approved IVA-LUM combination for the F508D mutation. The authors built a Markov-state model to assess the IVA-LUM for 12-year-old CF patients over several periods of time. "Markov states included mild CF (percentage of predicted forced expiratory volume in one second or FEV1 > 70%), moderate (FEV1 40–70%), severe (FEV1 < 40%) disease, post-transplant, and death. Pulmonary exacerbation and lung transplant were included as transition states." The IVA-LUM combination resulted in higher quality adjusted life years (QALY, 7.29 vs 6.84 for usual care) but at a cost of $1,778,920.88 per QALY compared to $116,155.76 for usual care. Both monetary amounts were over a 10-year period. The IVA-LUM combination was cost-effective at a threshold of $150,000 / QALY, which was estimated to occur at an annual drug cost of $4153 (Sharma et al., 2018).

Kessels et al. (2020) completed a systematic review of prenatal genetic testing for CF. Eight different databases were researched for this review. The authors found that after genetic testing "A change in clinical management was observed: termination of pregnancy (TOP) occurred in most cases where two pathogenic variants were identified in a fetus of carrier parents (158/167; 94.6%)" (Kessels et al., 2020). The authors conclude by stating that genetic testing for CF had good diagnostic performance and lead to fewer births affected by CF.

Avram et al. (2021) studied the cost-effectiveness of genotyping versus sequencing for prenatal CF carrier screening using three strategies: genotyping ("genotyping included the standard 23-variant panel recommended by ACMG/ACOG") both partners,

genotyping one partner then sequencing the second, and sequencing both partners. The authors used a decision-analytic model to generate a theoretical cohort of four million pregnant people and their partners. Sequencing both partners identified 1,099 carrier couples that would have been missed by genotyping of both partners, resulting in 273 fewer missed prenatal diagnoses, 152 more terminations, 152 fewer affected newborns, and screening with genotyping followed by sequencing identified 477 more carrier couples as compared to genotyping both partners, resulting in 119 fewer missed prenatal diagnoses, 66 more terminations, and 66 fewer affected newborns. The incremental cost-effectiveness ratio of genotyping followed by sequencing compared to genotyping both partners was $180,004/ quality-adjusted life year (QALY) and the incremental cost-effectiveness ratio of sequencing both partners compared to genotyping followed by sequencing was $17.6 million/QALY. "Compared to genotyping both partners, the cost per CF case averted for genotyping/sequencing was $1.2 million and sequencing both partners was $49.4 million. . . Sequencing both partners was cost-effective when the cost of sequencing fell below $339 per test. Genotyping/sequencing was cost-effective when the cost of sequencing was between $340 and 1837 per test. Lastly, genotyping both partners was cost-effective when sequencing cost above $1838 per test". The authors concluded that "before being routinely recommended, sequencing for CF carrier screening requires greater examination at a population-based level (Avram et al., 2021).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG)

The ACMG also recommends offering CF carrier screening to all individuals capable of becoming pregnant who are of reproductive age, regardless of ethnic background. Ideally, the testing would occur prior to pregnancy, but if the individual is pregnant, then they should be tested as early as possible during the pregnancy. ACMG also indicates that if the individual is found to be a CF carrier, then their reproductive partner should also be tested (Pletcher & Bocian, 2006). If the individual presents for testing late in the pregnancy, simultaneous testing of both reproductive partners of the fetus should be considered. When there is a paternal family history of CF, carrier testing of the father is warranted.

In 2020, the ACMG introduced technical guidelines for CFTR variant testing, particularly emphasizing considerations during pregnancy. These guidelines suggest that simultaneous testing might be necessary based on various factors like gestational age, family history, ethnicity, or patient preferences. Carrier testing is recommended for

individuals with a family history of CF, partners of those with such history, partners of males with CAVD, reproductive age women, and gamete donors. Additionally, CFTR variant testing can be conducted for prenatal diagnosis using cells obtained through procedures like amniocentesis or chorionic villus sampling (CVS). To ensure inclusivity, "the ACMG recommends either a classification-based reporting approach or a classification-based (targeted) testing approach (which has historically been used for CFTR carrier screening). For those laboratories who wish to continue using a targeted testing approach, the ACMG-23 variant panel remains as the minimum list of CFTR variants that should be included. Laboratories may want to consider adding additional variants to their panel depending on the ethnic composition of their expected test population. However, the minimum list of CFTR variants recommended for pan-ethnic carrier screening has not been increased at this time" (Deignan et al., 2020).

In 2023, the ACMG issued updated recommendations for CFTR carrier screening, introducing a new minimum CFTR variant set (Table 1) that replaces the previous set of 23 variants. These revised recommendations specifically apply to carrier screening and do not affect CFTR variant testing for diagnosis or newborn screening. However, all other aspects of the 2020 ACMG CFTR technical standards remain unchanged (Deignan et al., 2023).

Table 1 (adapted from Deignan et al. (2023)) : *CFTR* Carrier Screening Variant Set (n=100)

[a]Variants that were part of the previously recommended minimum 23-variant set.

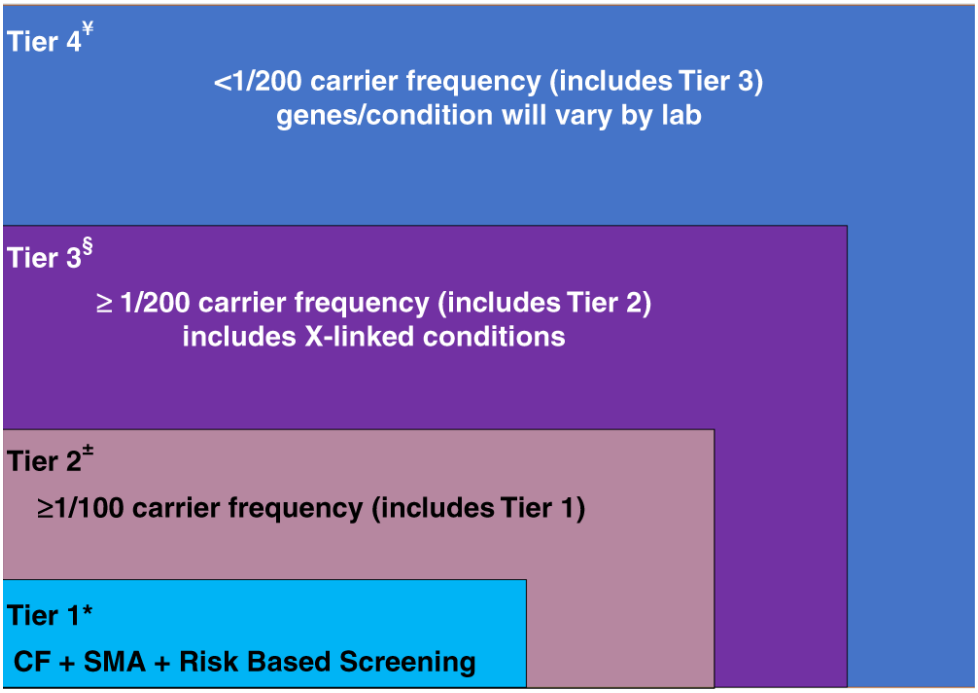
The ACMG also recommends that testing for the IVS8 polyT variant be performed only when carrier screening reveals a R117H mutation, as the polyT variant influences the clinical severity of the mutation but does not cause CF by itself (ACMG, 2011).

The ACMG provides guidance on indications for CFTR variant testing. Diagnostic testing can be used for the molecular confirmation of a clinical CF diagnosis, for infants with meconium ileus, for individuals with CAVD, individuals with idiopathic pancreatitis or bronchiectasis, and as a follow-up to newborn screening. Regarding carrier testing, ACMG recommends that carrier testing be offered to individuals with a positive family history of CF, to partners of individuals with a positive family history, to partners of individuals with CAVD, to reproductive age individuals capable of becoming pregnant, and to gamete donors (Deignan et al., 2020).

Prenatal testing can be performed using cells obtained for diagnostic cytogenetic testing (i.e., amniocentesis or chorionic villus sampling [CVS]). Testing can take place on cultured or uncultured amniocytes or villous trophoblasts. According to the guidelines, targeted sequencing for specific CFTR variants may be considered when:

a. "A pathogenic or likely pathogenic variant is confirmed in both partners.
b. A pathogenic or likely pathogenic variant is confirmed in one partner and a VUS or variant associated with variable expressivity is confirmed in the other partner
c. As part of preimplantation genetic testing when both biological parents are confirmed carriers of a pathogenic or likely pathogenic variant" (Deignan et al., 2020).

Comprehensive CFTR sequencing may be considered when:



a. "One member of a couple is known to be a carrier of a pathogenic or likely pathogenic variant and any of the following is also true:
    - The partner is unavailable for screening
    - The partner has not been screened and any of the following is also true:
        - Screening that partner would be cost prohibitive
        - The results from the partner would not be available in time to allow for reproductive decision making
        - A diagnostic procedure (e.g., CVS, amniocentesis) is also being performed for other reasons (e.g., ultrasound abnormality).
b. An ultrasound finding (i.e., fetal echogenic bowel) suggests an affected fetus and CFTR variant information is not available from either biological parent" (Deignan et al., 2020).

The ACMG recommends the following regarding testing of intronic variants, deletions/duplications, reporting VUS and variable expressivity, and reporting of intron 9 polyT and TG regions:

- "ACMG recommends the reporting of the c.2657+5G>A and c.3718–2477C>T intronic variants. If these variants are not detectable with the laboratory's methodology (e.g., exome sequencing), then a separate assay should be performed to test for these variants.
- For all prenatal, postnatal, and adult diagnostic testing and carrier screening indications for CFTR testing, the ACMG does not recommend the testing of any specific exon-level or gene-level deletion or duplication variants.

- For all prenatal, postnatal, and adult diagnostic testing indications for CFTR where comprehensive methods are used, the ACMG recommends the reporting of VUS. For all adult carrier screening indications for CFTR where comprehensive methods are used, VUS should generally not be reported. However, laboratories may want to consider reporting VUS in the partner of an individual who had a pathogenic or likely pathogenic variant detected during screening.
- For all prenatal, postnatal, and adult diagnostic testing indications for CFTR where comprehensive methods are used, the ACMG recommends the reporting of any variants associated with variable expressivity.
- For all prenatal, postnatal, and adult diagnostic testing indications for CFTR, the ACMG recommends the reporting of R117H status as well as the results from at least the associated polyT tract. For all adult carrier screening indications for CFTR, polyT status should be reported when the R117H variant is detected; laboratories may also want to consider reporting the results from the associated polyT tract in the partner of an individual who had a pathogenic or likely pathogenic variant detected during screening" (Deignan et al., 2020).

The ACMG released recommendations for preconception and prenatal carrier screening. The following tier-based approach to carrier screening was produced and recommendations were made (Gregg et al., 2021):

CF: cystic fibrosis, SMA: spinal muscular atrophy.

- Preconception screening is recommended over prenatal screening.
- Concurrent partner testing should be offered if testing done during pregnancy.
- Tier 3 screening is recommended which includes 97 autosomal recessive genes and 16 X-linked genes, including DMD and Fragile X.
- The second biological parent may be offered Tier 3 carrier screening (for autosomal recessive conditions) when carrier screening is being performed at the same time in their reproductive partner who is capable of becoming pregnant.
- All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening.
- Tier 4 screening should be considered when a pregnancy arises from a known or possible consanguineous relationship (second cousins or closer) or when a family or personal medical history warrants further risk assessment.
- ACMG does not recommend offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups and routine offering of Tier 4 panels (Gregg et al., 2021).

Cystic Fibrosis Foundation

The Cystic Fibrosis Foundation (Farrell et al., 2017) convened a group of to develop clear and actionable consensus guidelines on the diagnosis of CF and to clarify diagnostic criteria and terminology for other disorders associated with *CFTR* mutations. The experts determined that "diagnoses associated with *CFTR* mutations in all individuals, from newborn to adult, be established by evaluation of CFTR function with a sweat chloride test. The latest mutation classifications annotated in the Clinical and Functional Translation of CFTR project (http://www.cftr2.org/index.php) should be used to aid in diagnosis."

The committee approved 27 consensus statements (Farrell et al., 2017):

1	Sweat chloride testing should be performed according to approved procedural guidelines published in established, international protocols such as the CLSI 2009 Guidelines.
2	Newborns with a positive CF newborn screen, to increase the likelihood of collecting an adequate sweat specimen, should have the test performed

	bilaterally and when the infant weighs >2 kg, and is at least 36 wk of corrected gestational age.
3	Newborns greater than 36 wk gestation and >2 kg body weight with a positive CF newborn screen, or positive prenatal genetic test, should have sweat chloride testing performed as soon as possible after 10 d of age, ideally by the end of the neonatal period (4 wk of age).
4	In infants with presumptive CF identified through NBS, CF treatment should not be delayed while efforts to establish a diagnosis of CF are initiated.
5	Sweat chloride analysis should be performed within a few hours of sweat collection and the results and interpretations should be reported to clinicians and parents or patients, as soon as possible and certainly on the same day.
6	In individuals presenting with a positive newborn screen, clinical features consistent with CF, or a positive family history, a diagnosis of CF can be made if the sweat chloride value is ≥60 mmol/L.
7	Individuals who are screen-positive and meet sweat chloride criteria for CF diagnosis should undergo *CFTR* genetic testing if the *CFTR* genotype was not available through the screening process or is incomplete.
8	In individuals with a positive newborn screen, a sweat chloride <30 mmol/L indicates that CF is unlikely.
9	Individuals with clinical features that may be consistent with CF who have a sweat chloride <30 mmol/L indicates that CF is less likely. It may, however, be considered if evolving clinical criteria and/or *CFTR* genotyping support CF and not an alternative diagnosis.
10	Individuals presenting with a positive newborn screen, symptoms of CF, or a positive family history, and sweat chloride values in the intermediate range (30-59 mmol/L) on two separate occasions may have CF. They should be considered for extended *CFTR* gene analysis and/or CFTR functional analysis.

11 The latest classifications identified in the CFTR2 project (http://www.cftr2.org/index.php) should be used to aid with CF diagnosis:

CF-causing mutation: individuals with 2 copies on separate alleles will likely have CF (clinical sweat confirmation needed)
Mutation of varying clinical consequence (MVCC): a mutation that in combination with a CF-causing mutation or another MVCC mutation may result in CF
Uncharacterized mutation/mutation of UNK: mutation that has not been evaluated by CFTR2 and may be disease causing or of variable clinical consequence or benign
Non-CF-causing mutation: individuals with 1 or more are unlikely to have CF (as a result of that allele)

12 In individuals presenting with a positive newborn screen, symptoms of CF, or a positive family history, the identification of 2 CF-causing mutations (defined by CFTR2) is consistent with a diagnosis of CF. Sweat chloride testing is necessary, though, to confirm the diagnosis.

13 The absence of detection of 2 CF-causing *CFTR* mutations does not exclude a diagnosis of CF.

14 If further CF functional testing is needed (NPD and ICM), it should be performed in a validated reference center with trained staff certified by the CF Foundation TDN or ECFS Clinical Trial Network.

15 In individuals with a positive newborn screen but variable or uncharacterized *CFTR* mutations (<2 CF-causing mutations), the diagnosis of CF can be made by demonstrating CFTR dysfunction (a sweat chloride ≥ 60 mmol/L or CF-typical NPD or ICM).

16 The term CRMS is used in the US for healthcare delivery purposes and CFSPID is used in other countries, but these both describe an inconclusive diagnosis following NBS.

17 The term CRMS/CFSPID is reserved for individuals who screen positive without clinical features consistent with a diagnosis of CF.

18 The definition of CRMS/CFSPID is an infant with a positive NBS test for CF and either:

A sweat chloride value <30 mmol/L and 2 *CFTR* mutations, at least 1 of which has unclear phenotypic consequences

OR

An intermediate sweat chloride value (30-59 mmol/L) and 1 or 0 CF-causing mutations

19 Children designated as CRMS/CFSPID should undergo at least one repeat sweat chloride test at CF centers with suitable expertise, such as an accredited CF center.

20 Children designated as CRMS/CFSPID should have clinical evaluation performed by CF providers to identify the minority that may develop clinical symptoms.

21 Children designated as CRMS/CFSPID can be considered for extended *CFTR* gene analysis (sequencing and or deletion duplication testing), as well as CFTR functional analysis (NPD/ICM) testing to further define their likelihood of developing CF.

22 The decision to reclassify children designated as CRMS/CFSPID as CF is an integrated decision that should take into account functional assessment of CFTR (sweat chloride, and possibly NPD/ICM), *CFTR* genetic analysis, and clinical assessment by the CF clinicians caring for the patient.

23 Genetic counseling should be offered to families of individuals followed for CRMS/CFSPID, including a discussion of the risk in future pregnancies.

24 Research Recommendation: Infants with a designation of CRMS/CFSPID (by definition) do not have clinical features consistent with a diagnosis of CF and

	further research is needed to determine the prognosis and best practices for frequency and duration of follow-up.
25	For individuals presenting with CF symptoms, the same diagnostic criteria recommended for the screened population for sweat chloride testing, *CFTR* genetic analysis, and CFTR functional testing should be used to confirm a CF diagnosis.
26	The diagnosis of CFTR-related disorder has been defined as a monosymptomatic clinical entity (CBAVD/pancreatitis/bronchiectasis) associated with CFTR dysfunction that does not fulfill the diagnostic criteria for CF.
27	Clinicians should avoid the use of terms like classic/nonclassic CF, typical/atypical CF, delayed CF, because these terms have no harmonized definition and could be confusing for families or caregivers.

The Cystic Fibrosis Foundation (Ren et al., 2018) also convened a multidisciplinary committee of CF caregivers to develop evidence-based guidelines for CFTR modulator therapy. The committee defined patients with CF as individuals who met the above CFF criteria for diagnosis of CF, combined with evidence of abnormal CFTR function, as demonstrated by elevated sweat chloride, detection of two CF-causing CFTR mutations, or abnormal nasal potential differences.

For adults and children aged six years and older with CF due to gating mutations other than G551D or R117H, the guideline panel made a conditional recommendation for treatment with IVA. For those with the R117H mutation, the guideline panel made a conditional recommendation for treatment with IVA for *1*) adults aged 18 years or older, and *2*) children aged 6–17 years with a forced expiratory volume in one second (FEV_1) less than 90% predicted. For those with the R117H mutation, the guideline panel made a conditional recommendation against treatment with IVA for *1*) children aged 12–17 years with an FEV_1 greater than 90% predicted, and *2*) children less than six years of age. Among those with two copies of F508del, the guideline panel made a strong recommendation for treatment with IVA/LUM for adults and children aged 12 years and older with an FEV_1 less than 90% predicted; and made a conditional recommendation for treatment with IVA/LUM for *1*) adults and children aged 12 years

or older with an FEV_1 greater than 90% predicted, and *2*) children aged 6–11 years (Ren et al., 2018).

American College of Obstetrics and Gynecology (ACOG)

The ACOG recommends offering CF carrier screening to all individuals who are considering becoming pregnant or who are currently pregnant. Expanded mutation panels which enhance the sensitivity for carrier screening can be considered for carrier detection, especially in non-Caucasian ethnic groups, but testing should not be repeated if performed previously (e.g., during previous pregnancy). If the patient is found to be a carrier, then her partner should be tested. They also indicate that newborn screening is not a replacement for carrier screening in a population.

Prenatal diagnosis is indicated after genetic counseling if both parents are carriers, or if the mother is a carrier and the father is unknown or unavailable for testing.

The ACOG recommends that complete gene sequencing of the CTFR gene is not appropriate for use in carrier screening, rather reserved for patients with cystic fibrosis, patients with negative carrier screening but a family history of cystic fibrosis, individuals with congenital bilateral absence of the vas deferens, or newborns with a positive newborn screening after the standard 23 gene screen has a negative result.

They also recommend referral to genetic counseling for couples in which both partners are CF carriers, prenatal diagnosis, and advanced reproductive technologies to decrease the risk of affected offspring should be discussed (ACOG, 2017).

These statements were reaffirmed in 2023.

c.

National Society of Genetic Counselors (NSGC)

The National Society of Genetic Counselors (NSGC) recommends that for all individuals capable of becoming pregnant and who are of reproductive age, carrier screening for CG should be offered "regardless of ancestry; preferably pre-conceptionally. CF carrier testing should also be offered to any individual with a family history of CF and to partners of mutation carriers and people with CF" (Langfelder-Schwind et al., 2014).

Regarding what mutations should be included in the carrier screening test, the NSGC states, "Carrier testing panels should include the mutations recommended by ACOG

and ACMG. For individuals of non- Northern European descent, pan-ethnic panels that include additional mutations more commonly identified in minority populations are appropriate to consider. Focus general population CF screening practices on identifying carriers of established disease-causing CFTR mutations" (Langfelder-Schwind et al., 2014).

The NSGC agrees with the ACMG regarding testing for IVS 8 5T/7T/9T as a reflex when mutation R117H is found in the CF carrier screen. They also assert that "in the absence of an R117H mutation, assessment of the intron 8 polyT or TG tracts is not recommended for routine CF carrier testing" (Langfelder-Schwind et al., 2014).

European Cystic Fibrosis Society (ECFS)

The ECFS mentioned CFTR modulators in their standards of care guideline. Recommendations state that "in patients with the G551D mutation ivacaftor should be part of standard of care"; at the time of writing, only one CFTR modulator had been shown to "demonstrate clinical efficacy" (Smyth et al., 2014).

In 2018, the ECFS published a revised version of their best practice guidelines. The ECFS has published the following requirement to when providing a CF diagnosis:

- "To be able to perform genetic testing for the most appropriate panel of *CFTR* mutations for the local population. Access to extended exon DNA analysis should be available when required" (Castellani et al., 2018).

The ECFS also states that genetic counseling should be offered when reporting a CF diagnosis to a patient.

National Institute for Health and Care Excellence (NICE)

In 2017, the NICE published guidelines on the diagnosis and management of CF. NICE includes the following recommendations on CF diagnoses:

- "Be aware that cystic fibrosis can be diagnosed based on:
  - positive test results in people with no symptoms, for example infant screening (blood spot immunoreactive trypsin test) followed by sweat and gene tests for confirmation or
  - clinical manifestations, supported by sweat or gene test results for confirmation or
  - clinical manifestations alone, in the rare case of people with symptoms who have normal sweat or gene test results.

- Assess for cystic fibrosis and, when clinically appropriate, perform a sweat test (for children and young people) or a cystic fibrosis gene test (for adults) in people with any of the following:
  - family history
  - congenital intestinal atresia
  - meconium ileus
  - symptoms and signs that suggest distal intestinal obstruction syndrome
  - faltering growth (in infants and young children)
  - undernutrition
  - recurrent and chronic pulmonary disease, such as:
    - recurrent lower respiratory tract infections
    - clinical or radiological evidence of lung disease (in particular bronchiectasis)
    - persistent chest X-ray changes
    - chronic wet or productive cough
  - chronic sinus disease
  - obstructive azoospermia (in young people and adults)
  - acute or chronic pancreatitis
  - malabsorption
  - rectal prolapse (in children)
  - pseudo-Bartter syndrome.
- Refer people with suspected cystic fibrosis to a specialist cystic fibrosis center if:
  - they have a positive or equivocal sweat test result
  - their assessment suggests they have cystic fibrosis but their test results are normal
  - gene testing reveals 1 or more cystic fibrosis mutations" (NICE, 2017).

Physicians Committee for Responsible Medicine (PCRM)

The PSRM has published guidelines on diagnosis of cystic fibrosis. Below are the recommended guidelines:

1. A sweat chloride test can be performed as early as 48 hours after birth, which is the mainstay of laboratory confirmation.
2. Newborn Screening is mandatory in all 50 states.

A patient with symptoms may require a sweat chloride test or genetic testing. "Patients who exhibit signs and symptoms but do not have a positive sweat test should have a genetic test. Prenatal testing and newborn screening may be used. Early detection renders a better clinical course. While not widely available, nasal potential difference

measurements can confirm the diagnosis if sweat testing and genetic testing results are inconclusive" (PCRM, 2023).

Food and Drug Administration (FDA)

On March 28, 2006, the FDA approved eSensor Cystic Fibrosis Carrier Detection System as a device for the detection of carrier status for cystic fibrosis for all adult couples contemplating pregnancy, regardless of ethnicity. It is a qualitative genotyping assay that simultaneously detects mutations currently recommended by the American College of Medical Genetics and American College of Obstetricians and Gynecologists (ACMG/ACOG). The eSensor® CFCD System is not indicated for prenatal screening or to establish a diagnosis for cystic fibrosis (FDA, 2006a).

On June 7, 2006, the FDA approved Tag-It™ Cystic Fibrosis Kit as a device used to simultaneously detect and identify a panel of mutations and variants in the cystic fibrosis transmembrane conductance regulator (CFTR) gene in human blood specimens. The panel includes mutations and variants currently recommended by the American College of Medical Genetics and American College of Obstetricians and Gynecologists (ACMG/ACOG), plus some of the world's most common and North American-prevalent mutations. The Tag-It™ Cystic Fibrosis Kit is a qualitative genotyping test which provides information intended to be used for carrier testing in adults of reproductive age, as an aid in newborn screening, and two in confirmatory diagnostic testing in newborns and children (FDA, 2006b).

On September 9, 2007, the FDA approved Cystic Fibrosis Genotyping Assay as a qualitative in vitro diagnostic device used to genotype a panel of mutations and variants in the cystic fibrosis transmembrane conductance regulator (CFTR) gene in genomic deoxyribonucleic acid (DNA) isolated from human whole blood specimens. The panel includes mutations and variants recommended by the American College of Medical Genetics (ACMG, 2004) and the American College of Obstetricians and

Gynecologists (ACOG, 2005) plus additional multiethnic mutations. The Cystic Fibrosis Genotyping Assay provides information intended to be used for carrier testing in adults of reproductive age, as an aid in newborn screening and in confirmatory diagnostic testing of newborns and children. This test is not indicated for use in fetal diagnostic or pre-implantation testing. This test is also not indicated for stand-alone diagnostic purposes (FDA, 2007).

On March 13, 2008, the FDA approved InPlex™ CF Molecular Test as an in vitro diagnostic device used to simultaneously detect and identify a panel of mutations and variants in the cystic fibrosis transmembrane conductance regulator (CFTR) gene in genomic DNA samples isolated from human peripheral whole blood specimens. The panel includes mutations and variants recommended by the 2004 American College of Medical Genetics (ACMG). The InPlex™ CF Molecular Test is a qualitative genotyping test that provides information intended to be used for cystic fibrosis carrier screening as recommended by ACMG and the 2005 American College of Obstetricians and Gynecologists (ACOG) for adults of reproductive age, as an aid in newborn screening for cystic fibrosis, and in confirmatory diagnostic testing for cystic fibrosis in newborns and children. The test is not indicated for use in fetal diagnostic or pre-implantation testing. This test is also not indicated for stand-alone diagnostic purposes and results should be used in conjunction with other available laboratory and clinical information (FDA, 2008).

On July 6, 2009, the FDA approved eSensor® CF Genotyping Test as an in vitro diagnostic device used to simultaneously detect and identify a panel of mutations and variants in the cystic fibrosis transmembrane conductance regulator (CFTR) gene in genomic DNA samples isolated from human peripheral whole blood specimens. The panel includes mutations and variants recommended by the 2004 American College of Medical Genetics (ACMG). The eSensor® CF Genotyping Test is a qualitative genotyping test that provides information intended to be used for cystic fibrosis carrier screening as recommended by ACMG and the 2005 American College of Obstetricians and Gynecologists (ACOG) for adults of reproductive age, as an aid in newborn screening for cystic fibrosis, and in confirmatory diagnostic testing for cystic fibrosis in newborns and children. The test is not indicated for use in fetal diagnostic or pre-implantation testing. This test is also not indicated for stand-alone diagnostic purposes and results should be used in conjunction with other available laboratory and clinical information (FDA, 2009a).

On July 24, 2009, the FDA approved Verigene®CFTR and Verigene®CFTR PolyT Nucleic Acid Tests as qualitative in vitro diagnostic devices used to genotype a panel of mutations and variants in the cystic fibrosis transmembrane conductance regulator

(CFTR) gene in genomic DNA isolated from human peripheral whole blood specimens. The panel includes mutations and variants recommended by the 2004 American College of Medical Genetics (ACMG) and the 2005 American College of Obstetricians and Gynecologists (ACOG). The Verigene®CFTR Nucleic Acid Test provides information intended to be used for carrier testing in adults of reproductive age and in confirmatory diagnostic testing of newborns and children. These tests are not indicated for use in fetal diagnostic or pre-implantation testing and not indicated for stand-alone diagnostic purposes and the results should be used in conjunction with other available laboratory and clinical information (FDA, 2009b).

On December 11, 2009, the FDA approved xTAG® Cystic Fibrosis 60 Kit v2 as a device used to simultaneously detect and identify a panel of mutations and variants in the cystic fibrosis transmembrane conductance regulator (CFTR) gene in human blood specimens. The panel includes mutations and variants currently recommended by the American College of Medical Genetics and American College of Obstetricians and Gynecologists (ACMG/ACOG), plus some of the world's most common and North American prevalent mutations. The xTAG® Cystic Fibrosis 60 Kit v2 is a qualitative genotyping test which provides information intended to be used for carrier testing in adults of reproductive age, as an aid in newborn screening, and in confirmatory diagnostic testing in newborns and children. The kit is not indicated for use in fetal diagnostic or pre-implantation testing. This kit is also not indicated for stand-alone diagnostic purposes (FDA, 2009c). On December 15, 2016, a modification to this test was approved for new software thresholds for 2183/2184 variants (FDA, 2016b).

On November 19, 2013, the FDA approved Illumina MiSeqDx™ Cystic Fibrosis 139-Variant Assay is a qualitative in vitro diagnostic system used to simultaneously detect 139 clinically relevant cystic fibrosis disease-causing mutations and variants of the cystic fibrosis transmembrane conductance regulator (CFTR) gene in genomic DNA isolated from human peripheral whole blood specimens. The variants include those recommended in 2004 by the American College of Medical Genetics (ACMG) and in 2011 by the American College of Obstetricians and Gynecologists (ACOG). The test is intended for carrier screening in adults of reproductive age, in confirmatory diagnostic testing of newborns and children, and as an initial test to aid in the diagnosis of individuals with suspected cystic fibrosis. The results of this test are intended to be interpreted by a board-certified clinical molecular geneticist or equivalent and should be used in conjunction with other available laboratory and clinical information. This test is not indicated for use for newborn screening, fetal diagnostic testing, preimplantation testing, or for stand-alone diagnostic purposes (FDA, 2013b).

On November 19, 2013, the FDA also approved Illumina MiSeqDxTM Cystic Fibrosis Clinical Sequencing Assay as a targeted sequencing in vitro diagnostic system that re-sequences the protein coding regions and intron/exon boundaries of the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) gene in genomic DNA isolated from human peripheral whole blood specimens collected in K2EDTA. The test detects single nucleotide variants, and small InDels within the region sequenced, and additionally reports on two deep intronic mutations and two large deletions. The test is intended to be used on the Illumina MiSeqDx Instrument. The test is intended to be used as an aid in the diagnosis of individuals with suspected cystic fibrosis (CF). The test is most appropriate when the patient has an atypical or non-classic presentation of CF or when other mutation panels have failed to identify both causative mutations. The results of the test are intended to be interpreted by a board-certified clinical molecular geneticist or equivalent and should be used in conjunction with other available information including clinical symptoms, other diagnostic tests, and family history. This test is not indicated for use for stand-alone diagnostic purposes, fetal diagnostic testing, for pre-implantation testing, carrier screening, newborn screening, or population screening (FDA, 2013a).

On December 15, 2016, the FDA approved the XTAG Cystic Fibrosis 39 Kit V2 by Luminex Molecular Diagnostics, Inc. This test can identify the 23 CFTR mutations related to cystic fibrosis and could aid in carrier screening, newborn screening, and diagnostic testing (FDA, 2016a).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81220	CFTR (cystic fibrosis transmembrane conductance regulator) (e.g., cystic fibrosis) gene analysis; common variants (e.g., ACMG/ACOG guidelines)
81221	CFTR (cystic fibrosis transmembrane conductance regulator) (e.g., cystic fibrosis) gene analysis; known familial variants
81222	CFTR (cystic fibrosis transmembrane conductance regulator) (e.g., cystic fibrosis) gene analysis; duplication/deletion variants

CPT	Code Description
81223	CFTR (cystic fibrosis transmembrane conductance regulator) (e.g., cystic fibrosis) gene analysis; full gene sequence
81224	CFTR (cystic fibrosis transmembrane conductance regulator) (e.g., cystic fibrosis) gene analysis; intron 8 poly-T analysis (e.g., male infertility)
81479	Unlisted molecular pathology procedure
96040	Medical genetics and genetic counseling services, each 30 minutes face-to-face with patient/family
S0265	Genetic counseling, under physician supervision, each 15 minutes

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Diagnosis of Inherited Peripheral Neuropathies

Policy Number: AHS – M2072 – Genetic Testing for Diagnosis of Inherited Peripheral Neuropathies	Prior Policy Name and Number, as applicable: • AHS – M2124 - Charcot-Marie-Tooth Disease
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

The inherited peripheral neuropathies are a heterogeneous group of diseases that may be inherited in an autosomal dominant, autosomal recessive, or X-linked dominant manner. The inherited peripheral neuropathies can be divided into hereditary motor and sensory neuropathies (such as Charcot-Marie-Tooth disease), hereditary neuropathy with liability to pressure palsies, hereditary sensory and autonomic neuropathies, and other miscellaneous types (e.g., hereditary brachial plexopathy, giant axonal neuropathy). In addition to clinical presentation, nerve conduction studies, and family history, genetic testing can be used to diagnose specific inherited peripheral neuropathies (Kang, 2024c).

When pursuing genetic testing for inherited peripheral neuropathies, genetic counseling is strongly recommended.

II. Related Policies

Policy Number	Policy Title
AHS-M2112	Nerve Fiber Density Testing
AHS-M2145	General Genetic Testing, Germline Disorders
AHS-M2146	General Genetic Testing, Somatic Disorders
AHS-M2179	Prenatal Screening (Prevention Genetics)

AHS-G2043	Celiac Disease Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with clinical features of Charcot-Marie-Tooth (CMTA) disease, but for whom a definitive diagnosis cannot be made without genetic testing, genetic testing for *PMP22* deletions/duplication, *GJB1* mutations, **and/or** *MFN2* mutations **MEETS COVERAGE CRITERIA**.

2) For individuals with clinical features of CMT disease who have tested negative for common deleterious variants (*PMP22* deletions/duplication; *GJB1* or *MFN2* mutations), single gene or multi-gene panel testing for CMT disease risk genes **MEETS COVERAGE CRITERIA**.

3) For asymptomatic individuals who have a close blood relative (see Note 1) with a known deleterious mutation in a CMT gene, genetic testing for the known familial mutation **MEETS COVERAGE CRITERIA**.

4) For individuals who are clinically suspected of having hereditary neuropathy with liability to pressure palsies (HNPP), but for whom a definitive diagnosis cannot be made without genetic testing, genetic testing for *PMP22* deletions and duplications **MEETS COVERAGE CRITERIA**.

5) For individuals who are clinically suspected of having hereditary motor neuropathy (HMN), but for whom a definitive diagnosis cannot be made without genetic testing, genetic testing for *BSCL2* mutations **MEETS COVERAGE CRITERIA**.

NOTES:

Note 1: Close blood relatives include 1st-degree relatives (e.g., parents, siblings, and children), 2nd-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings), and 3rd-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins).

Note 2: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AAN	American Academy of Neurology
AANEM	American Academy of Neuromuscular and Electrodiagnostic
AAPM&R	American Academy of Physical Medicine and Rehabilitation
AARS	Alanine-tRNA ligase, cytoplasmic
AIFM1	*Apoptosis-inducing factor 1*
BSCL2	*Seipin lipid droplet biogenesis associated*
DYNC1H1	*Dynein cytoplasmic 1 heavy chain 1*
EFNS	European Federation of Neurological Societies
EGR2	*Early growth response protein 2*
GARS	Glycyl-t-ribonucleic acid synthetase
GDAP1	*Ganglioside-induced differentiation-associated protein-1*
GJB1	Gap junction beta-1 protein (connexin 32)
HMN	Hereditary motor neuropathy
HNPP	Hereditary neuropathy with predisposition to pressure palsy
HSANs	Hereditary sensory and autonomic neuropathies
HSPB1	*Heat-shock protein beta-1*
HSPB8	*Heat-shock protein beta-8*
KIF1B	*Kinesin family member 1B*
LITAF	Lipopolysaccharide induced tumor necrosis factor
LMNA	Lamin A/C
MED25	*Mediator complex subunit 25*
MPZ	Myelin protein P_0
NEFL	Neurofilament light polypeptide
NINDS	National Institute of Neurological Disorders and Stroke
PDK3	*Pyruvate dehydrogenase kinase isoform 3*
PMP22	*Peripheral myelin protein 22*
PRPS1	*Ribose-phosphate pyrophosphokinase 1*
RAB7A	*Member RAS oncogene family*
Sep T9	*Septin 9*
SH3TC2	*SH3 domain and tetratricopeptide*
TRPV4	*Transient receptor potential cation channel subfamily V*
WES/WGS	Whole exome or genome sequencing

V. Scientific Background

Peripheral neuropathies encompass the set of disorders that primarily lead to peripheral nerve dysfunction. Symptoms typically include weakness of muscles at extremities, spine curvature, and loss of sensation at extremities (Kang, 2024c; UpToDate, 2024). Neuropathies may be caused by a variety of different factors, such as metabolic issues (including Fabry disease, Niemann-Pick disease, et al.) or present as a secondary symptom to another condition (such as Tangier disease) (Kang, 2024c).

Charcot-Marie-Tooth (CMTA) disease, also known as hereditary motor sensory neuropathy, is a group of progressive disorders that affect the peripheral nerves. CMT is caused by a mutation in one of several myelin genes that result in defects in myelin structure, maintenance, or function within peripheral nerves. Charcot-Marie-Tooth disease is one of the most common inherited neurological disorders, affecting approximately 1 in 2,500 people in the United States (Kang, 2024a).

Symptoms

The neuropathy of CMT affects both motor and sensory nerves. Symptoms usually start in childhood and have a gradual progression. The severity of symptoms varies greatly among individuals and even among family members with the disease and gene mutation (Bird, 2023; NINDS, 2007, 2023). Typical symptoms include the following:

- "Weakness or paralysis of the foot and lower leg muscles, which can cause difficulty lifting the foot (foot drop)
- A high-stepped gait with frequent tripping or falling
- Balance problems
- Foot deformities, such as high arches and curled toes (hammertoes)
- Lower legs may take on an "inverted champagne bottle" shape due to the loss of muscle bulk
- Reduced ability to feel heat, cold, and touch
- Weakness and atrophy may occur in the hands, causing difficulty with fine motor skills
- Decreased sense of vibration and position (proprioception)
- Curvature of the spine (scoliosis)
- Hip displacement
- Contractures (chronic shortening of muscles or tendons around joints)
- Muscle cramping
- Nerve pain" (NINDS, 2023)

Pain can range from mild to severe, and some people may need to rely on foot or leg braces or other orthopedic devices to maintain mobility. Some people living with CMT

experience tremor, and vision and hearing can also be affected. In rare cases, breathing difficulties may occur if the nerves that control the muscles of the diaphragm are affected (NINDS, 2023).

Causes

CMT is caused by mutations in genes that produce proteins involved in the structure and function of either the peripheral nerve axon or the myelin sheath. Although different proteins are abnormal in different forms of CMT disease, all mutations affect the normal function of the peripheral nerves. There is little correlation between the genotype and phenotype of CMT; it is common to see differing mutations result in various clinical phenotypes all within the same gene (Kang, 2024a).

Pattern of Inheritance

The pattern of inheritance varies with the type of CMT disease. CMT1, most cases of CMT2, and most intermediate forms are inherited in an autosomal dominant pattern. CMT4, a few CMT2 subtypes, and some intermediate forms are inherited in an autosomal recessive pattern. CMTX is inherited in an X-linked pattern. Some cases of CMT disease result from a new mutation and occur in people with no history of the disorder in their family. In rare cases the gene mutation causing CMT disease is a new mutation which occurs spontaneously in the individual's genetic material and has not been passed down through the family (Kang, 2024a).

CMT1

Charcot-Marie-Tooth disease type 1 (CMT1) is a demyelinating peripheral neuropathy characterized by distal muscle weakness and atrophy, sensory loss, and are usually slowly progressive and often associated with *pes cavus* foot deformity and bilateral foot drop (Bird, 2023). The six subtypes of CMT1 shown in Table 1 are clinically indistinguishable and are designated solely on molecular findings (Saporta et al., 2011)

Table 1: Molecular Genetics of CMT1 (Saporta et al., 2011)

Locus Name	Proportion of CMT1 (excluding CMTX)	Gene	Protein Product
CMT1A	70%-80%	*PMP22*	Peripheral myelin protein 22
CMT1B	10%-12%	*MPZ*	Myelin protein P_0
CMT1C	~1%	*LITAF*	Lipopolysaccharide-induced tumor necrosis factor-alpha factor

CMT1D	Unknown	*EGR2*	Early growth response protein 2
CMT1E	~1%	*PMP22*	Peripheral myelin protein 22 (sequence changes)
CMT1F/2E	Unknown	*NEFL*	Neurofilament light polypeptide

Charcot-Marie-Tooth disease type 1A (CMT1A) is an autosomal dominant disease that results from a duplication of the gene on chromosome 17 that carries the instructions for producing the peripheral myelin protein-22 (PMP-22). Overexpression of this gene causes the structure and function of the myelin sheath to be abnormal. A different neuropathy distinct from CMT1A called hereditary neuropathy with predisposition to pressure palsy (HNPP) is caused by a deletion of one of the PMP-22 genes. In this case, abnormally low levels of the PMP-22 gene result in episodic, recurrent demyelinating neuropathy (NINDS, 2007, 2023).

Charcot-Marie-Tooth disease type 1B (CMT1B) is an autosomal dominant disease caused by mutations in the gene that carries the instructions for manufacturing the myelin protein zero (P0), which is another critical component of the myelin sheath. Most of these mutations are point mutations. As a result of abnormalities in P0, CMT1B produces symptoms similar to those found in CMT1A (NINDS, 2007, 2023).

Other less common causes genetic causes of CMT1 result from mutations within *LITAF, EGR2, PMP22*, and *NEFL* genes, respectively (NINDS, 2023).

CMT2

Charcot-Marie-Tooth disease type 2 (CMT2) is an axonal (non-demyelinating) peripheral neuropathy characterized by distal muscle weakness and atrophy. Axonal peripheral neuropathy shows extensive clinical overlap with CMT1 (Bird, 2023). In general, individuals with CMT2 tend to be less disabled and have less sensory loss than individuals with CMT1 (Bird, 2023). It is less common than CMT1. CMT2A, the most common axonal form of CMT, is caused by mutations in Mitofusin 2, a protein associated with mitochondrial fusion. Symptoms are similar to those seen in CMT1, but people with CMT2 often have less disability and sensory loss than individuals with CMT1. Additionally, symptoms for CMT2 may have vocal cord or phrenic nerve involvement, causing speech or respiratory problems (NINDS, 2023).

Table 2: Molecular Genetics of CMT2 (Anthony Antonellis, 2018; Bird, 2023; Peter De Jonghe, 2011; Schindler, 2014; Züchner, 2013)

Locus	Proportion of CMT	Gene / Chromosome Locus	Protein Product
CMT2A1	Unknown	*KIF1B*	Kinesin-like protein KIF1B
CMT2A2[1]	20%	*MFN2*	Mitofusin-2
CMT2B	Unknown	*RAB7*A	Ras-related protein Rab-7
CMT2B1	Unknown	*LMNA*	Lamin A/C
CMT2B2	Unknown	*MED25*	Mediator of RNA polymerase II transcription subunit 25
CMT2C[2]	Unknown	*TRPV4*	Transient receptor potential cation channel subfamily V member 4
CMT2D[3]	3%	*GARS*	Glycyl-tRNA synthetase
CMT2E/1F[4]	4%	*NEFL*	Neurofilament light polypeptide
CMT2F	Unknown	*HSPB1*	Heat-shock protein beta-1
CMT2G	Unknown	12q12-q13	Unknown
CMT2H/2K	5%	*GDAP1*	Ganglioside-induced differentiation-associated protein-1
CMT2I/2J	Unknown	*MPZ*	Myelin protein P_0
CMT2L	Unknown	*HSPB8*	Heat-shock protein beta-8
CMT2N	Unknown	*AARS*	Alanine--tRNA ligase, cytoplasmic
CMT2O	Unknown	*DYNC1H1*	Cytoplasmic dynein 1 heavy chain 1
CMT2P	Unknown	*LRSAM1*	E3 ubiquitin-protein ligase LRSAM1
CMT2S	Unknown	*IGHMBP2*	DNA-binding protein SMUBP-2
CMT2T	Unknown	*DNAJB2*	DnaJ homolog subfamily B member 2
CMT2U	Unknown	*MARS*	Methionine--tRNA ligase, cytoplasmic

CMT3

Dejerine-Sottas disease (CMT3), is a severe demyelinating neuropathy that begins in infancy. Infants have severe muscle atrophy, weakness, and sensory problems. This rare disorder can be caused by mutations in multiple genes, including *PMP22, MPZ,* and *EGR2*, and can be inherited either dominantly or recessively (NINDS, 2023).

CMT4

Charcot-Marie-Tooth disease type 4 (CMT4) comprises several different subtypes of autosomal recessive demyelinating motor and sensory axonal neuropathies. Each neuropathy subtype is caused by a different genetic mutation, may affect a particular

ethnic population, and produces distinct physiologic or clinical characteristics. Affected individuals have the typical CMT phenotype of distal muscle weakness and atrophy associated with sensory loss and, frequently, pes cavus foot deformity. Several genes have been identified as causing CMT4, including *GDAP1* (CMT4A), *MTMR13* (CMT4B1), *MTMR2* (CMT4B2), *SH3TC2* (CMT4C), *NDG1* (CMT4D), *EGR2* (CMT4E), *PRX* (CMT4F), *FDG4* (CMT4H), and *FIG4* (CMT4J) (Kang, 2024a; NINDS, 2007, 2023).

Table 3: Molecular Genetics of CMT4 (Bird, 2017; Delague, 2013; Hamid Azzedine, 2015; Li, 2013)

Locus Name	Proportion of CMT4	Gene	Protein Product
CMT4A[1]	Unknown	*GDAP1*	Ganglioside-induced differentiation-associated protein 1
CMT4B1		*MTMR2*	Myotubularin-related protein 2
CMT4B2		*SBF2*	Myotubularin-related protein 13
CMT4C[2]		*SH3TC2*	SH3 domain and tetratricopeptide repeats-containing protein 2
CMT4D		*NDRG1*	Protein NDRG1
CMT4E		*EGR2*	Early growth response protein 2
CMT4F		*PRX*	Periaxin
CMT4H[3]		*FGD4*	FYVE, RhoGEF and PH domain-containing protein 4
CMT4J[4]		*FIG4*	Phosphatidylinositol 3, 5 biphosphate

CMTX

CMTX is caused by a point mutation in the connexin-32 gene on the X chromosome. The connexin-32 protein is expressed in Schwann cells, which wrap around nerve axons and make up a single segment of the myelin sheath (NINDS, 2007, 2023). CMTX type 1 is characterized by a moderate to severe motor and sensory neuropathy. Hearing loss and central nervous system symptoms may also occur in certain affected families (Abrams, 2020).

Table 4: Molecular Genetics of CMTX (Bird, 2023; Kim, 2013)

Disease Name	Proportion of X-Linked CMT	Gene / Chromosome Locus	Protein Product
CMTX1[1]	90%	*GJB1*	Gap junction beta-1 protein (connexin 32)

CMTX2[2]	Unknown	Xp22.2	
CMTX3[1]			Not applicable
CMTX4[1]		*AIFM1*	Apoptosis-inducing factor 1
CMTX5[2]		*PRPS1*	Ribose-phosphate pyrophosphokinase 1
CMTX6[1]		*PDK3*	Pyruvate dehydrogenase kinase isoform 3

Hereditary Brachial Plexopathy (Hereditary Neuralgic Amyotrophy)

This condition is primarily characterized by painful injuries to the brachial plexus nerves as well as episodic weakness of the shoulder and arm. Other symptoms such as winging of the scapula, short stature, neck folds, small face, and hypotelorism may be present. Nerve conduction velocity is typically normal, and the histopathology of this condition is non-specific. The *septin 9 gene* (*SEPT9*) on chromosome 17 has been associated with this condition (Bromberg, 2023).

Giant Axonal Neuropathy

This condition is characterized by disorganization of cytoskeletal intermediate filaments stemming from a mutated form of gigaxonin. Patients with this disorder often have a signature physical appearance; red and kinked hair, high foreheads, long eyelashes, and pale complexions are all hallmarks of this condition. The central nervous system may be affected as well with cerebellar dysfunction, spasticity, and potentially intellectual disability as possible symptoms. Nerve biopsy may show axonal loss or another axonal dysfunction. This diagnosis is confirmed by testing of the *GAN* gene (Kang, 2024c).

Hereditary Sensory and Autonomic Neuropathies (HSANs)

This subsection of disorders primarily encompasses non-motor neuropathies and are characterized by major loss of myelinated and unmyelinated fibers. These conditions are not as common as hereditary motor neuropathies and primarily present with sensory dysfunction, although motor functions may be affected. There are five main types of HSAN, each caused by different genes. Genes are associated as shown below (Eichler, 2024):

Disease Name (subtype)	Gene(s) or Locus	Examples of symptoms
HSAN1 (A)	*SPTLC1*	Distal sensory loss, distal muscle wasting
HSAN1 (B)	3p24-p22	Axonal neuropathy with distal sensory impairment

HSAN1 (C)	*SPTLC2*	Distal sensory loss, distal muscle wasting
HSAN1 (D)	*ATL1*	Distal sensory loss, distal muscle wasting
HSAN1 (E)	*DNMT1*	Hearing loss, progressive dementia
HSAN1 (F)	*ATL3*	Distal sensory impairment
HSAN2 (A)	*HSN2*	Loss of pain, pressure, touch, and temperature sensation
HSAN2 (B)	*FAM134 B*	Loss of pain, pressure, touch, and temperature sensation
HSAN2 (C)	*KIF1A*	Loss of pain, pressure, touch, and temperature sensation
HSAN2 (D)	*SCN9A*	Loss of pain and temperature sensation, hearing loss
HSAN3/Familial Dysautonomia	9q31	Dysautonomic crises, orthostatic hypotension
HSAN4/Congenital Insensitivity to Pain with Anhidrosis	*NTRK1*	Loss of pain sensation, thermoregulatory dysfunction
HSAN5	*NGFB*	Loss of pain and temperature sensation
HSAN6	*DST*	Lack of psychomotor development, respiratory difficulties
HSAN7	*SCN11A*	Inability to experience pain

Other unclassified HSANs exist, such as spastic paraplegia with ulcerations of the hands and feet (associated with *CCT5*) and sensory neuropathy with ichthyosis and anterior chamber syndrome (Eichler, 2024).

Genetic Testing

Charcot-Marie-Tooth disease is usually diagnosed by an extensive history and physical examination. The clinical diagnosis is then confirmed by electrodiagnostic tests like electromyography and nerve conduction velocity tests, and sometimes by nerve biopsy. Genetic testing is available for most types of CMT, and results are usually enough to confirm a diagnosis. Genetic testing can simplify the diagnosis of CMT by avoiding invasive procedures, such as nerve biopsy. In addition, early diagnosis can facilitate early interventions, including physical therapy. However, most therapies are only supportive (occupational, physical) and generally do not rely on the results of specific genetic testing (Kang, 2024a, 2024b). A positive genetic test can confirm diagnosis in most people with CMT. But a negative result does not exclude the disease, as an unidentified gene may be missed by DNA sampling (Charcot-Marie-Tooth News, 2023).

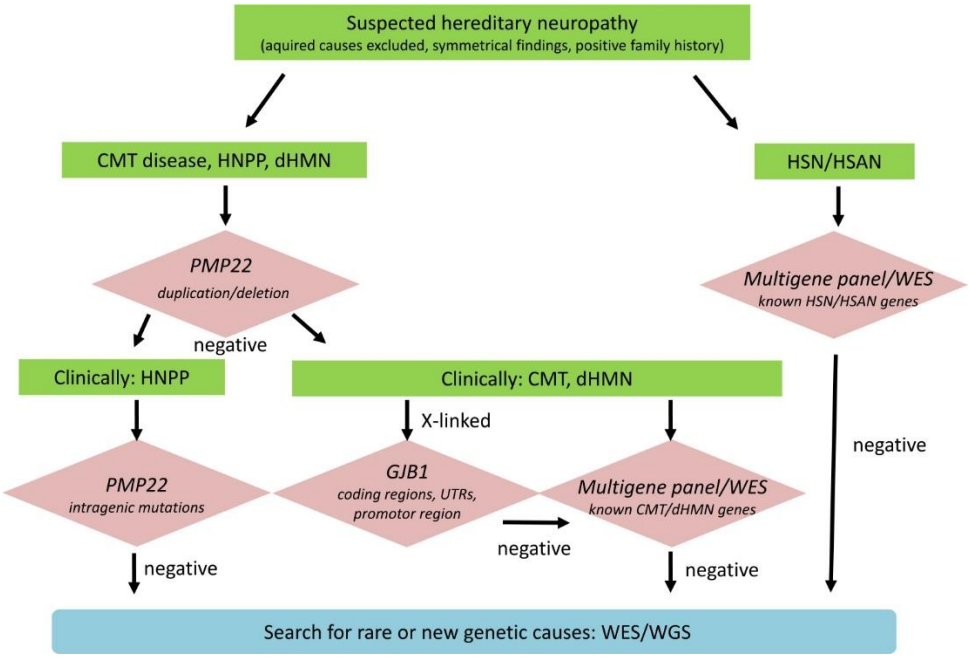
Genetic testing for CMT is complicated by the extensive underlying genetic heterogeneity. The CMT spectrum of disorders can be inherited in an autosomal dominant, autosomal recessive, or X-linked manner. The most commonly identified CMT subtypes are CMT1A (*PMP22* duplication), CMTX1 (*GJB1* mutation), hereditary neuropathy with liability to pressure palsies (*PMP22* deletion), CMT1B (*MPZ* mutation), and CMT2A (*MFN2* mutation). Together, these five subtypes account for 92 percent of genetically defined CMT cases. All other CMT subtypes and associated mutations each account for <1 percent of genetically defined CMT (CMTA, 2023; Kang, 2024a). Genetic screening for relatives of a patient diagnosed with CMT is an option, but risk assessment depends on several factors, including accuracy of the diagnosis, determination of the mode of inheritance for the individual family, and results of molecular genetic testing (Kang, 2024a).

Proprietary Testing

Numerous genetic panels are available for the assessment of peripheral neuropathies, such as GeneDx's panel (64 genes) and Invitae's panel (83 genes) (GeneDx, 2024; Invitae, 2024). Other pane's include ones by Athena Diagnostics (23 genes) (Athena Diagnostics, 2023), Claritas Genomics (*PMP22* gene) (Claritas Genomics, 2023), MNG Laboratories (139 genes) (MNG Laboratories, 2022), Prevention Genetics (44 genes) (Prevention Genetics, 2023), and Variantyx's Genomic Unity panel (25 genes).

Clinical Utility and Validity

DiVincenzo et al. (2014) performed an analysis of the genetic landscape of CMT. 14 genes associated with CMT (*PMP22, GJB1, MPZ, MFN2, SH3TC2, GDAP1, NEFL, LITAF, GARS, HSPB1, FIG4, EGR2, PRX*, and *RAB7A*) were evaluated out of 3312 individuals. Deletions and duplications in the PMP22 gene consisted of about 78% of positive findings, followed by mutations in the *GJB1* (6.7%), *MPZ* (5.3%), and *MFN2* (4.3%) genes. 71% of the pathogenic mutations found were missense mutations. Overall, 95% of the positive results involved one of four genes (*PMP22, GJB1, MPZ, MFN2*). The authors conclude that these four genes should be screened first before proceeding with further genetic testing (DiVincenzo et al., 2014).



Pareyson et al. (2017) reviewed the current literature on CMT diagnosis stating that data justifies a step-wise algorithm considering a variety of factors, such as phenotype, nerve conduction velocities, and ethnicity. The authors note that NGS is steadily replacing older methods of sequencing in this algorithm. The authors propose evaluating the first few common genes (*PMP22*, *MPZ*, et al) and then considering larger sequencing methods such as NGS. However, due to the growing number of genes associated with CMT, these larger sequencing methods may be considered first-line.

Finally, the authors state that due to the growing number of associated genes, newer classifications need to be discussed and validated further (Pareyson et al., 2017).

Rudnik-Schoneborn et al. (2016) evaluated the clinical features and genetic results of 1206 CMT patients and 124 affected relatives. Genetic detection rates were 56% in demyelinating CMT and 17% in axonal CMT. "Three genetic defects (*PMP22* duplication/deletion, *GJB1*/*Cx32* or *MPZ*/P0 mutation) were responsible for 89.3% of demyelinating CMT index patients in whom a genetic diagnosis was achieved, and the diagnostic yield of the three main genetic defects in axonal CMT (*GJB1*/*Cx32*, *MFN2*, *MPZ*/P0 mutations) was 84.2%". The authors concluded that "diagnostic algorithms are still useful for cost-efficient mutation detection and for the interpretation of large-scale genetic data made available by next generation sequencing strategies" (Rudnik-Schoneborn et al., 2016).

Vaeth et al. (2019) evaluated the effect of implementing a targeted next-generation sequencing (NGS) approach for identifying CMT. The authors stated that from 1992-2012, a total of 1442 CMT analyses were performed (through Sanger sequencing and other quantitative analyses) and a pathogenic variant was discovered in 21.6% of these cases. From this cohort, 195 samples that did not reach a definitive diagnosis were sequenced by a custom 63-gene panel. The authors identified a 5.6% increase in diagnostic yield using this targeted NGS approach (Vaeth et al., 2019).

Cortese et al. (2020) investigated the effectiveness of NGS panels in CMT. 220 patients were enrolled in the study and a targeted CMT NGS panel was performed. After NGS sequencing, a molecular diagnosis based on a pathogenic variant was found in 30% of the cases and variants of unknown significance were found in 33% of the cases. 39% of the cases held mutations in *GJB1, MFN2*, and *MPZ* while the others held mutations in *SH3TC2, GDAP1, IGHMBP2, LRSAM1, FDG4,* and *GARS*. Copy number changes were detected in *PMP22, MPZ, MFN2, SH3TC2,* and *FDG4*. The authors conclude that "NGS panels are effective tools in the diagnosis of CMT, leading to genetic confirmation in one-third of cases negative for *PMP22* duplication/deletion, thus highlighting how rarer and previously undiagnosed subtypes represent a relevant part of the genetic landscape of CMT" (Cortese et al., 2020).

Rudnik-Schöneborn et al. (2020) suggested a diagnostic algorithm for genetic testing of suspected hereditary neuropathy. Advanced genetic sequencing allows for comprehensive evaluation of the pathogenic relevance of identified variants. As shown in the chart above, "If *PMP22* copy number analysis is negative, then clinical distinction of HNPP and CMT/dHMN will sort out patients for *PMP22* mutation analysis only and those for broader multigene testing. If a pedigree is compatible with X-linked inheritance, it is recommended to analyze coding and non-coding regions of *GBJ1*. Patients who are tested negative for known neuropathy genes may be included in further whole exome or genome sequencing (WES/WGS) to detect mutations in rare and new genes" (Rudnik-Schöneborn et al., 2020).

Yalcintepe et al. (2021) studied the importance of multiple gene analysis for diagnosis of Charcot Marie Tooth Disease. Fifty-five patients with suspected CMT phenotype were examined using a customized multigene panel which was compared to the Multiplex Ligand Probe Amplification (MLPA) method. The custom panel identified 13 cases (7.15%) with a pathogenic/likely pathogenic variant. "The affected genes were *MARS1, NDRG1, GJB1, GDAP1, MFN2, PRX, SH3TC2*, and *FGD4*. Six cases (10.9%) had pathogenic variants in *GJB1* and *FGD4* genes, variants of unknown significance (VUS) in *HSPB3, CHRNA1, ARHGEF10,* and *KIF5A* genes. 21 cases (11.55%) had VUS with the genes *HSPB3, KIF1B, SCN11A, CHRNA1, HSPB1, FIG4, ARHGEF10, DHTKD1, SBF1, EGR2, SBF2, IGHMBP2, KIF5A*, and *DNAJB2*." The authors concluded that the NGS customized panel was beneficial, time-saving, and cost-effective in the diagnosis of CMT (Yalcintepe et al., 2021).

VI. Guidelines and Recommendations

American Academy of Neurology (AAN), the American Academy of Neuromuscular and Electrodiagnostic Medicine (AANEM), and the American Academy of Physical Medicine and Rehabilitation (AAPM&R)

The Polyneuropathy Task Force that included 19 physicians with representatives from the American Academy of Neurology (AAN), the American Academy of Neuromuscular and Electrodiagnostic Medicine (AANEM), and the American Academy of Physical Medicine and Rehabilitation (AAPM&R) concluded that "genetic testing is established as useful for the accurate diagnosis and classification of hereditary polyneuropathies (Class I)" (England et al., 2009).

The Task Force stated that "for patients with a cryptogenic polyneuropathy who exhibit a classic hereditary neuropathy phenotype, routine genetic screening may be useful for CMT1A duplication/deletion and *Cx32* mutations in the appropriate phenotype (Class III). Further genetic testing may be considered guided by the clinical question." The Task Force recommended that "genetic testing should be conducted for the accurate diagnosis and classification of hereditary neuropathies (Level A)". The Task force further recommended that "Genetic testing may be considered in patients with a cryptogenic polyneuropathy and classic hereditary neuropathy phenotype (Level C). Initial genetic testing should be guided by the clinical phenotype, inheritance pattern, and electrodiagnostic features and should focus on the most common abnormalities which are CMT1A [*PMP22]* duplication/HNPP deletion, Cx32 (*GJB1*), and *MFN2* mutation screening. There is insufficient evidence to support or refute the usefulness of routine genetic testing in cryptogenic polyneuropathy patients without a classic hereditary phenotype (Level U)" (England et al., 2009).

These guidelines were reaffirmed on January 22, 2022.

European Federation of Neurological Societies (EFNS)

The EFNS released recommendations on genetic testing for various types of peripheral neuropathies. Regarding CMT, they noted that "Given the rarity of AR CMT in the European population routine diagnostic screening of the many known genes is currently not feasible" but acknowledged that "Currently, molecular genetic testing can be offered for several of the more prevalent CMT genes." EFNS stated that PMP22 duplication should be tested first in patients presenting with CMT1, followed by sequencing of *GJB1*, *MPZ*, and *PMP22*. If a patient presents with CMT2, *MFN2* should be screened first, followed by *MPZ*. If a patient presents with intermediate CMT, *GJB1* and *MPZ* should be screened. EFNS notes that in patients with hereditary neuropathy

with liability to pressure palsies will be investigated for a *PMP22* deletion at the same time as a screening for a *PMP22* duplication (Burgunder et al., 2011).

However, routine diagnostic screenings for hereditary motor neuropathy (HMN) and hereditary sensory-autonomic neuropathy (HSAN) are not feasible due to low mutation frequencies. If screening is performed for these conditions, EFNS recommends *BSCL2* as the first candidate for screening in HMN. NTRK1 may also be screened for in congenital insensitivity to pain with anhidrosis patients (CIPA, a sub-phenotype of HSAN) and *RAB7* may be screened in CMT2B patients. Finally, *SEPT9* may be screened in the context of hereditary neuralgic amyotrophy (HNA) (Burgunder et al., 2011).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81324	PMP22 (peripheral myelin protein 22) (eg, Charcot-Marie-Tooth, hereditary neuropathy with liability to pressure palsies) gene analysis; duplication/deletion analysis
81325	PMP22 (peripheral myelin protein 22) (eg, Charcot-Marie-Tooth, hereditary neuropathy with liability to pressure palsies) gene analysis; full sequence analysis

81326	PMP22 (peripheral myelin protein 22) (eg, Charcot-Marie-Tooth, hereditary neuropathy with liability to pressure palsies) gene analysis; known familial variant
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81448	Hereditary peripheral neuropathies (eg, Charcot-Marie-Tooth, spastic paraplegia), genomic sequence analysis panel, must include sequencing of at least 5 peripheral neuropathy-related genes (eg, BSCL2, GJB1, MFN2, MPZ, REEP1, SPAST, SPG11, SPTLC1)

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Muscular Dystrophies

Policy Number: AHS – M2074 – Genetic Testing for Dystrophies	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Muscular dystrophies, genetic conditions characterized by progressive muscle atrophy, can be caused by several genetic mutations. Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are due to mutations in the dystrophin gene on the X chromosome (Darras, 2024a). Facioscapulohumeral muscular dystrophy (FSHD) occurs due to a contraction of the polymorphic macrosatellite repeat D4Z4 on chromosome 4q35 (Darras, 2024c). The limb-girdle muscular dystrophies (LGMDs) are a group of approximately 30 rare hereditary progressive neuromuscular disorders (Murphy & Straub, 2015) LGMDs result from mutations in genes required for normal muscle function and vary in severity, phenotype, pathology, and age of onset (Darras, 2024d).

Pretest genetic counseling and genetic counseling at time of result disclosure is strongly recommended for individuals pursuing genetic testing for muscular dystrophies.

Terms such as male and female are used when necessary to refer to sex assigned at birth.

For guidance on prenatal or preconception screening for muscular dystrophies, please see AHS-M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with clinical signs of a dystrophinopathy, genetic testing for likely pathogenic or pathogenic variants of *dystrophin (DMD)* **MEETS COVERAGE CRITERIA**.

2) For individuals with clinical signs of facioscapulohumeral muscular dystrophy (FSHD), genetic testing to confirm a diagnosis of FSHD **MEETS COVERAGE CRITERIA**.

3) For individuals who are clinically suspected of having limb-girdle muscular dystrophy (LGMD), genetic testing for likely pathogenic or pathogenic variants associated with LGMD **MEETS COVERAGE CRITERIA**.

4) For individuals with clinical signs of congenital muscular dystrophy (CMD), genetic testing to confirm a diagnosis of CMD **MEETS COVERAGE CRITERIA**.

5) For individuals for whom genetic testing was negative for dystrophinopathies, FSHD, LGMD, or CMD, but for whom the clinical suspicion of a muscular dystrophy remains, genetic testing for rare muscular dystrophies (e.g., myotonic dystrophy, Emery-Dreifuss muscular dystrophy, oculopharyngeal muscular dystrophy, distal muscular dystrophy) **MEETS COVERAGE CRITERIA**.

6) For first- and second-degree relatives (see Note 1) of individuals with a muscular dystrophy, the following genetic testing **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial likely pathogenic or pathogenic variant.
   b) Comprehensive disorder specific genetic testing when the specific familial likely pathogenic or pathogenic variant is unknown.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

7) For all other situations not discussed above, genetic testing for muscular dystrophies **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: First-degree relatives include parents, full siblings, and children of the individual. Second-degree relatives include grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings of the individual.

Note 2: For two or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AAN	American Academy of Neurology
AANEM	American Association of Neuromuscular and Electrodiagnostic Medicine
ACMG	American College of Medical Genetics
ALT	Alanine aminotransferase
AMP	Association for Molecular Pathology
ANO5	*Anoctamin 5*
AST	Aspartate aminotransferase
BMD	Becker Muscular Dystrophy
CAPN3	*Calpain 3*
cDNA	Copy/complementary DNA
CGH	Comparative genomic hybridization
CK	Creatine phosphokinase
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMA	Chromosomal microarray
CMD	Congenital muscular dystrophy
CMS	Centers for Medicare and Medicaid
CNBP	*CCHC-type zinc finger nucleic acid binding protein*
CNVs	Copy number variations
COL6A1/2/3	*Collagen type VI alpha [1, 2, or 3] chain*
CRPPA	CDP-L-ribitol pyrophosphorylase A
CVS	Chorionic villus sampling
DAG1	*Dystroglycan 1*
DCM	Dilated cardiomyopathy
DM1/DM2	Myotonic dystrophy
DMD	Duchenne muscular dystrophy
DMD	*Dystrophin*

DMPK	*Dystrophia myotonica protein kinase*
DNA	Deoxyribonucleic acid
DNAJB6	*DnaJ heat shock protein family (Hsp40) member B6*
DNMT3B	*DNA-methyltransferase 3 beta*
DPPI	Duchenne Parent Project Italy
DUX4	Double homeobox protein 4
DYSF	*Dysferlin*
EDMD	Emery-Dreifuss Muscular Dystrophy
EMQN	European Molecular Genetics Quality Network
EPNS	European Paediatric Neurology Society
FCMD	Fukuyama congenital muscular dystrophy
FDA	Food and Drug Administration
FKRP	*Fukutin-related protein*
FKTN	*Fukutin*
FSHD	Facioscapulohumeral Muscular Dystrophy
GMPPB	*GDP-Mannose pyrophosphorylase B*
HNRNPDL	*Heterogeneous nuclear ribonucleoprotein D like protein*
Hsp40	Heat shock protein 40 kD
LAMA2	*Laminin subunit alpha 2*
LDTs	Laboratory-developed tests
LGMDs	Limb-girdle muscular dystrophies
LRIF1	*Ligand-dependent nuclear receptor-interacting factor 1*
MDA	Muscular Dystrophy Association
MLPA	Multiplex ligation-dependent probe amplification
mPCR	Multiplex polymerase chain reaction
mRNA	Messenger ribonucleic acid
NGS	Next-generation sequencing
NMDs	Neuromuscular disorders
OMIM	Online Mendelian Inheritance in Man
OPMD	Oculopharyngeal muscular dystrophy
PABPN1	*Polyadenosine RNA binding protein, polyadenylate-binding nuclear protein 1*
PCR	Polymerase chain reaction
PLEC1	*Plectin*
POGLUT1	*Protein O-glucosyltransferase 1*
POMGNT1	*Protein O-linked mannose N-acetylglucosaminyltransferase 1*
POMGNT2	*Protein O-linked mannose N-acetylglucosaminyltransferase 2*
POMT1	*Protein O-mannosyltransferase 1*
POMT2	*Protein O-mannosyltransferase 2*

PPMD	Parent Project Muscular Dystrophy
RHDO	Relative haplotype dosage analysis
RNA	Ribonucleic acid
SEPN1	*Selenon*
SGCA	*Sarcoglycan alpha*
SGCB	*Sarcoglycan beta*
SGCD	*Sarcoglycan delta*
SGCG	*Sarcoglycan gamma*
SMCHD1	*Structural maintenance of chromosomes flexible hinge domain containing 1*
SNPs	Single nucleotide polymorphisms
SNVs	Single nucleotide variants
TCAP	*Telethonin*
TNPO3	*Transportin 3*
TRAPPC11	*Trafficking protein particle complex 11*
TRIM32	*Tripartite m-containing 32*
TTN	*Titin*
USPSTF	U.S. Preventive Services Task Force
WES	Whole-exome sequencing
ZAK	Former gene name of *MAP3K20 (mitogen-activated protein kinase kinase kinase 20)*

V. Scientific Background

Neuromuscular disorders (NMDs) encompass a diverse set of conditions, many of which arise from specific genetic mutations that impair muscle function and nervous system communication. NMDs are an inherited group of progressive disorders that involve muscle weakness as the primary symptom. Among the most prominent are DMD, BMD, facioscapulohumeral muscular dystrophy (FSHD) and LGMD. Each disorder has distinct genetic causes and clinical presentations.

Duchenne Muscular Dystrophy is caused by mutations in the dystrophin gene on the X chromosome, leading to a lack of functional dystrophin, a protein vital for stabilizing muscle fibers. This disorder typically presents in early childhood with muscle weakness, progressive loss of mobility and cardiac or respiratory complications (Darras, 2024a).

Becker muscular dystrophy, similar to DMD, results from mutation in the dystrophin gene but allows for the production of partially functional dystrophin. As a result, symptoms may appear later in life and progress more slowly, often enabling individuals to remain ambulatory into adulthood (Darras, 2024a).

Facioscapulohumeral Muscular Dystrophy occurs due to the contraction of the D4Z4 repeat region on chromosome 4q35, which leads to the abnormal expression of the *DUX4* gene with a protein toxic to muscle cells. Symptoms include weakness in the facial, shoulder and upper arm muscles, with variability in disease severity and progression among individuals (Darras, 2024c).

Limb-Girdle Muscular Dystrophy represents a group of over 30 hereditary disorders characterized by weakness in the muscles around the hips and shoulders. Different genetic mutations affect the proteins required for normal muscle structure and function, resulting in a wide range of severity, onset stages, and disease progression patterns (Darras, 2024d).

In addition to the more well-known forms of muscular dystrophy, several lesser-known types of muscular dystrophy may present clinically. Congenital muscular dystrophies (CMDs) are a heterogeneous group of disorders that present at birth or in early infancy (within the first two years), caused by mutations in genes involved in muscle and connective tissue development. Examples include Walker-Warburg syndrome and Ullrich CMD (Darras, 2024e). Myotonic Dystrophy (DM1 and DM2) occurs as an adult-onset muscular dystrophy characterized by muscle stiffness, weakness, and systemic involvement (such as cardiac issues). This disorder results from mutations in the *DMPK* or *CNBP* genes. Emery-Dreifuss Muscular Dystrophy (EDMD) is caused by mutations in genes encoding nuclear envelope proteins, and leads to early contractures, progressive muscle wasting and cardiomyopathy (Darras, 2024b). Oculopharyngeal Muscular Dystrophy (OPMD) is a rare adult-onset dystrophy (mainly autosomal dominant inheritance) associated with mutation in the *PABPN1* gene, causing ptosis, difficulty swallowing and proximal muscle weakness (Darras, 2024e). Distal muscular dystrophies are a heterogenous group (over 12 different disorders of myopathies) that affect distal muscles (hands, feet, and forearms) (Darras, 2024e).

Duchenne Muscular Dystrophy (DMD) and Becker Muscular Dystrophy (BMD)

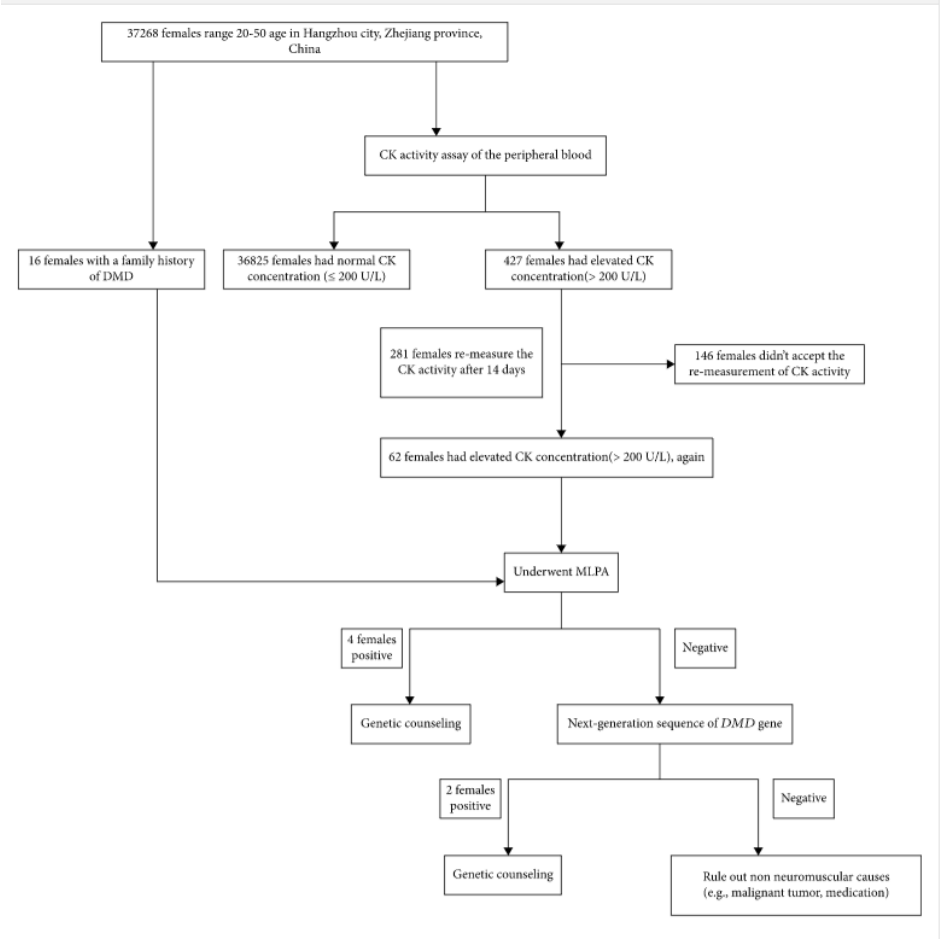
Dystrophinopathies are due to mutations in the *DMD* (Dystrophin) gene located on the X chromosome inherited in a recessive pattern. All hemizygous males will exhibit the characteristic phenotype whereas heterozygous females for a pathogenic mutation may exhibit a range of clinical manifestations. If skeletal muscles are affected, dystrophinopathies are classified as either DMD or BMD; however, if cardiac muscle is primarily affected, it is characterized as *DMD*-associated dilated cardiomyopathy (DCM) (Darras, 2024c; Darras et al., 2000).

Duchenne muscular dystrophy, the more severe phenotype of the skeletal muscle dystrophinopathies, typically presents in males before the age of five with progressive, symmetric muscle weakness and calf hypertrophy. Affected males are typically

wheelchair-dependent before their teens, and the individual rarely survives beyond their thirties due to respiratory complications and heart failure. BMD is often less severe and manifests later in affected individuals at 30 years of age. Most of these individuals remain ambulatory into adulthood, with some reported to remain ambulatory as late as their sixties. Although skeletal muscle deterioration progresses more slowly in BMD, cardiomyopathy is the most common cause of death in these patients, shortening the life expectancy to the mid-forties. Many BMD patients receive heart transplants within five years after diagnosis of cardiomyopathy (Darras et al., 2000). The prevalence of DMD in the United States has been estimated between 1.3 and 2.1 cases per 10,000 live male births, though the number differed by race/ethnicity in a recent study (Romitti et al., 2015).

Duchenne muscular dystrophy or BMD should be suspected in males with elevated serum creatine phosphokinase (CK) levels (>ten-times of normal and >five-times of normal, respectively) and clinical symptoms of dystrophinopathy. As permeability of the sarcolemma increases due to muscle damage, creatine phosphokinase is released beyond the normal range, which can be used as a diagnostic value. In DMD, serum CK peaks by age two years, with levels reaching ten to 20 times the upper limit of normal (Darras, 2024a). As the disease progresses, dystrophic muscle fibers begin to decay and the rate of CK release decreases (Kim et al., 2017). Hemizygous female carriers can also exhibit elevated serum CK levels, which are two to ten times that of the normal range. (Darras et al., 2000). A normal CK level, however, makes DMD and BMD unlikely and alternative diagnoses should be considered in these cases.

A variety of genetic testing methodologies are available to assist in the diagnosis of DMD/BMD. In general, it is advisable to try larger deletion/duplication genetic testing first and, if negative, move on to next-generation exome or genome sequence analysis, which can detect "small" mutations [like single nucleotide polymorphisms (SNPs)] as well as micro deletion and duplications (Darras, 2024a). Multiplex ligation-dependent probe amplification (MLPA) has been used successfully to detect duplication or deletion mutations that cause DMD/BMD. It has also been reported that up to 98% of disease-causing deletions could be detected with multiplex polymerase chain reaction (PCR) (Chamberlain et al., 1992). Quantitative PCR, long-range PCR, and chromosomal microarray (CMA) may also be considered; however, CMA is not recommended as a primary confirmatory assay for dystrophinopathies as the sensitivity of the assay may not be sufficient to detect all exon level DMD deletions and duplications (Darras et al., 2000).



Clinical Utility and Validity of DMD/BMD Genetic Testing

A recent Chinese study of 146 at-risk pregnancies in 131 DMD families report a 99% mutation detection rate using "a prenatal diagnosis algorithm for dystrophinopathies that combines multiplex ligation-dependent probe amplification (MLPA), quantitative PCR, sequencing and linkage analyses" (Wang et al., 2017). This data also shows that 51.1% of the probands had de novo exon deletions. Recombination of the *DMD* gene occurred in nine of the 146 pregnancies. The authors conclude that "the present results demonstrate the importance of considering maternal germline mosaicism in the genetic assessment. Prenatal diagnosis should be suggested to the parent with a DMD proband whether carrier testing found the causative mutation in the mother's blood or not" (Wang et al., 2017). The reported accuracy rate of this multiplex/quantitative PCR-based method is considerably higher that the reported accuracy rate (>70%) of a real-time PCR assay of the *DMD* gene (Zhang et al., 2013).

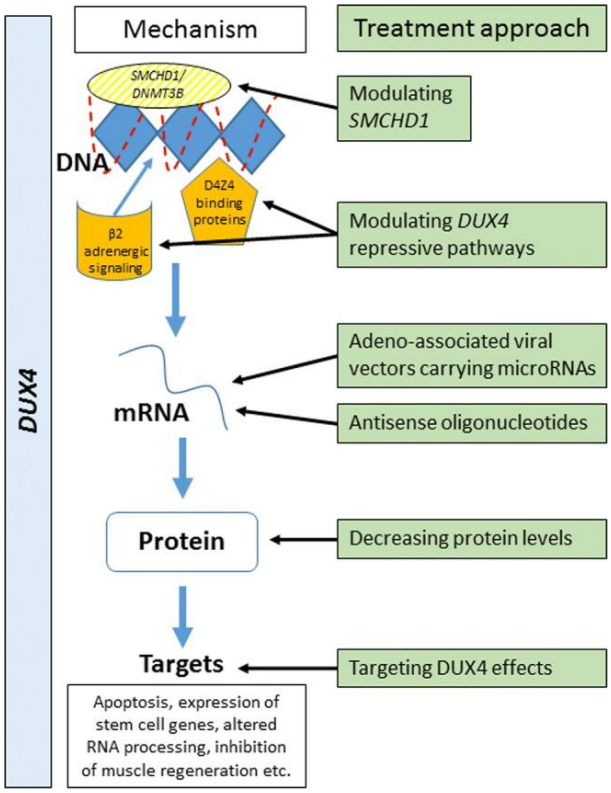
The MLPA-based genetic testing of dystrophinopathies has been reported in many studies with varying degrees of sensitivity. A large study of 1053 Chinese DMD/BMD patients using MLPA testing reported identifying 70.56% of the probands (Yang et al., 2013) whereas a smaller study of 121 individuals (both male and female) reports confirmation of only 63% of patients and symptomatic females (Luce et al., 2016). A third study of using an algorithm of mPCR and MLPA on 150 male patients reported a 75% confirmation rate (Murugan et al., 2010). Another study using MLPA concluded that "the reading-frame rule held in 90% to 94% of children, which is consistent with reports from other parts of the world. However, testing by MLPA is a limitation, and advanced sequencing methods including analysis of the structure of mutant dystrophin is needed for more-accurate assessments of the genotype-phenotype correlation" (Vengalil et al., 2017).

In a study by Han et al. (2020), 37,268 females of reproductive age were recruited in Hangzhou, China, to identify definite DMD carriers prior to or early in pregnancy. Participants were screened for high CK activity (>200 U/L), a typical finding in 50-70% of asymptomatic heterozygous female DMD carriers (Brandsema & Darras, 2015), and DMD family history. The screening process narrowed down the number of participants for DMD genetic sequencing performed with MLPA to detect gross deletions and duplications and next-generation sequencing (NGS) based on multiplex PCR to detect the small point mutations, insertions, and deletions. From the 37,268 participants, 427 females were identified to have CK levels above 200 U/L and 16 females with a previous family history of DMD. A total of 427 females with high CK levels were asked to repeat CK testing, to which 281 females agreed, and 62 females showed to have sustained elevated serum CK levels. The 16 participants with DMD family history and 62 females with sustained CK levels >200 U/L were asked to undergo *DMD* genetic

testing. "MLPA and NGS of the *DMD* gene identified six definite DMD carriers with clear pathogenic variants (3 of the 16 subjects with positive family history and three of the 62 subjects with negative family history) … Four cases had deletions and/or duplications of *DMD* gene, mostly located in a hotspot mutation region (exons 44-55), one case carried a previous reported pathogenic missense variant, and a novel deleterious frameshift pathogenic variant was found in one case" (Han et al., 2020). Results of the screening for DMD carriers are summarized in the figure below (Han et al., 2020).

Confirmed carriers of DMD pathogenic variant were provided professional genetic counseling and several reproductive choices such as preimplantation genetic diagnosis, prenatal genetic testing through chorionic villus, amniotic fluid, or umbilical cord blood sampling during different gestation weeks as needed. The authors state that current carrier screening for DMD, which is provided for females with a family history of DMD, misses the many spontaneous cases resulting from unsuspected variants. Therefore, the authors suggest that "Carrier screening before or early in pregnancy will allow carrier females to receive genetic counseling and be informed of fertility choices and recurrent risk. Moreover, carrier screening will help carriers prepare

for the possibility of manifesting DMD-related symptoms later on in life… Furthermore, female relatives of positive carriers should be recommended for genetic testing in order to evaluate their carrier status" (Han et al., 2020).



Facioscapulohumeral Muscular Dystrophy (FSHD)

Facioscapulohumeral muscular dystrophy is the third most common type of muscular dystrophy , with an estimated prevalence of four to 12 per 100,000 population (Darras et al., 2000). It is an autosomal dominant genetic disorder that is caused by a deletion of the macrosatellite repeat regions D4Z4 of the *DUX4* gene in the subtelomeric region of chromosome 4q. In healthy individuals, the *DUX4* gene is epigenetically silenced in somatic tissues; however, contraction of the D4Z4 repeats allows for inefficient chromatin silencing due to abnormal chromatin structure, resulting in inappropriate somatic expression. Unaffected individuals have a variable number of D4Z4 repeats, ranging from 11 to more than 100, whereas FSHD1 patients have only one to ten repeats on one of the copies of chromosome four. The DUX4 protein is usually only expressed in the germline as a DNA-binding protein with presumed transcription factor activity. Its toxicity in somatic cells is unknown. Two forms of FSHD have been classified—FSHD1, the major form due to a major contraction of the D4Z4 macrosatellite repeat sequences, and FSHD2, a minor form with a normal number of D4Z4 repeats but abnormal D4Z4 chromatin structure. FSHD2 patients have a disease status that cannot be confirmed by using the standard molecular diagnostic testing used in FSHD1 patients (van der Maarel et al., 2011). Further, 85% of patients with FSHD2 have mutations in the *SMCHD1* gene on chromosome 18, which encodes for a chromatin modifier believed to be involved in maintaining the D4Z4 chromatin structure (R. J. Lemmers et al., 2012). Pathogenic variants of *DNMT3B* and *LRIF1* genes are less common causes of FSHD2 (Hamanaka et al., 2020; van den Boogaard et al., 2016). Despite the different genetic causes, the phenotypes of FSHD1 and FSHD2 patients are often clinically indistinguishable (de Greef et al., 2010).

Facioscapulohumeral muscular dystrophy patients exhibit a progressive muscular dystrophy with variability of affected muscles between patients. Generally, muscles of the face, arms, legs, shoulders, and abdomen can be affected. Serum-based diagnostic testing for FSHD has been elusive. A cross-sectional study by Petek and colleagues, using high-throughput proteomics, shows that the levels of creatine kinase MM and MB isoforms, carbonic anhydrase III, and troponin I type two were elevated at least 1.5-fold in affected individuals and correlated with the severity and state of disease (Petek et al., 2016). Because of the variability of FSHD, genetic testing is still "the preferred diagnostic choice" (R. J. L. F. Lemmers et al., 2012).

Methylation of the D4Z4 regions also plays a role in disease expression and progression (Haynes et al., 2018; Mul et al., 2018; van der Maarel et al., 2011). A study by Mul and colleagues researched the clinical variability of FSHD1 patients for a possible linkage between the severity of disease, the repeat array size of D4Z4, and D4Z4 methylation. Unsurprisingly, unaffected gene carriers had both a higher number of array repeats and higher methylation levels. One interesting result is that the location of the affected body region did show a correlation between disease severity and DNA modification. "The D4Z4 repeat array size and D4Z4 methylation contribute to variability in disease severity and penetrance, but other disease modifying factors must be involved as well, such as polyadenylation of the *DUX4* transcript. Polyadenylated *DUX4* transcripts are not degraded and lead to the development of FSHD by a toxic gain of function mechanism (Darras, 2024c). The larger effect of the D4Z4 repeat array on facial muscle involvement suggests that these muscles are more sensitive to the influence of the FSHD1 locus itself, whereas leg muscle involvement seems highly dependent on modifying factors" (Mul et al., 2018).

Inappropriate expression of *DUX4* in somatic tissue is ultimately responsible for the pathogenesis of FSHD; hence, recent efforts to treat the disorder have targeted the expression of this gene and/or its protein product, as summarized in the table below (Hamel & Tawil, 2018).

Clinical Utility and Validity of FSHD Genetic Testing

The data on the clinical validity and utility of FSHD genetic testing is limited. The American Academy of Neurology and the American Association of Neuromuscular & Electrodiagnostic Medicine released joint guidelines stating the following: "our systematic review identified nine Class III studies from specialty clinics that, together, demonstrate that the finding of a D4Z4 contraction on chromosome 4q35 likely has a sensitivity of 93% and a specificity of 98% for diagnosis of clinically defined FSHD" (Tawil et al., 2015). A 2010 study of more than 800 individuals, however, question the criteria for the molecular diagnosis of FSHD. In this study, three percent of asymptomatic, healthy individuals reported a reduced number of D4Z4 repeats, varying four to eight units on chromosome four; further, almost one-half of probands had a normal copy number of D4Z4 repeats. These "results suggest that the genetic basis of FSHD, which is remarkably heterogeneous, should be revisited because this has important implications for genetic counseling and prenatal diagnosis of at-risk families" (Scionti et al., 2012).

The most common method of molecular diagnosis for FSHD is pulsed-field gel electrophoresis with Southern Blotting to discriminate between chromosome four and chromosome ten D4Z4 arrays. A study by Dai and colleagues describes a novel method to characterize the D4Z4 repeat numbers in FSHD by using a single molecule optical mapping platform that helps detect structural variants. With Bionano genome mapping, the number of D4Z4 repeats with 4qA allelic configuration and the levels of postzygotic mosaicism were determined. In the study, the primary cohort consisting of five patients had a confirmed positive diagnosis of FSHD based on Southern blot analysis. The second cohort consisted of eight patients that were suspected to have FSHD, but the patients did not have a prior molecular diagnosis. Optical mapping was performed, and Southern blot was used as a validation assay. In both cohorts, the results obtained from optical mapping have 100% concordance with the results from Southern blot analysis. Although optical mapping is a novel method that can improve accuracy and reliability of FSHD molecular testing, the authors also discuss the disadvantages of the optical mapping platform. Optical mapping is an expensive and time consuming tool compared to Southern blot, which works reliably for diagnosing patients with one to ten D4Z4 repeats in a cost-effective manner. Despite the disadvantages, the authors believe that costs for optical mapping will decrease and the tool will be incorporated into the clinical setting (Dai et al., 2020).

The genetic diagnosis of FSHD can be confounded by false positive or false negative results. A common test for FSHD uses a p13E-11 DNA probe to confirm a specific deletion that is indicative of the disorder. However, a false negative may occur if the patient has a deletion that affects the diagnostic probe's region of recognition (Lemmers et al., 2003). A "false" negative result may also occur with this test for patients with FSHD2, since they may not possess the characteristic deletion that is

present in typical FSHD1 cases. If clinical suspicion of FSHD exists in patients with a negative test result, then further genetic testing that includes the *SMCHD1*, *DNMT3B,* and/or *LRIF1* genes may be warranted to confirm FSHD2. Genetic testing should also include haplotype analysis, since a false positive result may occur "if the contracted D4Z4 array is located on the non-permissive 4qB haplotype" (Darras, 2024c).

Limb-Girdle Muscular Dystrophies (LGMDs)

Together, the group of disorders that constitute LGMD occur with an estimated minimum prevalence between ten and 23 per 100,000 (Wicklund, 2019).The LGMDs vary widely in their genetics and clinical features, ranging from mild forms allowing patients to maintain a fairly normal life to severe deterioration of proximal limb muscles with significant physical weakness and shortened life-span (Monies et al., 2016). A newer definition of LGMD has been proposed as "a genetically inherited condition that primarily affects skeletal muscle leading to progressive, predominantly proximal muscle weakness at presentation caused by a loss of muscle fibres. To be considered a form of limb girdle muscular dystrophy the condition must be described in at least two unrelated families with affected individuals achieving independent walking, must have an elevated serum creatine kinase activity, must demonstrate degenerative changes on muscle imaging over the course of the disease, and have dystrophic changes on muscle histology, ultimately leading to end-stage pathology for the most affected muscles" (Straub et al., 2018).

Approximately 30 LGMDs are recognized currently, most of which are inherited in an autosomal recessive pattern. The table below displays the recognized LGMDs according to the updated classification system (Wicklund, 2019):

Nomenclature, genes, and protein products of limb-girdle muscular dystrophies

New nomenclature	Old nomenclature	Gene	Protein product
Autosomal dominant			
LGMD D1	LGMD1D	*DNAJB6*	DnaJ heat shock protein family (Hsp40) member B6
LGMD D2	LGMD1F	*TNPO3*	Transportin 3
LGMD D3	LGMD1G	*HNRNPDL*	Heterogeneous nuclear ribonucleoprotein D like protein
LGMD D4	LGMD1I	*CAPN3*	Calpain 3
LGMD D5		*COL6A1*	Collagen type VI alpha 1 chain
Autosomal recessive			

New nomenclature	Old nomenclature	Gene	Protein product
LGMD R1	LGMD2A	*CAPN3*	Calpain 3
LGMD R2	LGMD2B	*DYSF*	Dysferlin
LGMD R3	LGMD2D	*SGCA*	Sarcoglycan alpha
LGMD R4	LGMD2E	*SGCB*	Sarcoglycan beta
LGMD R5	LGMD2C	*SGCG*	Sarcoglycan gamma
LGMD R6	LGMD2F	*SGCD*	Sarcoglycan delta
LGMD R7	LGMD2G	*TCAP*	Telethonin
LGMD R8	LGMD2H	*TRIM32*	Tripartite motif-containing 32
LGMD R9	LGMD2I	*FKRP*	Fukutin-related protein
LGMD	LGMD2J	*TTN*	Titin
LGMD	LGMD2K	*POMT1*	Protein O-
LGMD	LGMD2L	*ANO5*	Anoctamin 5
LGMD	LGMD2M	*FCMD*	Fukutin
LGMD	LGMD2N	*POMT2*	Protein O-
LGMD R15	LGMD2O	*POMGNT1*	Protein O-linked mannose *N*-acetylglucosaminyltransferase 1 (beta 1,2–)
LGMD	LGMD2P	*DAG1*	Dystroglycan 1
LGMD	LGMD2Q	*PLEC1*	Plectin
LGMD	LGMD2S	*TRAPPC11*	Trafficking protein particle
LGMD	LGMD2T	*GMPPB*	GDP-mannose
LGMD	LGMD2U	*CRPPA*	CDP-L-ribitol
LGMD	LGMD2Z	*POGLUT1*	Protein O-glucosyltransferase
LGMD		*COL6A1/2/3*	Collagen type VI alpha 1, 2, or
LGMD		*LAMA2*	Laminin subunit alpha 2
LGMD R24		*POMGNT2*	Protein O-linked mannose *N*-acetylglucosaminyltransferase 2 (beta 1,4–)

The autosomal recessive LGMD R1 is considered the most common form of LGMD worldwide, making up an estimated 15 to 40 percent of all cases of LGMD (Nallamilli et al., 2018; Wicklund & Kissel, 2014).

Dilated cardiomyopathy (DCM) is the most common cardiac phenotype associated with LGMD, and its prevalence varies in the different subgroups of patients. The risk of developing DCM is particularly high in the LGMD1B patient subgroup, such that clinicians might consider preventive interventions due to the high risk of sudden death (Arbustini et al., 2018).

Clinical Utility and Validity of LGMD Genetic Testing

Based on published literature, the clinical validity of genetic testing for LGMD is difficult to ascertain; however, broad genetic testing is becoming the standard for LGMD diagnosis for patients suspected of having LGMD (Wicklund, 2019). Testing should be performed by way of an LGMD or neuromuscular gene panel that looks for alterations in genes known to be involved in LGMD or other dystrophies and myopathies. If such a panel is inconclusive, broader testing by way of whole-exome sequencing or whole genome sequence with NGS may be used (Ghaoui et al., 2015; Ozyilmaz et al., 2019). Unless clinical findings suggest a particular subtype of LGMD, whole-exome or whole genome testing may increase the likelihood of an accurate diagnosis as compared to single gene sequencing (Narayanaswami et al., 2014).

The yield of genetic testing in patients with signs and symptoms of LGMD varies depending on the mutation and population characteristics. Some studies conclude that the clinical validity is reasonably high (Fanin et al., 2009; Norwood et al., 2007). According to Norwood et al. (2007), "DNA analysis directed to provide confirmation of mutation in the affected gene(s) is the gold standard of diagnosis, and necessary to be able to offer carrier or presymptomatic testing to other family members." Other researchers have attempted to utilize whole-exome sequencing to diagnose LGMD in 100 individuals with familial LGMD; however, a diagnostic success rate of only 45% was achieved (Ghaoui et al., 2015).

Monies et al. (2016) screened 50 random genetically unstudied families with LGMD via a gene panel incorporating 759 OMIM (Online Mendelian Inheritance in Man) genes associated with neurological disorders. OMIM is a catalogue of human genes and genetic disorders that provides comprehensive information based on the periodical biomedical literature (Amberger et al., 2014). The panel "identified the mutation in 76% of families (38/50; 11 novel). A total of 34 families had mutations in LGMD-related genes with four others having variants not typically associated with LGMD. The majority of cases had recessive inheritance with homoallelic pathogenic variants (97.4%, 37/38), as expected considering the high rate of consanguinity in the study population." The authors concluded that the "neurological panel achieved a high clinical sensitivity (76%) and is an effective first-line laboratory test in patients with LGMD and other myopathies. This sensitive, cost-effective, and rapid assay significantly assists clinical practice especially in these phenotypically and genetically heterogeneous disorders. Moreover, the application of the American College of Medical Genetics (ACMG) and Association for Molecular Pathology (AMP) guidelines applied in the classification of variant pathogenicity provides a clear interpretation for physicians on the relevance of such findings" (Monies et al., 2016).

Harris et al. (2017) performed whole-exome sequencing (WES) on 104 patients with LGMD in which standard gene testing had not yet yielded a diagnosis, and 91 patients using sequential gene by gene testing. They found that "patients selected for WES had undergone more extensive prior testing than those undergoing standard genetic testing, and on average had had eight genes screened already. In this extensively investigated cohort WES identified the genetic diagnosis in 28 families (28/75, 37%), including the identification of the novel gene ZAK and two unpublished genes. WES of a single affected individual with sporadic disease yielded a diagnosis in 13/38 (34%) of cases. In comparison, conventional gene by gene testing provided a genetic diagnosis in 28/84 (33%) families." The authors concluded that "WES was able to overcome many limitations of standard testing and achieved a higher rate of diagnosis than standard testing even in this cohort of extensively investigated patients. Earlier application of WES is therefore likely to yield an even higher diagnostic rate. We obtained a high diagnosis rate in simplex cases and therefore such individuals should be included in exome or genome sequencing projects. Disease due to somatic mosaicism may be increasingly recognized due to the increased sensitivity of next generation sequencing techniques to detect low level mosaicism" (Harris et al., 2017). A similar study by Reddy and colleagues reported 40% of the LGMD families tested "had novel and previously reported pathogenic mutations, primarily in LGMD genes, and also in genes for Duchenne muscular dystrophy, facioscapulohumeral muscular dystrophy, congenital myopathy, myofibrillar myopathy, inclusion body myopathy and Pompe disease" (Reddy et al., 2017).

Congenital Muscular Dystrophy (CMD)

Congenital Muscular Dystrophy is a group of genetically diverse disorders that typically manifest at birth or within the first two years of life, marked by muscle weakness, hypotonia, and delayed motor milestones. Initially, CMD was recognized in infants who presented with generalized weakness and abnormal muscle biopsies, revealing fibrosis, fatty tissue infiltration and degeneration of muscle fibers. Arthrogryposis, or joint contractures present at birth, is also common in newborns with CMD (Darras, 2024e).

CMD encompasses both "classic" forms, like merosin-deficient CMD, and more complex "syndromic" forms such as Walker-Warburg syndrome, Fukuyama muscular dystrophy, and muscle-eye-brain disease. Syndromic CMDs often involve structural abnormalities in the brain detected by neuroimaging; these can present with cognitive impairments, developmental delays, and cardiac involvement. Genes associated with CMD in targeted gene panels encompass genes such as *LAMA2, COL6A1-3, FKTN*, and *POMT1-2*, among others. Dysfunction can occur across multiple organ symptoms in merosin-deficient CMD (associated with mutations in the *LAMA2* gene) (Darras, 2024e).

Clinical Utility and Validity of CMD Genetic Testing

O'Grady et al. (2016) compared targeted next-generation (NGS) panels with traditional candidate gene sequencing in diagnosing CMD. The study included 123 participants with evidence of muscle weakness and hypotonia in the first two years of life. These participants were identified over a 35-year period. Genetic testing targeted key genes, including *LAMA2, FKRP, COL6A1-3*, and *SEPN1*. A genetic diagnosis was confirmed for 39 participants (32%), with two additional probable cases. Further NGS using a 45-gene panel, a 336-gene panel, or WES identified causative variants in 11 more individuals, bringing the total diagnostic yield to 59 out of 123 (48%). The study concluded that NGS should serve as the first-line diagnostic tool for CMD, with muscle biopsy reserved for secondary evaluation (O'Grady et al., 2016).

Clinical Utility and Validity of Multi-gene Panel Testing for NMDs

Ebert et al. (2024) drove a retrospective review to analyze the clinical utility and detection rate of genetic testing for individuals with suspected neuromuscular disease. Genetic testing results were gathered for individuals who had received multi-gene panel testing for neuromuscular disorders; the authors analyzed individual records to determine whether the results confirmed or denied a neuromuscular disease diagnosis. A pathogenic mutation or a variant of unknown significance (or both) was found in 77.1% of the study individuals, allowing the confirmation of diagnosis in 35.9%. The most common presenting symptom and indication for testing was suspected neuropathy (53.3%). Myopathy was found in 48.7% of cases. Overall, the authors concluded that the existing evidence constitutes additional confirmatory evidence towards the use of multi-gene panel genetic testing to help the diagnosis and management of neuromuscular disorders. The genetic panel testing was done through Invitae (Ebert et al., 2024).

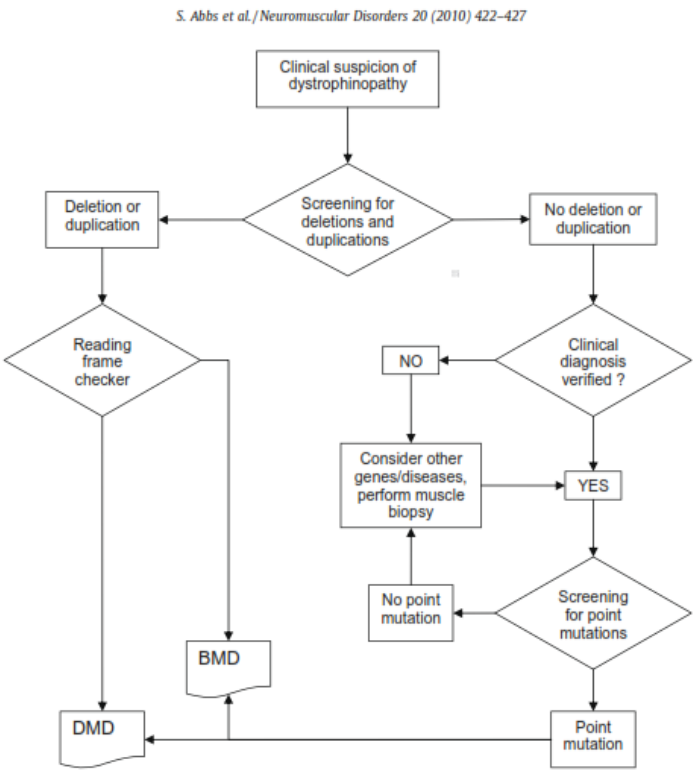
Rosenberg et al. (2023) investigated the use of multi-gene panel genetic testing to confirm a diagnosis of neuromuscular diseases among 155 patients. They note that clinical evaluation for NMDs has increasingly incorporated molecular genetics as a first or second tier diagnosis practice, especially over the past ten years and that “curated multigene panels of several hundreds of genes remain the most used methodology for the diagnosis of many NMDs. WES is an increasingly popular testing choice when disease presentation is complex and nonclassical.” The authors gathered patient data between 2018 and 2020 using 26 separate genetic tests for a total of 262 individual tests (average of 1.7 tests per patient). Of the patients who had tests performed, over half had a comprehensive NMD panel ordered with between 110 and 211 genes known to be associated with NMDs, inherited myopathies and congenital myasthenic syndrome. The comprehensive NMD panel that was ordered for over half of patients

had a diagnostic yield of 14% with 21% of all patients receiving a confirmative diagnosis, which the authors note was low due to the heterogeneity of NMDs and the specific challenge of conditions such as myotonic dystrophy type 1 and facioscapulohumeral muscular dystrophy, which require specialized molecular testing (Rosenberg et al., 2023).

VI. Guidelines and Recommendations

Best Practice Guidelines on Molecular Diagnostics in Duchenne/Becker Muscular Dystrophies Workshop Report

The international workshop comprised of scientists from Europe, the US, India, and Australia was organized and sponsored by the European Neuro-Muscular Centre, the European Molecular Genetics Quality Network, TREAT-NMD, and Euro-Gentest. The flow chart for the recommended diagnostic work-up of a dystrophinopathy is shown below in Figure 1, located below (Abbs et al., 2010).



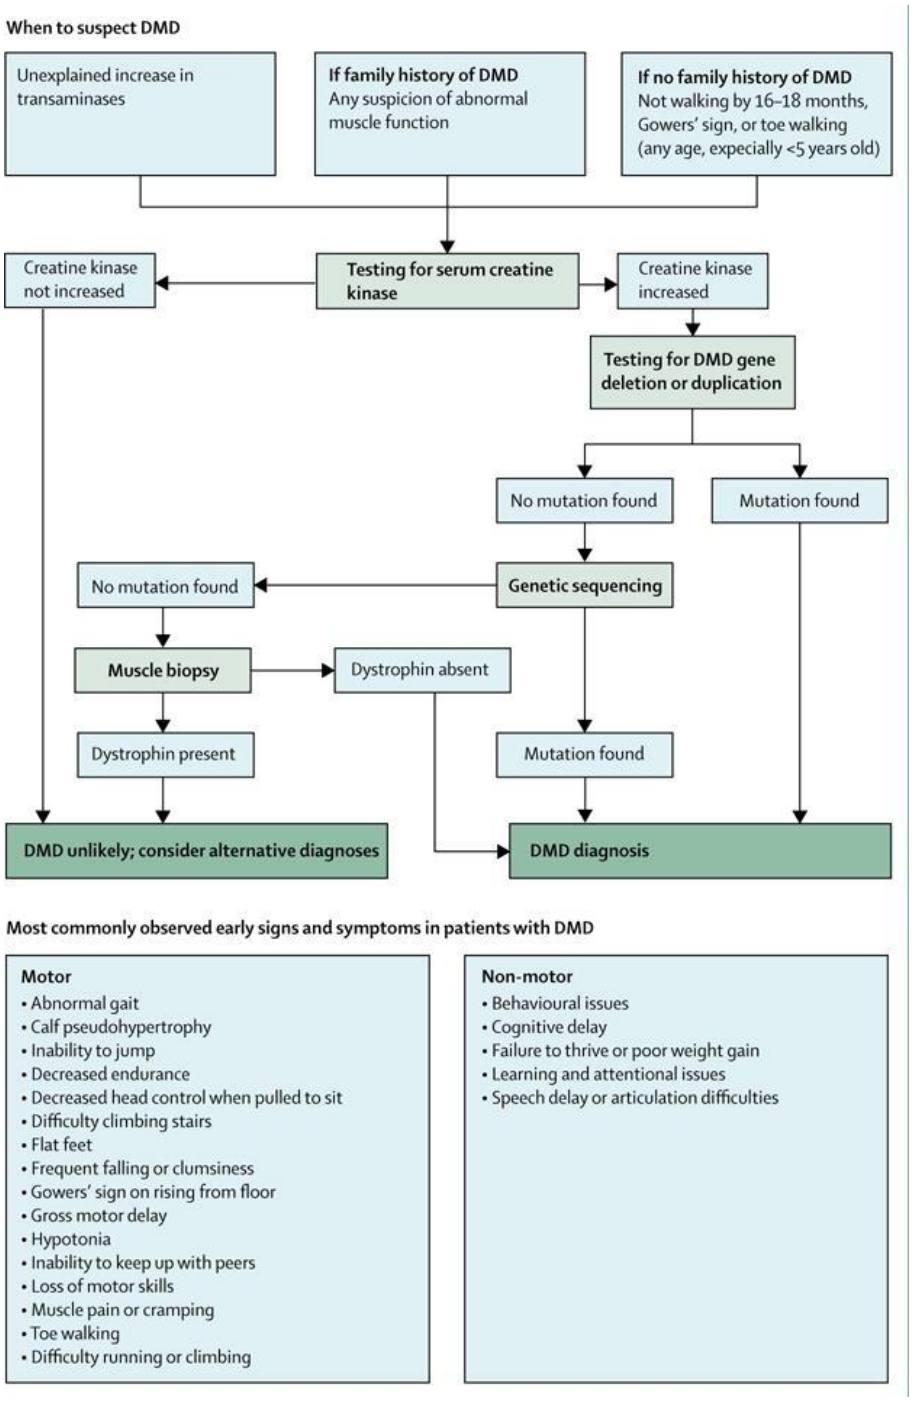


Fig. 1. Flow chart for the diagnostic work-up of a dystrophinopathy.

Recommendations for testing are as follows: if there is a clinical suspicion of a dystrophinopathy, first screen for deletions and duplications. Then, if no deletion or duplication is detected, but the clinical diagnosis is verified, screening for point mutations should be performed (Abbs et al., 2010).

The DMD Care Considerations Working Group

The CDC selected 84 clinicians to comprise the DMD Care Considerations Working Group to develop recommendations regarding all aspects of DMD care, including the diagnosis and genetic testing of muscular dystrophy. They state the following: "Testing for a DMD mutation in a blood sample is always necessary even if DMD is first confirmed by the absence of dystrophin protein expression on muscle biopsy. The results of genetic testing provide the clinical information required for genetic counselling, prenatal diagnosis, and consideration for future mutation-specific therapies... If analysis by one or more of these techniques leads to the identification and full characterisation of a dystrophin mutation, then no further testing is required. If deletion/ duplication testing is negative, then dystrophin gene sequencing should be done to look for point mutations or small deletions/insertions. Full characterisation of the mutation (deletion endpoints or exact position of any point mutation) is required to allow correlation of the predicted effect of the mutation on the reading frame of the gene, which is the major determinant of the phenotypic variability seen in dystrophinopathy, as well as to determine eligibility for the mutation-specific treatments currently in trials" (Bushby et al., 2010).

An update of the 2010 DMD Care considerations was published to further improve patient care. A diagnostic flow chart for DMD was provided and can be found below (Birnkrant et al., 2018).

The DMD Care Considerations Working Group has stated that "Because approximately 70% of individuals with DMD have a single-exon or multi-exon deletion or duplication in the dystrophin gene, dystrophin gene deletion and duplication testing is usually the first confirmatory test. Testing is best done by multiplex ligation-dependent probe amplification (MLPA) or comparative genomic hybridisation array, since use of multiplex PCR can only identify deletions…If deletion or duplication testing is negative, genetic sequencing should be done to screen for the remaining types of mutations

that are attributed to DMD (approximately 25–30%)…Finally, if genetic testing does not confirm a clinical diagnosis of DMD, then a muscle biopsy sample should be tested for the presence of dystrophin protein by immunohistochemistry of tissue cryosections or by western blot of a muscle protein extract" (Birnkrant et al., 2018). Also stated is that "Family members of an individual with DMD should receive genetic counselling to establish who is at risk of being a carrier. Carrier testing is recommended for female relatives of a boy or man who has been genetically confirmed to have DMD" (Birnkrant et al., 2018).

American Academy of Neurology (AAN) and the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM)

The Guideline Development Subcommittee of the AAN and the Practice Issues Review Panel of the AANEM published recommendations that "Targeted genetic testing often identifies causative mutations in the classic CMD subtypes... Genetic diagnoses are beneficial to the patient, as they often enable physicians to provide more accurate prognoses and facilitate genetic counseling and family planning discussions, and may enable patients to become more aware of future clinical trials for which they may be eligible… when available and feasible, physicians might order targeted genetic testing for specific CMD subtypes that have well-characterized molecular causes" and "In individuals with CMD who either do not have a mutation identified in one of the commonly associated genes or have a phenotype whose genetic origins have not been well characterized, physicians might order whole-exome or whole-genome sequencing when those technologies become more accessible and affordable for routine clinical use" (Kang et al., 2015).

In 2014, the AAN and the Practices Issues Review Panel of the AANEM issued evidenced-based guidelines for the diagnosis and treatment of limb-girdle and distal dystrophies, who made the following recommendations (Narayanaswami et al., 2014) that were reaffirmed in 2022:

For the diagnosis of LGMD:

- For patients with suspected muscular dystrophy, clinicians should use a clinical approach to guide genetic diagnosis based on the clinical phenotype, including the pattern of muscle involvement, inheritance pattern, age at onset and associated manifestations (e.g., early contractures, cardiac or respiratory involvement) (Level B recommendation).
- In patients with suspected muscular dystrophy in whom initial clinically directed genetic testing does not provide a diagnosis, clinicians may obtain genetic consultation or perform parallel sequencing of targeted exomes, whole-exome

sequencing, whole genome screening, or next-generation sequencing to identify the genetic abnormality (Level C recommendation).

The AAN Guidelines state: "Diagnosis assists in defining the long-term prognosis, since some dystrophies are more rapidly progressive, involve the cardiorespiratory systems more frequently, or are associated with other disorders. The identification of these dystrophies through genetic testing will not only inform long-term prognosis but will also assist in directing care more efficiently (e.g., more frequent cardiorespiratory monitoring and prophylactic treatments such as pacer/defibrillator placement for those disorders known to be associated with cardiac involvement). Precise identification of the disorder also eliminates the need for repeated testing for an acquired, treatable disorder such as an inflammatory myopathy, because some dystrophies have inflammation on muscle biopsy, making diagnosis difficult on the basis of routine biopsy findings. In addition, the temptation to try immunosuppressive agents repeatedly, looking for a therapeutic response, is not unusual when there is no diagnosis and the patient is worsening. This exposes patients to potentially serious side effects of immunosuppressive medications. Patients on immunosuppressants need regular monitoring, adding logistical difficulties to a population that may have significantly impaired mobility. Health care costs are increased by repeated investigations, immunosuppressive treatments, and laboratory monitoring. Although establishing a genetic diagnosis is expensive on the front end, the costs of continued investigation for other causes and the risks and expenses associated with empiric trials of immunosuppressants make a strong case for establishing a genetic diagnosis, which often provides patients a sense of closure. Establishing a genetic diagnosis is crucial for genetic counseling to inform decision-making about having children and for screening of offspring. Treatment of cardiomyopathy, arrhythmias, and ventilatory failure prolongs life and improves quality of life in patients with other neuromuscular diseases" (Narayanaswami et al., 2014). These guidelines were reaffirmed in 2022.

For the diagnosis of CMD:

"CMDs are often autosomal recessive, but some cases have been found to follow autosomal dominant patterns, by direct inheritance, spontaneous mutations, or mosaicism. The genetic origins of many cases of CMD have been discovered. However, many affected individuals remain without a genetic diagnosis, an indicator that novel disease genes have yet to be identified. Clinical genetic testing is available for virtually all genes known to be associated with CMD."

Two recommendations regarding CMD diagnosis via genetic testing (reaffirmed 2021):

"1. When available and feasible, physicians might order targeted genetic testing for specific CMD subtypes that have well-characterized molecular causes (Level C). Our

systematic review indicates that many patients with CMD do not have mutations in one of the currently known genes. The cost of next-generation sequencing (whole-exome and whole-genome sequencing) is dropping rapidly, to the point where these technologies are now readily available to many researchers who seek novel causative disease genes.

2. In individuals with CMD who either do not have a mutation identified in one of the commonly associated genes or have a phenotype whose genetic origins have not been well characterized, physicians might order whole-exome or whole genome sequencing when those technologies become more accessible and affordable for routine clinical use (Level C)" (Kang et al., 2015).

American Academy of Neurology (AAN)

The American Academy of Neurology published evidence-based guidelines which found that "the finding of a D4Z4 contraction on chromosome 4q35 likely has a sensitivity of 93% and a specificity of 98% for diagnosis of clinically defined FSHD." They recommend that "Clinicians should obtain genetic confirmation of FSHD1 in patients with atypical presentations and no first-degree relatives with genetic confirmation of the disease [Level B]." Concerning the use of genetics as a predictor of severity in FSHD, they recommend, "Large D4Z4 deletion sizes (contracted D4Z4 allele of 10–20 kb) should alert the clinician that the patient is more likely to develop more significant disability and at an earlier age. Patients with large deletions are also more likely to develop symptomatic extramuscular manifestations [Level B]" (AAN, 2018; Tawil et al., 2015). These guidelines were reaffirmed in 2021.

International Standard of Care Committee for Congenital Muscular Dystrophy

As a part of the guidelines concerning newly diagnosed patients, the International Standard of Care Committee for Congenital Muscular Dystrophy recommends that "if a genetic diagnosis is known, the recurrence risk and impact on future family planning should be discussed. Even if the exact genetic defect is not known, recurrence risk can sometimes be discussed using a common genetic model that is often associated with the diagnosis" (Wang et al., 2010).

171st European Neuromuscular Centre International Workshop on Standards of Care and Management of Facioscapulohumeral Muscular Dystrophy (FSHD)

In a report from the 171st European Neuromuscular Centre International Workshop Standards of Care and Management of FSHD held in January 2010, it is stated that "when a physician concludes facioscapulohumeral syndrome based on clinical findings,

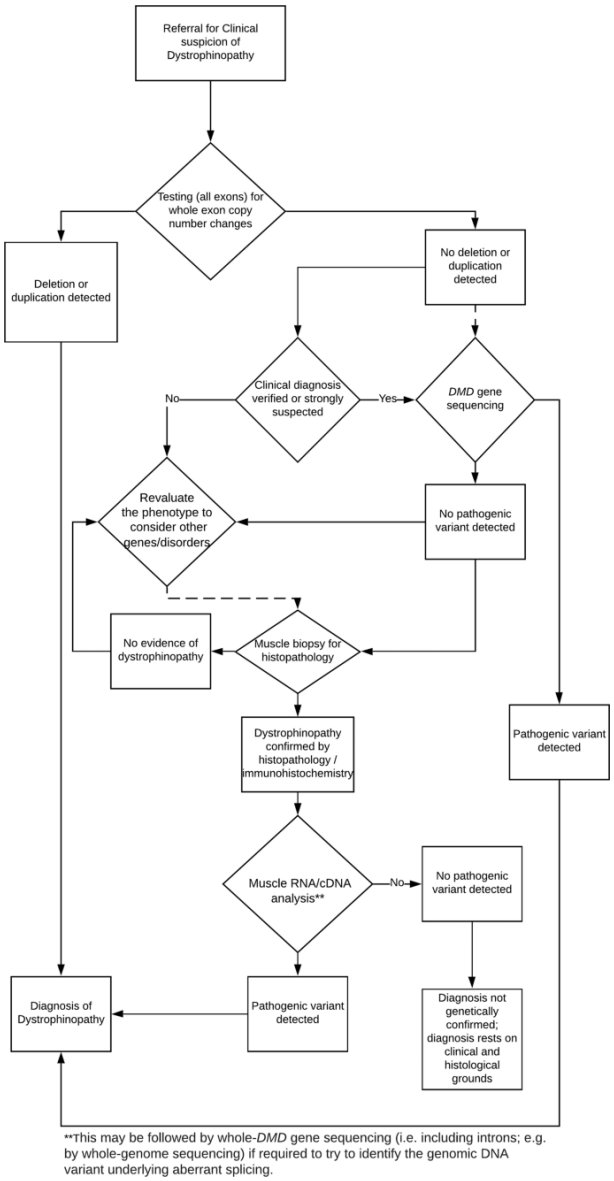
the odds are in favor of FSHD, and genetic testing is the preferred diagnostic choice" (R. J. L. F. Lemmers et al., 2012).

Evidence-Based Consensus and Systematic Review on Reducing the Time to Diagnosis of Duchenne Muscular Dystrophy Joint Report of the EPNS, MDA, PPMD, TREAT-NMD, and DPPI

According to this evidence-based report endorsed by the European Paediatric Neurology Society (EPNS), the Muscular Dystrophy Association (MDA), Duchenne Parent Project Italy (DPPI), Parent Project Muscular Dystrophy (PPMD), and TREAT-NMD, "Genetic testing is crucial for obtaining a complete diagnosis of DMD, and should be considered the gold standard" (Aartsma-Rus et al., 2019); accepted DMD symptoms are listed and include "calf hypertrophy (pseudohypertrophy); delayed walking; difficulty climbing/descending stairs; difficulty rising from the floor; difficulty running/walking; elevated serum CK levels (including elevated ALT and AST); a family history of DMD; frequent falls; Gowers' sign; male sex; and muscle weakness;" additional recommendations include that "patients with signs and symptoms of DMD and elevated serum CK levels should be referred for genetic testing to either a clinical geneticist or a neuromuscular specialist" (Aartsma-Rus et al., 2019). Regarding testing of other family members, Aartsma-Rus et al. (2019) recommends that "After a patient receives a complete genetic diagnosis of DMD, it is mandatory that carrier testing of the mother and other at-risk female family members be offered with appropriate pre- and postgenetic counseling."

U.S. Preventive Services Task Force (USPSTF)

No U.S. Preventive Services Task Force recommendations for genetic testing for muscular dystrophy have been identified. A search for "muscular dystrophy" on the USPSTF website turned up zero relevant results in October of 2024.



European Molecular Genetics Quality Network (EMQN) Best Practice Guidelines on molecular diagnostics in the Duchenne/Becker muscular dystrophies

The EMQN summarizes current diagnostic methods to analyze the *DMD* gene and categorizes these methods according to specificity of the tests into Level one (copy number variations detection), Level two (small variants detection), and Level three (RNA Analysis). Seventy-eight percent of the pathogenic *DMD* variants is due to whole-exon deletions and duplications; therefore, detection of the relative copy number of all exons within the *DMD* gene (copy number variations) is the first level of diagnostic tests offered. Several quantitative tests can be used to detect these copy number variations (CNVs). The most reliable method is MLPA, which detects the number of deletions or duplications to the exon level. MLPA is more reliable when there are

multiple exons involved, but less if there is a single-exon deletion. Therefore, real-time PCR, multiplex PCR, Sanger sequencing, or microsatellite marker analysis must follow to confirm single-exon deletions. Comparative genomic hybridization (CGH) is another method which provides a slightly higher detection rate than MLPA by use of oligonucleotide probes to interrogate copy number across the entire 2.2 Mb genomic region of the *DMD* gene. The last method is NGS, which can detect single nucleotide variants (SNVs) and CNVs; however, NGS is not routinely used to detect CNVs because it is not sensitive enough to pick up on all types of CNVs. Level two testing detects missense, nonsense, small insertions and deletions, and indel and splicing variants through either Sanger sequencing or NGS. NGS is less time consuming as it allows for many targets to be sequenced with deep sequence coverage in multiple patients at a time and enhances detection of low level somatic mosaicism in patients' or probands' mothers; however, Sanger sequencing is still the standard method used for known familial variant testing. Level three testing, such as muscle cDNA analysis, is used when a patient presents with clinical symptoms of a dystrophinopathy, but no CNVs or small variants were detected from Level one and Level two diagnostic techniques.

A flowchart for the recommended molecular diagnostic algorithm for dystrophinopathy is shown in the figure above (Fratter et al., 2020). When dystrophinopathy is suspected due to clinical symptoms, high serum creatine kinase levels, and a possible family history, molecular testing to detect CNVs is recommended. If a pathogenic deletion and duplication is not detected, the next step is to sequence the coding region of the entire *DMD* gene. If a pathogenic variant is not detected from these two tests, a muscle biopsy, dystrophin gene analysis via immunohistochemistry, or muscle cDNA sequencing may be performed. If the patient presents with a positive muscle biopsy test and positive symptoms of a dystrophinopathy, but no pathogenic variant is detected through genetic testing, the patient should still be diagnosed with a dystrophinopathy (Fratter et al., 2020).

The EMQN also provides guidelines on genetic testing for females affected by dystrophinopathies. Although dystrophinopathies predominantly affect males, females

could have a pathogenic *DMD* variant and present with a milder phenotype most likely due to a skewed X-inactivation. In this case, the diagnostic method would be identical to the one presented in the flowchart: evaluation of clinical symptoms, CNV analysis and *DMD* gene sequencing followed by muscle biopsy, dystrophin gene analysis, and muscle cDNA sequencing as needed. If a female presents with the complete DMD phenotype, karyotyping is recommended due to possible chromosomal aberrations or autosomal translocations that could cause 100% skewed X-inactivation.

Females who are carriers of dystrophinopathies are usually clinically asymptomatic but may develop some symptoms during their lifetime or pass it down to their children.

Therefore, carrier testing is important for family planning. If the familial pathogenic variant is known, then two complementary tests should be performed (MLPA and Sanger Sequencing or MLPA and microsatellite analysis). High density array CGH can also be used, which is a single test that interrogates multiple loci within the deletion or duplication. If the familial pathogenic variant is not known and an affected male in the family is not available, then female carriers who are at risk of being carriers should be offered CNV analysis and *DMD* gene sequencing followed by muscle biopsy, dystrophin gene analysis, and muscle cDNA sequencing as needed. Measuring serum creatine kinase levels may also be helpful (Fratter et al., 2020).

The EMQN also comments on prenatal diagnosis of dystrophinopathies. Since it is not possible to predict whether a female will present symptoms of a dystrophinopathy, prenatal diagnosis should only be performed on pregnancies with a male fetus unless there is documented familial reoccurrence of complete skewed X-inactivation. Prenatal testing is performed on placental biopsy through chorionic villus sampling (CVS) within 11-12 weeks of gestation or amniocentesis within 15-17 weeks of gestation. CVS is the preferred method as it provides higher DNA quality and greater safety for the pregnancy. The obtained DNA from placental biopsy can be analyzed through NGS or CNV detection. For non-invasive prenatal diagnostic options, relative haplotype dosage analysis (RHDO) may be performed. "RHDO analysis examines SNPs in the cell-free DNA from a maternal blood sample and shows whether the male foetus has inherited the high risk or low risk haplotype across the *DMD* gene" (Fratter et al., 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81161	DMD (dystrophin) (eg, duchenne/becker muscular dystrophy) deletion analysis, and duplication analysis, if performed
81187	CNBP (CCHC-type zinc finger nucleic acid binding protein) (eg, myotonic dystrophy type 2) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81234	DMPK (DM1 protein kinase) (eg, myotonic dystrophy type 1) gene analysis; evaluation to detect abnormal (expanded) alleles
81239	DMPK (DM1 protein kinase) (eg, myotonic dystrophy type 1) gene analysis; characterization of alleles (eg, expanded size)
81312	PABPN1 (poly[A] binding protein nuclear 1) (eg, oculopharyngeal muscular dystrophy) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP] by techniques such as restriction enzyme digestion or melt curve analysis)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81408	Molecular pathology procedure, Level 9 (eg, analysis of >50 exons in a single gene by DNA sequence analysis)
81479	Unlisted molecular pathology procedure
0218U	Neurology (muscular dystrophy), DMD gene sequence analysis, including small sequence changes, deletions, duplications, and variants in non-uniquely mappable regions, blood or saliva, identification and characterization of genetic variants Proprietary test: Genomic Unity® DMD Analysis Lab/Manufacturer: Variantyx Inc
S3853	Genetic testing for myotonic muscular dystrophy

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Epilepsy

Policy Number: AHS – M2075 – Genetic Testing for Epilepsy	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Epilepsy is a group of disorders characterized by recurrent, unprovoked seizures due to abnormal, synchronized neuronal firing in the brain that can be distinguished by seizure type, age of onset, developmental status, co-morbid features and etiology (Berg et al., 2010; Myers & Mefford, 2015).

For guidance on the use of chromosomal microarray or low-pass whole genome sequencing for the diagnosis of epilepsy, please reference policy AHS-M2033-Chromosomal Microarray and Low-pass Whole Genome Sequencing.

II. Related Policies

Policy Number	Policy Title
AHS-M2033	Chromosomal Microarray and Low-pass Whole Genome Sequencing
AHS-M2085	Genetic Testing of Mitochondrial Disorders
AHS-M2176	Testing for Autism Spectrum Disorder and Developmental Delay

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with infantile- and early-childhood–onset epilepsy syndromes (in which epilepsy is the core clinical symptom), genetic testing for mutations associated with infantile- and early-childhood–onset epilepsy syndromes (see Note 1) **MEETS COVERAGE CRITERIA** only when a positive test result would lead to changes in at least **one** of the following:

a) Medication management.

b) Diagnostic testing (alternative potentially invasive tests are avoided).

c) Reproductive decision making.

2) For individuals with an epilepsy syndrome with a suspected genetic cause, targeted mutation testing **MEETS COVERAGE CRITERIA** to assess for the following clinical situations:

a) *ALDH7A1* testing for pyridoxine-related epilepsy.

b) *BTD* testing for biotinidase deficiency-related epilepsy.

c) *FOLR1* testing for cerebral folate deficiency-related epilepsy.

d) *GRIN2A* testing for GRIN2A-related epileptic encephalopathy.

e) *KCNQ2* testing for KCNQ2-related epileptic encephalopathy.

f) *KCNT1* testing for KCNT1-related migrating partial epilepsy of infancy.

g) *PCDH19* testing for epilepsy female-restricted with mental retardation (EFMR).

h) *PHGDH*, *PSAT1,* and *PSPH* testing for epilepsy due to serine biosynthesis defects.

i) *SCN1A* testing for SCN1A-related seizure disorders.

j) *SCN8A* testing for SCN8A-related epileptic encephalopathy.

k) *SLC2A1* testing for glucose transporter type 1 deficiency syndrome.

l) *SLC6A8, GATM,* and *GAMT* testing for epilepsy due to creatine deficiency syndromes.

m) *TSC1* and *TSC2* testing for tuberous sclerosis complex-related epilepsy.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For all other situations and/or mutations not described above, genetic testing for epilepsy **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AAN	American Academy of Neurology
ALDH7A1	*Aldehyde dehydrogenase 7 family member A1*
AMA	Antiseizure medication
ANK2	*Ankyrin 2*
ASD	Autism spectrum disorders
BTD	*Biotinidase*
CACNA1A	*Calcium voltage-gated channel subunit alpha 1A*
CACNA1AE	*Calcium voltage-gated channel subunit alpha 1AE*
CACNA1D	*Calcium voltage-gated channel subunit alpha 1D*
CACNA1H	*Calcium voltage-gated channel subunit alpha 1H*
CACNA2D3	*Calcium voltage-gated channel subunit alpha 1A*
CDKL5	Calcium voltage-gated channel subunit alpha2delta3
CGH	Comparative genomic hybridization
CHD2	*Chromodomain helicase DNA binding protein 2*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMA	Chromosomal microarray analysis
CMS	Centers for Medicare and Medicaid Services
CNS	Child Neurology Society
CNV	Copy number variant
DEE	Developmental and epileptic encephalopathy
DLG4	*Discs large homolog 4*
DS	Dravet syndrome
EE	Epileptic encephalopathy
EEG	Electroencephalography
EFMR	Epilepsy female-restricted with mental retardation
EFNS	European Federation of Neurological Societies
EP	Epileptic panels
FGF12	*Fibroblast growth factor 12*
FOLR1	*Folate receptor 1*
GABRA1	*Gamma-aminobutyric acid type A receptor alpha1*
GABRG2	*Gamma-aminobutyric acid type A receptor gamma2*
GAMT	*Guanidinoacetate n-methyltransferase*
GATM	*Glycine amidinotransferase*
GGE	Genetic generalized epilepsy
Glut1DS	Glucose transporter 1 deficiency syndrome
GRIA2	*Glutamate ionotropic receptor AMPA type subunit 2*
GRIN2A	*Glutamate ionotropic receptor NMDA type subunit 2a*
GRIN2B	*Glutamate ionotropic receptor NMDA type subunit 2b*

GS	Genome sequencing
GTAC	Genetic Testing Advisory Committee
HNRNPU	*Heterogeneous nuclear ribonucleoprotein U*
IC-CODE	International Classification of Cognitive Disorders in Epilepsy
ID	Intellectual disability
ILAE	International League Against Epilepsy
KANSL1	*KAT8 regulatory NSL complex subunit 1*
KB	Kilo-base pair
KCNC1	*Potassium voltage-gated channel subfamily C member 1*
KCNQ2	*Potassium voltage-gated channel subfamily Q member 2*
KCNT1	*Potassium sodium-activated channel subfamily T member 1*
KD	Ketogenic diet
LDTs	Laboratory-developed tests
MECP2	*Methyl-CpG binding protein 2*
MGP	Multigene panel
mTOR	Mammalian target of rapamycin
NDD	Neurodevelopmental disorders
NGS	Next-generation sequencing
NICE	National Institute for Health and Care Excellence
PCDH19	*Protocadherin 19*
PHGDH	*Phosphoglycerate dehydrogenase*
PNPO	*Pyridoxamine 5'-phosphate oxidase*
PRRT2	Proline-rich transmembrane protein 2
PSAT1	*Phosphoserine aminotransferase 1*
PSPH	*Phosphoserine phosphatase*
PURA	*Pur-alpha*
SCN1A	*Sodium voltage-gated channel alpha subunit 1*
SCN2A	*Sodium voltage-gated channel type 2 alpha subunit*
SCN8A	*Sodium voltage-gated channel type 8 alpha subunit*
SE	Status epilepticus
SIGN	Scottish Intercollegiate Guidelines Network
SLC2A1	*Solute carrier family 2 member 1*
SLC6A1	*Solute carrier family 6 member 1*
SLC6A8	*Solute carrier family 6 member 8*
SMEI	Severe myoclonic epilepsy of infancy
STX1B	*Syntaxin 1B*
STXBP1	Syntaxin-binding protein 1
TCF4	Transcription factor 4
TSC	Tuberous sclerosis complex

TSC1	Tuberous sclerosis complex 1
TSC2	Tuberous sclerosis complex 2
UBE3A	*Ubiquitin protein ligase E3A*
WES	Whole exome sequencing
WGS	Whole genome sequencing
YWHAG	*Tyrosine 3-monooxygenase/tryptophan 5-monooxygenase activation protein gamma*

V. Scientific Background

Epilepsy, defined as having two or more unprovoked seizures, is a common neurologic disorder, affecting an estimated three million adults and 470,000 children in the United States (CDC, 2020). The biological and genetic mechanisms that disturb the balance between excitatory and inhibitory neuronal circuits to result in epilepsy are extremely heterogeneous (Ottman et al., 2010; Williams & Battaglia, 2013). Approximately 20–30% of epilepsy diagnoses can be attributed to other primary conditions, such as stroke, tumor or head injury, but the remaining 70–80% of cases are believed to be due to one or more genetic factors (Hildebrand et al., 2013; Myers & Mefford, 2015).

The epilepsies can be classified by multiple approaches. Clinically, they can be broadly grouped into three classes: genetic generalized epilepsy (GGE), focal epilepsy, and epileptic encephalopathy (EE). GGE is characterized by generalized seizures that involve both sides of the brain, start in childhood or adolescence, are usually associated with normal development and intellect, and include juvenile myoclonic epilepsy and childhood absence epilepsy, among others. Focal seizures originate in one hemisphere of the brain and include temporal lobe epilepsy and autosomal dominant nocturnal frontal lobe epilepsy. EE are severe, early onset conditions characterized by refractory seizures, developmental delay or regression associated with ongoing epileptic activity, and generally poor prognosis such as Dravet, Ohtahara, and West syndromes. Epilepsy is often a comorbid condition with intellectual disability (ID), autism, or schizophrenia, and may be a feature of many metabolic conditions and genetic syndromes (Myers & Mefford, 2015).

The International League Against Epilepsy (ILAE) classifies epilepsies at three levels: seizure types, epilepsy types, and epilepsy syndromes. The classification starts with seizure type as the least specific, epilepsy type as more specific, and epilepsy syndromes as the most specific classification. Seizure type is based on onset, of which there are three categories: focal, generalized, and unknown. The second category, epilepsy type, is divided into four categories; focal, generalized, combined generalized & focal, and unknown. This level of classification typically requires electroencephalography (EEG) data. The “combined generalized & focal” group is new

to the 2017 edition of the ILAE classification, and it was created to include patients with both types of seizures, such as patients with Dravet Syndrome. Finally, the "Unknown" category refers to a case where there is not enough information to determine the epilepsy type. This can occur for numerous reasons, such as the unavailability of an EEG. The third level of classification is "epilepsy syndromes." A syndrome refers to a cluster of features incorporating items such as seizure types, EEG results, and imaging results that tend to occur together. Other distinctive features, such as intellectual disability, may be a part of a syndrome (Scheffer et al., 2017).

Some conditions have well-known mutations caused by a singular gene. For example, in Dravet syndrome, (DS, previously known as severe myoclonic epilepsy of infancy or SMEI) the occurrence of *SCN1A* mutations is 70%-80%. About 90% of these mutations are *de novo*. Truncating mutations have found to be more severe (earlier onset of symptoms, faster cognitive decline) compared to missense mutations. *PCDH19*-related epilepsy is a rare syndrome characterized by focal and/or generalized seizures, which are commonly fever-induced and in clusters. Previously referred to as epilepsy female-restricted with mental retardation (EFMR), *PCDH19*-related epilepsy occurs primarily in females and has an early onset. A mutation in *PCDH19* can cause both DS and *PCDH19*-related epilepsy as *PCDH19* is thought to account for 5% of patients with DS (Andrade & Nascimento, 2023). Another example is tuberous sclerosis complex (TSC); as many as 89% of cases have mutations in either the *TSC1* or *TSC2* gene (Randle, 2023, 2024a, 2024b). Other mutations include *KCNQ2* with EE, *SLC2A1* with glucose transporter deficiency syndrome, *PRRT2* with general infantile convulsions, and *ALDH7A1* and *PNPO* with severe early-onset epilepsy (Poduri et al., 2014). Missense variants in *SLC32A1* can cause genetic epilepsy with febrile seizures plus (GEFS+) and idiopathic generalizes epilepsy (IGE) (Heron et al., 2021).

Epilepsy is genetically heterogeneous, and extensive phenotypic heterogeneity has been observed even in many monogenic epilepsies. This heterogeneity makes testing each gene individually through Sanger sequencing impractical despite its status as the gold standard (Lemke et al., 2012). Mutations in ion channels, chromatin remodeling, transcriptional regulation, and regulation of the mammalian target of rapamycin (mTOR) protein have been implicated in the etiology of epilepsy (Moller et al., 2016).

Clinical Utility and Validity

The DNA sequencing methods for epilepsy diagnosis have high analytic validity; the methods are well-established in laboratories. Sequencing bi-directionally has been evaluated at over 98% sensitivity (Stenhouse et al., 2013). Next generation sequencing (NGS) allows for parallel sequencing of any number of genes, thereby allowing for far superior testing of heterogenous conditions such as epilepsy. Since the number of new

epilepsy genes continues to grow and the phenotypes associated with mutations in each gene are so variable, NGS is a desirable option to diagnose epilepsy patients (Mefford, 2015).

New test options for epilepsy diagnosis have an increased yield of molecular diagnosis, particularly in patients with severe, early-onset epilepsies. For example, a study by Lemke et al. (2012) focused on targeted resequencing of 265 candidate genes, which identified mutations that were presumed to be pathogenic in 16 of 33 patients. Many of these patients had severe epilepsies associated with intellectual disability. This NGS method detected mutations that had been missed by the previous gold standard of Sanger sequencing (with at least one mutation missed due to artifacts from Sanger sequencing). Furthermore, the authors concluded that a patient with more than one possible gene responsible for their phenotype would benefit from this sequencing method compared to Sanger. The authors noted that NGS is only suited for conditions with at least one major gene effect and that whole exome sequencing (WES) would be a better option for more complex genetic conditions (Lemke et al., 2012).

In 2016, a gene panel targeting 46 epilepsy genes was used on 216 patients representing a wide spectrum of epilepsies with age of onset spanning from the neonatal period to adulthood. A presumed pathogenic variant was identified in 49 (23%) patients. The variants were found in 19 different genes including *SCN1A, STXBP1,* and *CDKL5*. Patients with neonatal-onset epilepsies had the highest rate of positive findings (57%). The overall yield for patients with EEs was 32%, compared to 17% among patients with generalized epilepsies and 16% in patients with focal or multifocal (Moller et al., 2016). Another study focusing on the diagnostic use of microarray was performed by Hrabik et al. (2015). Approximately 17.7% (26/147) of participants between the ages of birth to 23 years who were diagnosed with epilepsy and had a SNP microarray performed had an abnormal microarray as defined by laboratory guidelines (Hrabik et al., 2015). Gene panels and exome sequencing for clinical diagnostics provide better and less expensive options for testing and could be implemented early in the diagnostic process. Chromosome microarrays may be considered in severe cases and in GGE with co-morbid features (Myers & Mefford, 2015). Overall, sequencing of many genes at once may provide major benefits to those with epilepsy as epilepsy's genetic profile is widespread.

Copy number abnormalities also play an important role in patients with epilepsy. Of 973 patients who had chromosomal microarray (CMA) and ICD-9 codes for epilepsy or seizures, 805 patients satisfied criteria for epilepsy. 437 copy number variants (CNVs) in 323 patients (1-4 per patient), including 185 (42%) deletions and 252 (58%) duplications were observed. Forty (9%) were confirmed de novo, 186 (43%) were inherited, and parental data were unavailable for 211 (48%). Because the diagnostic

yield of CMA for epilepsy patients is similar to the yield in autism spectrum disorders (ASD) and in prenatal diagnosis (which published guidelines recommending testing with CMA), the authors recommended implementation of CMA in the evaluation of unexplained epilepsy (Olson et al., 2014).

Berg et al. (2017) conducted a prospective cohort study of 775 children with newly diagnosed epilepsy with an onset at less than three years of age to determine the role of genetic testing in the initial evaluation of early life epilepsies. Ninety-five children had brain injury, and of the other 680, 327 underwent genetic testing, such as microarrays, WES, and gene panels. In total, 132 (40.4%) children were found to have pathogenic variants. A total of 446 children were deemed to have an unknown etiology without genetic testing, and 180 of these children were tested. Pathogenic variants were found in 48 or 26.7% of the children, however, epilepsy gene-sequencing panels and whole-exome sequencing (WES) had substantially greater diagnostic yields than CMA. Epilepsy panels detected 28 of 96 (29.2%), WES detected five of 18 or (27.8%), and CMA detected eight for 101 or (7.9%). Without a clinically identified cause, testing yields were greater than 15% and as high as 47% depending on patient subgroups. The authors concluded that broad genetic sequencing methods have high diagnostic yields in diagnosing early-life epilepsies regardless of clinical features. Sequencing tests should be incorporated into the initial evaluation of newly presenting early-life epilepsies and not just reserved for those with severe presentations (Berg et al., 2017).

Gene panels including the most mutated genes have a 10%-50% diagnostic rate (depending on the panel used and the population) although it is possible that a greater number of genes in the panel does not necessarily equate to a higher diagnostic rate. A 67 gene panel and a 265 gene panel were found to have nearly equivalent diagnostic rates; however, the study using the 67 gene panel only included nineteen patients (Dunn et al., 2018; Mefford, 2015). Exome sequencing has been evaluated at a 25% diagnostic rate (without a prior diagnosis), and whole-genome sequencing (WGS) has been evaluated at as high as 60% with smaller studies and known phenotypes. The weaker sequencing depth contributes to the difficulty of locating copy number variants, which are a significant cause of epilepsy-related conditions. Nonetheless, the authors conclude that WES and WGS will become part of the regularly used tools for clinicians once their cost decreases (Dunn et al., 2018).

Stosser et al. (2017) conducted a retrospective analysis of "893 probands with epilepsy who had an epilepsy panel or WES performed and were positive for a pathogenic or likely pathogenic variant in one of nine genes (*CDKL5, GABRA1, GABRG2, GRIN2B, KCNQ2, MECP2, PCDH19, SCN1A*, or *SCN2A*)," which found "mosaic pathogenic variants… at an overall frequency of 3.5% (95% CI, 2.4%-4.9%) in nine genes associated with epilepsy-related disorders…. Mosaicism was most common in the *CDKL5,*

PCDH19, SCN2A, and *SCN1A* genes. Mosaicism was observed in *GABRA1, GABRG2,* and *GRIN2B*, which were not reported to have mosaicism prior to this study, and in *KCNQ2* and *MECP2*. Parental mosaicism was observed for pathogenic variants in multiple genes including *KCNQ2, MECP2, SCN1A*, and *SCN2A*." The authors concluded that patients with epilepsy who previously tested negative for pathogenic variants may benefit from an NGS test, which is superior at detecting mosaic variants. The authors also noted that targeted testing of parents of probands may use NGS to better assess risk and mosaicism (Stosser et al., 2017).

"Epilepsy-plus" patients tend to have highest yield for diagnostic testing; that is, patients with other symptoms such as autism in addition to their epilepsy. Still, even the diagnostic yield of these individuals only reached 50% with panel or exome sequencing (Poduri, 2017). The potential clinical utility of genetic testing for these syndromes is in avoiding further diagnostic testing, directing medication management, and assisting in reproductive decision making. Establishing the genetic basis of epilepsy in a given patient will help in making treatment decisions, genetic counseling, and more (Poduri et al., 2014). For instance, mutations in *ALDH7A1* or in the *PNPO* gene may lead to seizures not treated with typical antiepileptic drugs, but with pyridoxine (Falsaperla & Corsello, 2017). On the other hand, sodium channel agents may be avoided in patients with an *SCNA1* mutation. Genetic counseling revolving around topics such as recurrence or heritability risk for pregnancies or testing of relatives is also helpful, and proper care must be taken to ensure that the information is clearly explained to the patient and their family (Poduri et al., 2014).

Genetic testing for epilepsy could also be useful in diagnosing ASD. Peng et al. (2021) discussed, in their research on developing a multiplex gene and phenotype network to identify shared genes between epilepsy and autism, that mutations in genes for subunits of ion channels were related to epilepsy, and that general ion channel dysfunctions "are also linked to susceptibility to autism, as well as bipolar disorder, schizophrenia, and other neuropsychiatric disorders." The researchers "prioritize *ANK2, CACNA1AE, CACNA2D3, GRIA2,* and *DLG4*… as candidate epilepsy genes because of their overlap with the epilepsy-focused module 2 of the WES [whole-exome sequencing] network;" these genes originated as having association only with autism prior to this study (Peng et al., 2021). A study with similar intention done on co-occurring epilepsy and ASD in Chinese children found *SCN1A* and *MECP2* gene mutations to be the most common; *SCN1A* was more associated with epilepsy, while *MECP2* was more associated with Rett Syndrome. Mutations in *SCN2A, CACNA1A, CACNA1H, CACNA1D,* and *KCNQ2* were also identified, although individual cases for each gene were small in the latter set of genes (Long et al., 2019). Both studies contribute to the understanding of the beneficial utility for genetic testing of epilepsy in the context of other comorbidities, such as ASD.

Sanchez Fernandez et al. (2019) evaluated the cost-effectiveness of genetic testing in patients with epilepsy of unknown etiology. 20 studies were included, with eight evaluating chromosomal microarray (CMA), nine evaluating epileptic panels (EP) with deletion/duplication testing, and six evaluating whole exome sequencing (WES). The authors found WES to have the highest diagnostic yield at 0.45, followed by EP at 0.23 and then CMA at 0.08. EP was found to be the most cost-effective, at $15,848 per diagnosis. Although cost-effectiveness of strategies overlapped, the authors found CMA to be consistently less cost-effective than WES and EP (Sanchez Fernandez et al., 2019).

Borlot et al. (2019) analyzed the results of epilepsy gene panels from 64 patients. Up to 185 genes were tested. 14 probands were found to have "pathogenic or likely pathogenic" variants in the following genes: "*SCN1A, GABRB3, UBE3A, KANSL1, SLC2A1, KCNQ2, SLC6A1, HNRNPU, STX1B, SCN2A, PURA, and CHD2*". The authors also identified six mutations arising *de novo*, with unknown inheritance for eight mutations. Overall, the authors concluded that a commercial gene panel for epilepsy may be useful, as it detected etiology in 22% of patients with epilepsy and intellectual disability (Borlot et al., 2019).

Kim et al. (2021) analyzed the clinical utility of whole-exome sequencing (WES) for patients with infantile-onset epilepsy that had tested negative on gene panel tests for epilepsy. The study included 59 patients. Following WES, 55.4% of the participants received genetic conformation of epilepsy, indicating that WES increased diagnostic yield by 8%. Three epilepsy-causing genes (that were not included on the original gene panel) were identified: *YWHAG, KCNC1,* and *FGF12*. The authors conclude that WES could be an important way to reanalyze novel epilepsy-linked genes without updated gene panels (Kim et al., 2021).

Willimsky et al. (2021) studied the use of next generation sequencing (NGS) by comping the diagnostic yield of small and large gene panels. The authors completed a retrospective study of 190 patients under the age of 18 years who were diagnosed with epilepsy of unknown etiology. Small gene panels were defined as those under 25 kilo-base pair (kb), and large gene panels were defined as those over 25 kb. Diagnostic yield was defined as detection of pathogenic or likely pathogenic variants. The authors found that the diagnostic yield of large panels (29%) was significantly larger than small panels (13%). The authors then analyzed the differences in diagnostic yield in developmental and epileptic encephalography (DEE) and non-DEE. The authors found that the significant increase of diagnostic yield in large panels was only significant for non-DEE patients, and not for DEE patients. The authors conclude that large epilepsy gene panels have significantly higher diagnostic yield for non-DEE patients but note that small gene panels (a maximum of 10 genes) is sufficient for DEE patients

(Willimsky et al., 2021).

Stefanski et al. (2021) completed a meta-analysis and systematic review on the success rate of genetic testing of neurodevelopmental disorders (NDD). The study measured the diagnostic yield, defined as the "percent of pathogenic variant carriers identified in a cohort." The study included 103 clinical sequencing studies that used NGS in a total of 32,331 people with epilepsy, ASD, or ID. The diagnostic yield for epilepsy was 24%. The epilepsy subtypes with the highest diagnostic yield were epilepsy with ID (27.9%) and early onset seizures (36.9%). The authors then studied the diagnostic yield of each sequencing technology and found a diagnostic yield of 27.2% for exome sequencing and a diagnostic yield of 22.6% for target gene sequencing panels (Stefanski et al., 2021).

Sheidley et al. (2021) completed a similar meta-analysis and systematic review to Stefanski et al. (2021), except on 5985 studies on genetic testing of patients with epilepsy. "The overall diagnostic yield across all test modalities was 17%, with the highest yield for GS [genome sequencing] (48%), followed by ES [exome sequencing] (24%), MGP [multigene panel] (19%), and [genome-wide comparative genomic hybridization/chromosomal microarray] CGH/CMA (9%)." The authors also studied non-yield outcomes. 24 studies reported on changes in treatment based on genetic testing; "treatment changes were reported in 12-18% of patients with a genetic diagnosis, including avoiding, stopping, or initiating specific antiseizure medications (AMAs) or ketogenic diet (KD) and halting a plan for surgery in the presence of a specific genetic diagnosis" (Sheidley et al., 2021).

Beyond developing panels to identify genetic variants among epileptic patients, recent advancements in the study of epigenetics could potentially be of use with epilepsy symptoms but not a clear-cut genetic basis. In the patients with neurodevelopmental disorders an epilepsy phenotype, 23% of cases had rare differential methylations (Barbosa et al., 2018). "When the parents were able to be tested, ~40% of the methylation variants were *de novo*, suggesting that methylation abnormalities may be causative in 5-10% of their cohort. When identified, the underlying causes of the methylation changes were varied and included CNVs (copy number variants), sequence variants in regularly elements, or repeat expansions, each of which is easily missed by conventional (even next-generation) sequencing methods" (Hebbar & Mefford, 2020). Genetic and epigenetic testing could further help shape precision medicine in the best types of pharmaceutical drugs used to treat specific epilepsies, such as by understanding individual responses to antiepileptic drug treatment and alterations in drug pharmacokinetics and pharmacodynamics that could guide safer and more effective treatment strategies (Balestrini & Sisodiya, 2018).

McKnight et al. (2022) conducted a study on the diagnostic yield of genetic tests performed on adults with epilepsy. The study included 2,008 individuals and the authors analyzed their NGS targeted testing results of 89-189 genes and clinical information. Diagnostic yield was defined as a definitive molecular diagnosis. In total, 218 adults (10.9%) had clinically actionable findings. The authors compared the diagnostic yield with age of seizure onset and found that "the highest diagnostic yield was in adults with seizure onset during infancy (29.6%, 0–1 year), followed by in early childhood (13.6%, 2–4 years), late childhood (7.0%, 5–10 years), adolescence (2.4%, 11–17 years), and adulthood (3.7%, ≥18 years)." The authors also reported that "comorbid intellectual disability (ID) or developmental delay resulted in a high diagnostic yield (16.0%)." Overall, the authors conclude that genetic testing could impact clinical management and outcomes (McKnight et al., 2022).

VI. Guidelines and Recommendations

International League Against Epilepsy (ILAE)

In 2015, the ILAE Commission of Pediatrics issued a task force report which included the following related to genetic testing in epilepsy.

- "Genetic screening should not be undertaken at a primary or secondary level of care."
- "Standard care should permit genetic counseling by trained personnel to be undertaken at all levels of care (primary to quaternary)."
- "Genetic evaluation for Dravet syndrome and other infantile-onset epileptic encephalopathies should be available at tertiary and quaternary levels of care (optimal intervention would permit an extended genetic evaluation)."
- "Early diagnosis of some mitochondrial conditions may alter long-term outcome, but whether screening at quaternary level is beneficial is unknown." (Wilmshurst et al., 2015)

In 2017, the ILAE released a position paper containing a stance on the genetic etiologies of epilepsies. The ILAE states that "the epilepsies in which a genetic etiology has been implicated are quite diverse and, in most cases, the underlying genes are not yet known". The ILAE also notes that genetic is not equivalent to inherited; de novo mutations are being identified with increasing frequency, thereby making an epileptic syndrome not inherited. Furthermore, the ILAE states that environmental contributions to an epileptic syndrome should not be minimized and that a genetic etiology should be of significant effect in causing epilepsy (Scheffer et al., 2017).

In the 2021 report, the ILAE and the International Neuropsychological Society address the lack of an international taxonomy for cognitive disorders in epilepsy and proposes

the International Classification of Cognitive Disorders in Epilepsy (IC-CODE), stating that "a taxonomy built on the alignment of genetic, neuroimaging, and cognitive processes promises high precision for the diagnosis of cognitive disorders in epilepsy and their treatment" (Norman et al., 2021).

In 2022, ILAE released a position statement on epilepsy syndromes with onset in neonates and infants. The statement notes that "genetic testing [for Dravet syndrome, previously known as Severe Myoclonic Epilepsy of Infancy] is recommended at all ages, including in adults in whom the diagnosis is suspected but details of history in infancy may be difficult to access. A pathogenic variant in SCN1A is present in more than 80%–85% of cases." The statement did not mention recommendations on genetic testing for any other form of epilepsy (Zuberi et al., 2022).

In 2022, the ILAE released a position statement on idiopathic generalized epilepsy syndromes. Genetic testing is mentioned throughout the statement in relation to epilepsy occurring in individuals with intellectual disabilities. In patients suspected of childhood absence epilepsy or generalized tonic–clonic seizures alone, "investigations, including genetic testing, to exclude other etiologies should be considered" in individuals with intellectual disabilities. All other mentions of genetic testing for the diagnosis of epilepsy note that genetic testing is not currently part of the routine diagnostic evaluation but may be used soon, as more genetic determinants are identified (Hirsch et al., 2022).

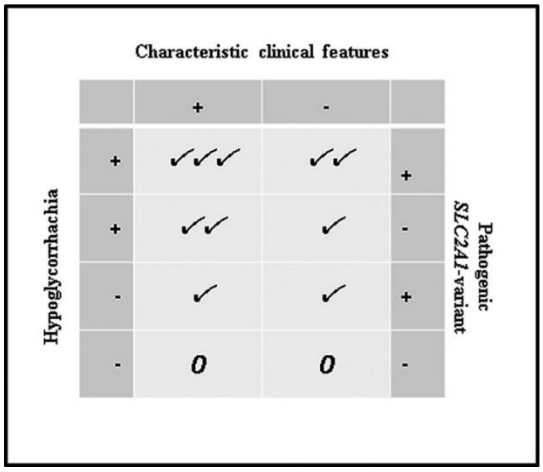
European Federation of Neurological Societies (EFNS)

In 2010, EFNS issued the following recommendations pertaining to epilepsy. The EFNS noted that molecular investigations may be useful for diagnosis but cannot be considered routine with the large number of mutations present and state that clinical or physiological methods are generally superior. However, they note severe myoclonic epilepsy of infancy (SMEI) has a mutation in the gene *SCN1A* in 80% of patients. Since 2010, this organization has been renamed to the European Academy of Neurology, but no new updates on epilepsy have been released (Burgunder et al., 2010).

American Academy of Neurology (AAN) and Child Neurology Society (CNS)

The AAN and CNS issued guidelines for clinicians on diagnostic assessment of the child with status epilepticus (SE) in 2006, reaffirmed 2019. The recommendations provided guidance for the assessment of laboratory studies, metabolic and genetic studies, electroencephalography, and neuroimaging in children with SE. The expert panel concluded that "there are insufficient data to support or refute whether genetic testing (chromosomal or molecular studies) should be done routinely in children with SE" (Riviello et al., 2006).

American Epilepsy Society Annual Meeting



In 2015, a talk presented at the American Epilepsy Society Annual Meeting focused on reviewing the genetics of epilepsy, which groups were likely to benefit from genetic testing, and how to approach genetic testing in the current evolution of medicine. Regarding who would benefit most, "it would make sense to focus testing at this time on those in whom there is a high likelihood of a diagnostic finding and on those whose refractory epilepsy may be influenced by a precise genetic diagnosis that can guide treatment." This study concluded that genetic testing is needed to determine if treatment regimens will be affected, especially in younger children and infants.

With regards to the proper way to approach genetic testing, "we should start with a clinical approach, defining a specific epilepsy syndrome when relevant, to guide the nature and sequence of genetic testing. Pre- and post- testing counseling, whether provided by a physician or genetic counselor, is critical to maintaining clear communication with patients about the implications and limitations of their genetic testing." The types of testing include chromosomal microarray analysis (CMA), complete genome sequencing, and exome sequencing (Poduri, 2017).

International Glut1DS Study Group

The International Glut1DS (glucose transporter 1 deficiency syndrome) put forth recommendations on the diagnosis and treatment of Glut1DS in 2020, which involves "characteristic clinical features, definite hypoglycorrhachia, and pathogenic *SLC2A1* variants." Hypoglycorrhachia is defined as a low glucose level in cerebrospinal fluid in

Symbol	diagnosis of Glut1DS	start KDT
✓✓✓	confirmed	yes
✓✓	probable	yes
✓	possible	consider
0	negative	not required

the setting normal glucose levels in blood, or normoglycemia. Their strength of support for a combination of the three features is shown below.

On genetic testing, the International Glut1DS group also stated that "the absence of *SLC2A1* pathogenic variants does not always exclude Glut1DS…*SLC2A1*-negative patients can be diagnosed on the basis of hypoglycorrhachia and distinctive clinical features, especially when responsive to KDT [ketogenic diet therapies]" (Klepper et al., 2020).

North American Consensus Panel on Dravet Syndrome

This panel was convened to establish standards for evaluation of Dravet Syndrome. The panel recommended that genetic testing be performed in patients whose symptoms indicated Dravet syndrome; the panel noted that either specific *SCN1A* sequencing or a larger gene panel may be performed, and a chromosomal microarray was not necessary.

The panel also notes that genetic testing should be pursued in a child <12 months and with ≥2 febrile seizures >15 minutes as well as a child 12-35 months old with at least one febrile seizure over 15 minutes. However, genetic testing should not be performed for a child <12 months with only one focal or generalized febrile seizure.

Genetic counseling should be provided, particularly information about heritability and risk of epilepsy in siblings. Other information about *SCN1A* mutations may also be provided (Wirrell et al., 2017).

Scottish Intercollegiate Guidelines Network (SIGN)

SIGN lists features suggesting genetic generalized epilepsies, which are as follows:

- childhood or teenage onset
- triggered by sleep deprivation and alcohol
- early morning tonic-clonic seizures or myoclonic jerks
- short absence seizures
- photoparoxysmal response on electroencephalography (EEG)
- generalized three per second spike and wave or polyspike and wave on EEG.

Genetics services are recommended for patients with a "very strong" family history of epilepsy, or with "a clinical phenotype suggestive of a monogenic epilepsy syndrome" (SIGN, 2018).

National Institute for Health and Care Excellence (NICE)

The NICE clinical guideline on epilepsies, in children, young people, and adults was updated in 2022 to include recommendations on genetic testing.

- Discuss with a neurologist or geneticist any uncertainties about whether to offer

genetic testing or which tests to offer to a person with epilepsy.

- Before carrying out genetic tests:
  - discuss the purpose of testing and the possible implications of the results with the person with epilepsy, and their family and carers if appropriate
  - obtain informed consent with appropriate genetic counselling in line with the NHS Genomic Medicine Service.
- Consider whole-genome sequencing for people with epilepsy of unknown cause who:
  - were aged under two years when epilepsy started **or**
  - have clinical features suggestive of a specific genetic epilepsy syndrome (for example, Dravet syndrome) **or**
  - have additional clinical features such as:
    - a learning disability
    - autism spectrum disorder
    - a structural abnormality (for example, dysmorphism or congenital malformation)
    - unexplained cognitive or memory decline.
- Consider whole-genome sequencing for people with epilepsy of unknown cause who were aged between two and three years when epilepsy started, if clinically agreed by a specialist multidisciplinary team (NICE, 2022).

United Kingdom Expert Group on Tuberous Sclerosis Complex

The expert group recommended, with consensus, to offer a genetic test at baseline to patients with definite or probable TSC. The group noted that a genetic test may clarify the diagnosis of TSC for patients that do not fulfill clinical criteria for the condition (Amin et al., 2018).

In 2019, the group released recommendations for provision of coordinated care. They state, "with wider availability of genetic testing, identification of pathogenic mutations in TSC1 or TSC2 is now sufficient to establish a diagnosis, regardless of the presence of clinical features, and is particularly useful in confirming a suspected diagnosis, as many clinical TSC manifestations are infrequent in young patients." The group further recommends that:

- For patients with newly diagnoses or suspected TSC:
  - "Obtain three-generation family history to assess for additional family members at risk of TSC.
  - Offer genetic testing for family counseling or when TSC diagnosis is in question but cannot be clinically confirmed."
- For patients already diagnosed with definite or possible TSC:

- "Offer genetic testing for family counseling or when TSC diagnosis is in question but cannot be clinically confirmed" (Annear et al., 2019)

Genetic Testing Advisory Committee (GTAC) for Ontario, Canada

These guidelines recommend the following as indications for genetic testing:

- "When the clinical features (age of onset, seizure semiology and EEG features) are consistent with a distinct epilepsy syndrome as defined by the International League Against Epilepsy (ILAE), with the exception of syndromes outlined in the following section."
- "When the prognosis based on clinical and EEG findings is poor or the likelihood of lethal outcome is high."
- "When epileptic seizures are refractory to medical treatment as defined by the ILAE12 (with no apparent acquired cause)."
- "When epilepsy is associated with features suggestive of inborn errors of metabolism."
- "When epilepsy is associated with distinctive patterns of malformations of cortical development identified on neuroimaging studies."
- "When epilepsy is associated with clinical signs of neurodegeneration."
- "When epilepsy is associated with paroxysmal neurological features such as paroxysmal dyskinesias, episodic ataxias and hemiplegic migraine."
- "When epilepsy is associated with additional syndromic features such as developmental delay/intellectual disability, multiple congenital anomalies and dysmorphic features."
- "When familial epilepsy is present, defined as at least two first- degree family members with related epilepsy syndromes, unless the epilepsy syndrome is benign."

The guidelines also recommend against genetic testing in the following situations:

- "Recognizable seizure syndrome with benign course."
- "Childhood epilepsy with centro-temporal spikes (previously termed benign rolandic epilepsy)."
- "Isolated mesial temporal lobe epilepsy with hippocampal sclerosis."
- "Typical childhood Absence epilepsy (although if it is early-onset or medically refractory epilepsy, one should consider and test for GLUT1 deficiency)."
- "Juvenile myoclonic epilepsy, which is well controlled on medications and without intellectual disability or any signs of neurodegeneration."
- "Acquired epilepsy."

The guideline also provides a list of "potentially treatable" genetic/metabolic

epilepsies, shown below

Table 3: Potentially treatable genetic/metabolic epilepsies

Effect on ion channels
Dravet syndrome (*SCN1A*)—avoidance of sodium-channel blockers
SCN8A-related epileptic encephalopathy—carbamazepine, phenytoin [sodium-channel blockers]
KCNQ2-related epileptic encephalopathy—retigabine [potassium-channel openers] or carbamazepine [sodium-channel blockers]
KCNT1-related migrating partial epilepsy of infancy—quinidine [gain-of-function mutations being treated by partial channel antagonist]
GRIN2A-related epileptic encephalopathy—memantine [NMDA (N-methyl-d-aspartate) receptor antagonists]
Alternative energy source
GLUT-1 deficiency syndrome (*SLC2A1* gene)—ketogenic diet
Modulate epileptogenesis
Tuberous sclerosis complex (*TSC1/2*)—mTOR inhibitors (Rapamycin/analogs)
Modulating biochemical pathways
Pyridoxine dependency (*ALDH7A1*)—B6 vitamin
Biotinidase deficiency (*BTD*)—biotin
Cerebral folate deficiency (*FOLR1*)—folinic acid
Creatine deficiency syndromes (*SLC6A8, GATM, GAMT*)—creatine, other amino acid supplementation (glycine, arginine, ornithine) or restriction (arginine)
Serine biosynthesis defects (*PHGDH, PSAT1, PSPH*)—serine, glycine

Finally, the guideline also makes recommendations for panel testing. Some situations in which a gene panel may be considered are if:

- epilepsy phenotyping is broad and does not easily classify the patient into a distinct group.
- "if the clinical diagnosis is clear and genetic heterogeneity is high, but clinical diagnosis is not indicative of a treatable condition."
- "if clinical diagnosis is unclear and genetic heterogeneity is unknown."

The guidelines further list examples of these situations, such as seizures with fever as a major trigger and idiopathic generalized epilepsy refractory to treatment (Jain et al., 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by

the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81407	Molecular pathology procedure, Level 8 (eg, analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)
81419	Epilepsy genomic sequence analysis panel, must include analyses for ALDH7A1, CACNA1A, CDKL5, CHD2, GABRG2, GRIN2A, KCNQ2, MECP2, PCDH19, POLG, PRRT2, SCN1A, SCN1B, SCN2A, SCN8A, SLC2A1, SLC9A6, STXBP1, SYNGAP1, TCF4, TPP1, TSC1, TSC2, and ZEB2
81479	Unlisted molecular pathology procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Familial Alzheimer Disease

Policy Number: AHS – M2038 – Genetic Testing for Familial Alzheimer Disease	Prior Policy Name and Number, as applicable: • AHS – M2038 – Genetic Testing for Familial Alzheimer's Disease
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Alzheimer disease (AD) is a neurodegenerative disease defined by a gradual decline in memory, cognitive functions, gross atrophy of the brain, and accumulation of extracellular amyloid plaques and intracellular neurofibrillary tangles (Karch et al., 2014).

Familial Alzheimer disease (FAD) is a rare, inherited form of AD. FAD has an earlier onset than other forms of Alzheimer disease with symptoms developing in individuals in their thirties or forties. Genetic counseling is strongly recommended for individuals pursuing genetic testing for FAD.

For recommendations on testing of *APOE* ε4 prior to medication administration, please refer to AHS-M2021-Pharmacogenetic Testing.

AHS-M2145	General Genetic Testing, Germline Disorders
AHS-M2146	General Genetic Testing, Somatic Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) When the results of the testing will inform reproductive decision making, genetic testing for *APP, PSEN1,* and *PSEN2* **MEETS COVERAGE CRITERIA** for individuals with **one** of the following conditions:
   a) For individuals with a family history of autosomal dominant dementia (one or more instances of early-onset Alzheimer disease [AD] [see Note 1]).
   b) For individuals with a first-degree (see Note 2) relative with a known mutation in the *PSEN1, PSEN2,* or *APP* genes.
   c) For symptomatic individuals (suspected early-onset AD [see Note 1]) with an unknown family history (e.g., adoption).

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) Outside of situations addressed in AHS-M2021-Pharmacogenetic Testing, testing of *APOE* **DOES NOT MEET COVERAGE CRITERIA.**

3) For all purposes other than reproductive decision making, genetic testing for AD **DOES NOT MEET COVERAGE CRITERIA**, including **any** of the following situations:
   a) Testing to confirm a diagnosis of Alzheimer disease (any type).
   b) Testing for familial Alzheimer disease in individuals less than 18 years of age.
   c) Testing of any other genes not listed above.
   d) Testing for purposes of Alzheimer disease risk assessment.
   e) Screening asymptomatic individuals.

NOTES:

Note 1: Early-onset Alzheimer disease is Alzheimer disease that developed before the individual was 65 years of age.

Note 2: First-degree relatives include parents, full siblings, and children of the individual.

Note 3: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AAN	American Academy of Neurology
AAO	Age at onset
ACMG	American College of Medical Genetics and Genomics
AD	Alzheimer disease
AMP	Association for Molecular Pathology
APOE	*Apolipoprotein E*
APP	*Amyloid precursor protein*
CASP7	*Caspase-7*
CLIA'88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CSF	Cerebrospinal fluid
DTC	Direct to consumer
ECRG4	*Esophageal cancer-related gene 4*
EFNS	European Federation of Neurological Societies
ENS	European Neurological Society
EOAD	Early-onset autosomal dominant Alzheimer disease
EOFAD	Early onset familial Alzheimer disease mutations
FAD	Familial Alzheimer disease
FDA	Food And Drug Administration
FTLD	Frontotemporal lobar degeneration
GRN	*Granulin precursor*
GRS	Genetic risk score
GWAS	Genome-wide association studies
HDAC9	*Histone deacetylase 9*
LDT	Laboratory-developed test
LOAD	Late-onset Alzheimer disease
MAPT	*Microtubule-associated protein tau*
MPS	Massive parallel resequencing
NGS	Next-generation sequencing
NIA	National Institute on Aging
NSGC	National Society of Genetic Counselors
PGS	Personal genome service
PSEN1	*Presenilin 1*
PSEN2	*Presenilin 2*

USPSTF	United States Preventive Services Task Force

V. Scientific Background

Alzheimer disease (AD) is a devastating neurodegenerative disease with a strong genetic component and is considered the predominant form of dementia. There are more than 55 million people living with dementia worldwide (WHO, 2023).This number is estimated to increase to 131.5 million by 2050 (Prince, 2016). The average lifetime risk of developing AD is 10–12%. This risk at least doubles with the presence of a first-degree relative with the disorder (Goldman et al., 2011). The genetic predisposition of AD, even for late-onset AD patients, is estimated to be 60–80% (Gatz et al., 2006).

Most patients develop clinical symptoms after the age of 65 (spontaneous or late-onset AD); however, up to 10% of patients have an earlier onset of disease (early-onset AD) (Kumar, 2018). AD is characterized by severe neuronal loss, aggregation of extracellular amyloid β plaques, and intraneuronal tau protein tangles resulting in progressive deterioration of memory and cognitive functions (Keene, 2023). Enormous burden on public health is due to the high costs associated with care and treatment. Aside from drugs that temporarily relieve symptoms, no treatment currently exists for AD (Van Cauwenberghe et al., 2016).

Autosomal dominant AD is rare (<1%), but the discovery of fully penetrant pathogenic mutations of *Amyloid precursor protein (APP)* (Goate et al., 1991; St George-Hyslop et al., 1987), *Presenilin 1 (PSEN1)* (Sherrington et al., 1995; Van Broeckhoven et al., 1992), and *Presenilin 2 (PSEN2)* (Sherrington et al., 1996), inherited in an autosomal dominant fashion, has identified molecular mechanisms and pathways involved in AD pathogenesis and valuable targets currently used in diagnosis and drug development (Schneider et al., 2014; Van Cauwenberghe et al., 2016).

One of the primary features of AD is the buildup of amyloid-β protein in the brain. This protein is poisonous to neurons and is normally cleaved by secretases. However, certain genetic mutations may cause these clearing mechanisms to weaken, leading to an overall increase in amyloid-β production. As amyloid-β starts to aggregate in the brain, it creates fibrils that ultimately cause neurological damage such as the characteristic dementia (Keene, 2023).

Amyloid precursor protein (APP) is proteolytically processed in the constitutive pathway by α- and γ-secretases, resulting in nonpathogenic fragments. However, in the amyloidogenic pathway, subsequent proteolysis of APP by β-secretase and γ-secretase gives rise to a mixture of Aβ peptides with different lengths, of which $A\beta_{1-42}$ are more aggregation-prone and are predominantly present in amyloid plaques in

brains of AD patients. A total of 39 *APP* mutations have been described; all of which affect proteolysis of APP in favor of $A\beta_{1–42}$ (Cruts et al., 2012).

Presenilin 1 (PSEN1) and *Presenilin 2 (PSEN2)* are highly homologous genes. Both proteins encoded by these genes are essential components of the γ-secretase complex, which catalyzes the cleavage of membrane proteins, including APP. Mutations in *PSEN1* and *PSEN2* impair the γ-secretase-mediated cleavage of APP, resulting in an increased proportion of $A\beta_{1–42}$ (Cruts & Van Broeckhoven, 1998) (Cruts & Van Broeckhoven, 1998). *PSEN1* is located on chromosome 14 whereas *PSEN2* is located on chromosome 1. However, *PSEN1* is generally associated with a worse prognosis; it has full penetrance compared to 95% penetrance for *PSEN2*, and age of onset was over 10 years earlier for *PSEN1* mutations compared to *PSEN2* (Ryman et al., 2014; Sherva & Kowall, 2023).

Late-onset AD is considered a multifactorial with a strong but complex genetic predisposition (Gatz et al., 2006) involving gene mutations and polymorphisms that may interact with each other or with environmental factors. The ε4 allele of *APOE* was the only major gene known to increase disease risk for both early-onset and late-onset AD. More recently, genome-wide association studies (GWAS) and massive parallel resequencing (MPS) efforts have identified of at least 21 additional genetic risk loci. These loci, shown in the table below from Van Cauwenberghe et al. (2016), are estimated to explain about 28% of the heritability of liability, 30% of familial risk, and over 50% of sibling recurrence risk of developing AD (Van Cauwenberghe et al., 2016). Researchers have recently identified a rare missense variant in the *CASP7* gene that

Gene	Genes in locus	Possible candidate genes	Function	Pathway	Effect on APP or tau
MS4A4A/MS4A6E locus (chr11:59,268,00-60,480,00)	17 genes	*MS4A2, MS4A3, MS4A4A, MS4A4E, MS4A6A, MS4A6E*	Signal transduction	Immune response	—
HLA-DRB5/HLA-DRB1 locus (chr6:3,609,009-4,535,100)	17 genes	Not defined due to the complex genetic organization of the locus	Immunocompetence and histocompatibility	Immune response	—
ZCWPW1 locus (chr7:99,905, 955-100,093,149)	10 genes	*ZCWPW1*; *NYAP1*: affecting brain size, neurite elongation, neuronal morphogenesis	Epistatic regulation (*ZCWPW1*); brain and neural development (*NYAP1*)	Neural development	—
SLC24A4/RIN3 locus (chr14:92,789,411-93,176,224)	2 genes	*SLC24A4*: brain expression; *RIN3*: known interactor of *BIN1* gene product	Neural development and regulation of blood pressure and hypertension	Neural development and synapse function	—
NME8 locus (chr7:37,779, 803-37,992,860)	4 genes	*NME8*: association signal adjacent to the gene	Ciliary functions	Cytoskeletal function and axonal transport	—
CELF1 locus (chr11:47,291, 161-47,666,021)	10 genes	*CELF1; MADD*: long-term neuronal viability in AD	RNA splicing, editing, and translation (*CELF1*); long-term neuronal viability (*MADD*)	Cytoskeletal function and axonal transport	Tau toxicity

For each locus, the number of genes in each locus is shown with the possible candidate genes. The pathway, function, and effect on APP or tau pathway are reported for each locus.

APP, amyloid precursor protein; GWAS, genome-wide association studies.

may be associated with familial late-onset AD (Zhang et al., 2019), as well as a T allele of the CD33 rs3865444 polymorphism also associated with late-onset AD (Mehdizadeh et al., 2019).

The *APOE* gene has several alleles, with the ε4 allele contributing to an increased risk of late-onset AD and the ε2 allele contributing to a decreased risk of late-onset AD compared to the common *APOE* ε3 allele (Yamazaki et al., 2019). Researchers now report that *APOE* influences tau pathology as well as neurodegeneration mediated by tau and microglial responses to AD pathologies; further, *APOE* ε4 is "either pathogenic or shows reduced efficiency in multiple brain homeostatic pathways, including lipid transport, synaptic integrity and plasticity, glucose metabolism and cerebrovascular function" (Yamazaki et al., 2019).

In 2023, the FDA approved Lecanemab (brand name Leqembi), an amyloid beta-directed antibody, for the treatment of Alzheimer Disease in adult patients (FDA, 2023). One potential side effect of Leqembi is amyloid related imaging abnormalities (ARIA), which may be more likely to occur in people who are homozygous *APOE* ε4 carriers (Leqembi, 2024). The FDA cautions that "the prescribing information states that testing for ApoE ε4 status should be performed before starting treatment with Leqembi to inform the risk of developing ARIA" (FDA, 2023).

Proprietary Testing

Early-Onset Alzheimer Disease

Several companies have developed hereditary AD panels. The Invitae Hereditary Alzheimer Disease Panel tests for three genes associated with early-onset hereditary AD: *APP, PSEN1* and *PSEN2*. This test may utilize a blood, DNA or saliva sample and has a 10-21 day turnaround time (Invitae, 2023). The ADmark® Early Onset Alzheimer's Evaluation also tests for the three known early-onset hereditary AD genes: *APP, PSEN1* and *PSEN2*. This test detects sequence variants in these genes, as well as duplications in the *APP* gene. A whole blood sample is required, and a turnaround time of 21-28 days can be expected (Athena, 2023b).

Another panel by Fulgent, termed the Parkinson-Alzheimer-Dementia NGS panel, tests for 35 genes that are associated with developing Parkinson disease, Alzheimer disease and dementia . Some of the genes tested in this panel include *APOE, APP, PSEN1* and *PSEN2*. This test also requires a blood sample or buccal swab and has a three to five week turnaround time (Fulgent, 2023).

Roche has developed the Elecsys® Amyloid Plasma Panel, which has received FDA Breakthrough Device Designation. According to Roche, it is the first qualitative test that combines the result of phosphorylated Tau (pTau) 181 protein assay and APOE ε4 in human plasma. This can leader to earlier diagnosis of Alzheimer's disease as patients "testing negative with the Elecsys Amyloid Plasma Panel are unlikely to be amyloid

positive and should be investigated for other causes of cognitive decline" (Roche, 2024).

Late-Onset Alzheimer Disease

Athena diagnostics developed the ADmark® ApoE Genotype Analysis and Interpretation test which detects *APOE* ε2, ε3, ε4 alleles using restriction fragment length polymorphism (Athena, 2023a). Athena will not perform this test on individuals younger than 18 years of age and recommends pre and post-test genetic counseling; a whole blood sample is required, and a turnaround time of 7-14 days can be expected.

Clinical Utility and Validity

Early-Onset Alzheimer Disease

Comprehensive genetic counseling protocols are available for AD diagnostic and predictive testing to provide a framework for clinicians and geneticists to evaluate which patients may benefit from genetic testing. Available genetic diagnostic and predictive screening for causal mutations of early-onset AD in *APP*, *PSEN1*, and *PSEN2* are only responsible for a small portion of AD patients' risk. They account for approximately 60%-70% of familial autosomal dominant AD, but less than 10 percent of early-onset AD and less than one percent of AD overall (Sherva & Kowall, 2023). For a significant number of patients for whom genetic diagnostic screening is requested, the tests will be negative without excluding a genetic cause of disease (Van Cauwenberghe et al., 2016). Furthermore, the identification of a mutation is not a certain predictor of disease or onset age, given that these mutations can vary in terms of penetrance and gene expression. Nevertheless, the ability to identify an explanation for the clustering of AD in a family and the ability to use this toward predictive testing in subsequent generations provide an important step toward autonomy of patients and at-risk individuals (Van Cauwenberghe et al., 2016). Testing for these highly penetrant mutations often carries significant personal and familial utility which the ACMG (American College of Medical Genetics) has recently supported as important clinical utilities (ACMG, 2015). New mutations in the *APP*, *PSEN1*, and *PSEN2* genes are constantly being identified. For example, two probable pathogenic variants, *PSEN2* p.A415S and p.M174I, were identified by Wong et al. (2020).

Janssen et al. (2003) aimed to determine the proportion of patients with early-onset AD with a positive family history that had mutations in the amyloid precursor protein (APP), presenilin 1 (*PSEN1*), and presenilin 2 (*PSEN2*) genes. A mutational analysis was performed in 31 probands with probable or definite AD from UK families (age at onset <61 years). A total of 23 patients fulfilled criteria for autosomal dominant inheritance. In 17 (55%) probands the authors identified eight novel *PSEN1* sequence variants and

eight recognized pathogenic mutations. In four (13%) probands the authors identified one novel *APP* sequence variant (H677R) and two recognized mutations. Further, 21 of 31 (68%) probands were associated with a sequence variant in *APP* or *PSEN1*. Nine of the 11 (82%) probands with neuropathologically confirmed AD who additionally fulfilled recognized criteria for autosomal dominant inheritance were associated with a sequence variant in *APP* or *PSEN1*. The 10 patients in whom the authors were unable to identify a mutation in *APP*, *PSEN1*, or *PSEN2* were older than the probands with sequence variants (55.4 vs 44.7 years, respectively). The authors concluded that sequence variants in *APP* and *PSEN1* accounted for the majority of neuropathologically confirmed autosomal dominant early-onset AD (Janssen et al., 2003).

Shea et al. (2016) conducted a study to assess the differences in clinical presentations of different genotypes of FAD. A total of 658 pedigrees were evaluated. The authors found that patients with *PSEN1* mutations tended to have earlier age of onset than either *PSEN2* or *APP* mutations. Patients with *PSEN1* were also more commonly affected by symptoms such as seizures or myoclonus, whereas patients with *PSEN2* mutations were more commonly affected by disorientation. Patients with *APP* mutations were more likely to present with aggression or apraxia (Shea et al., 2016).

Lanoiselee et al. (2017) completed a large genetic screening study of familial and sporadic cases of *APP*, *PSEN1*, and *PSEN2* mutations in early-onset AD. Data was taken from 23 French hospitals from 1993 onward; the total number of families identified with mutations was 170 (these families were required to have two first-degree relatives with early-onset AD with an age of onset ≤65 years). One hundred and twenty-nine sporadic cases were also screened with an age of onset ≤51 years. The authors not that "*APP*, *PSEN1*, or *PSEN2* mutations were identified in 53 novel AD-EOAD [early-onset AD] families. Of the 129 sporadic cases screened, 17 carried a *PSEN1* mutation and one carried an *APP* duplication (13%); this led to the conclusion that a portion of *PSEN1* mutations occur de novo (Lanoiselee et al., 2017).

Giau et al. (2019) screened 67 *de novo* early-onset AD cases by next-generation sequencing (NGS) to identify pathogenic variants linked to neurodegenerative disorders in the Korean population. They were able to find three missense mutations in *PSEN1* and a variant in *PSEN2* within 6% of the cases with early onset AD, but also found "67 missense mutations in susceptibility genes for late-onset AD… which may be involved in cholesterol transport, inflammatory response, and β-amyloid modulation." They also found "70 additional novel and missense variants in other genes, such as *MAPT*, *GRN*, *CSF1R*, and *PRNP*, related to neurodegenerative diseases, which may represent overlapping clinical and neuropathological features with AD." Multiple rare variants were found among this patient population as well (Giau et al., 2019).

Qin et al. (2020) conducted an analysis on the genotype and phenotype correlation for early onset familial AD in a Chinese population. With respect to specific mutations, the researchers found that for *APP* mutations, the clinical phenotype was relatively heterogeneous, with an average age at onset ranging from the 40s-50s and clinical presentations of "cognitive dysfunction, especially executive dysfunction and disorientation. Extrapyramidal signs, behavioral, and psychiatric symptoms could also be detected in Chinese *APP* EOFAD [early onset familial Alzheimer disease mutations]." For those with *PSEN1* mutations, the age at onset was in the early 40s, and with an amnestic cognitive profile, as well as myoclonus and seizures. "Extrapyramidal signs, behavioral, and psychiatric symptoms (anxiety, hallucinations, delusions) and ataxia are significantly more frequently found in EOFAD with *PSEN1* mutations." *PSEN2* mutations were found to be the least common, and "compared to PSEN1 mutation carriers, carriers with PSEN2 mutations have a later AAO, relatively longer disease duration and a more variable disease expression." Overall, the researchers found that most of the mutations in China were novel in comparison to pathogenic variants among Caucasians (Qin et al., 2020).

Late-Onset Alzheimer Disease

The primary gene associated with late-onset AD is the apolipoprotein E (*APOE*) gene on chromosome 19, particularly its epsilon (ε) allele. This apolipoprotein is thought to play a role in cholesterol homeostasis and aid in removal of the amyloid- β protein that is at the core of AD. There are three isoforms of this allele: ε2, ε3, and ε4. The ε4 allele binds much more rapidly to the amyloid protein; however, it is less efficient than the other two alleles in protein transfer. These characteristics combined have made the ε4 allele a potential genetic risk factor of AD (Sherva & Kowall, 2023).

The role of genetics in diagnosis and risk prediction in late-onset AD is much less straightforward. *APOE* ε4 is associated with changes in lipid metabolomics in AD patients, and is likely a factor in even the early stages of AD development (Pena-Bautista et al., 2020). Further, it has been suggested that *APOE* ε4 is a selective risk factor, affecting memory-related AD manifestations of the disease more than language-related implications (Weintraub et al., 2020). Despite the established evidence of *APOE* ε4 as a risk factor for AD, its value in disease prediction in a clinical setting is limited, and the relevance of clinical testing for common genetic variations identified in GWAS is even more limited. Combining multiple susceptibility loci into a global genetic risk score (GRS) might improve the prediction of individuals at risk. However, the most comprehensive risk prediction model developed to date only achieved a sensitivity of 55% and a specificity of 78%, impeding use in clinical practice (de Calignon et al., 2012; Van Cauwenberghe et al., 2016).

Naj et al. (2014) assessed the effect of *APOE* alleles on average age of onset in AD patients. Fourteen studies containing 9,162 patients were examined, and the *APOE* allele was found to contribute 3.9% of the variation of age of onset. Each copy of the ε4 was found to reduce the age of onset by 2.45 years (Naj et al., 2014).

Cohn-Hokke et al. (2017) examined the social and personal effects of testing for hereditary neurodegenerative diseases from 74 patient survey responds. The authors concluded that "the result of predictive testing on adult-onset neurodegenerative diseases does not have a large negative effect on social and personal life, although these observations should be interpreted with caution because of the small number of participants and low response rate" (Cohn-Hokke et al., 2017).

The ancestral *APOE* ε4 risk of AD has been studied across Puerto Rican and African American populations. A total of 1,986 participants with late-onset AD (1,766 African Americans and 220 Puerto Ricans) and 3,899 healthy controls older than 65 years of age (3,730 African Americans and 169 Puerto Ricans) participated in this study. The authors note that "*APOE* ε4 alleles on an African background conferred a lower risk than those with a European ancestral background, regardless of population" (Rajabli et al., 2018). This study shows that the risk conferred by the *APOE* ε4 allele differs across populations; the cause of this risk is unknown but may be due to genetic variation, environmental factors, or cultural factors associated with ancestry. Stevenson-Hoare et al. (2023) studied the plasma biomarkers and genetics used for AD diagnosis. The study included 1439 people with AD, with a mean age of 68 years, and 508 controls, with a mean age of 82 years. The authors measured plasma concentrations of 40 and 42 amino acid-long amyloid β fragments, tau phosphorylated at amino acid 181, neurofilament light, and glial fibrillary acidic protein. "The prediction accuracy of Alzheimer's disease clinical diagnosis by the combination of all biomarkers, APOE and polygenic risk score reached area under receiver operating characteristic curve (AUC) = 0.81" The genetic risk was compared to age of onset and disease duration. "All biomarkers were significantly associated with age in cases and controls." The authors conclude that "biomarker-based diagnosis is not perfect because the biomarker measurements in older controls are similar to those in younger clinically diagnosed AD cases" but, "blood plasma biomarkers can only be a useful tool for the assessment and prediction of AD in the context of other genetic and/or clinical information" (Stevenson-Hoare et al., 2023).

There is an ethical concern for mental and personal wellbeing after testing for late-onset AD. Pavarini et al. (2021) interviewed 31 people aged 16 to 26 whose grandparents had late-onset AD. The interviews focused on the participant's moral attitudes and motivations towards online and direct-to-consumer genetic testing for late-onset AD. The authors found that participants agreed that "people should have

the right to access these services," but were concerned about "potential distress in response to learning about risk." Overall, face-to-face services were preferred over online. The authors suggest that these results highlight the importance of support, particularly to young people, before and after testing (Pavarini et al., 2021).

Pavarini et al. (2021) studied the psychological impact of genetic testing on healthy individuals at risk for AD. This study included individuals that underwent counseling and testing protocol. The authors performed a psychological assessment at zero, six and 12 months following genetic test results on 24 participants from 13 families. The authors found that carriers of pathogenic variants (*PSEN1, PSEN2, GRN*) showed higher scores than noncarriers on the Resilience Scale for Adults, social competence, and the Multidimensional Health Locus of Control. The authors conclude that "at-risk individuals undergoing predictive testing showed benefit on personal life and no detrimental impact on a broad range of psychological outcomes" (Galluzzi et al., 2022).

Largent et al. (2021) studied the ethical, social, and legal concerns regarding sharing AD genetic testing results. The authors predict that genetic testing for AD in people who are not yet cognitively impaired will become more common in clinical practice. The authors analyzed the decisions to share genetic information of participants in the A4 Study and the API Generation Program, two clinical trials that shared genetic results with the participants. Participants with no elevated amyloid or no APOE ε4 alleles did not pay close attention to the decision regarding sharing this information, and they felt it was good or no news. Participants with elevated amyloid or APOE ε4 alleles felt the information was sensitive and burdensome to decide if they should share or hide it from others. These individuals felt more worried about stigmatization and discrimination, even though they were not currently cognitively impaired. Additionally, close friends and family members of these individuals are more likely to take up a "pre-caregiver" role, potentially changing their relationship; "12% of participants at increased risk for dementia stated that they disclosed their result so that they could 'count on other people to tell me if I'm changing.'" The authors state that these results and concerns "highlight the need for additional legal protections and policy changes in anticipation of the coming transformation of AD clinical care" (Largent et al., 2021).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG) and National Society of Genetic Counselors (NSGC)

The American College of Medical Genetics and Genomics (ACMG) and the National Society of Genetic Counselors (NSGC) issued joint practice guidelines related to the genetic assessment of AD. These guidelines include the following recommendations (Goldman et al., 2011):

- "Pediatric testing for AD should not occur."
- "Prenatal testing for AD is not advised if the patient intends to continue a pregnancy with a mutation."
- "Genetic testing for AD should only occur in the context of genetic counseling (in-person or through videoconference) and support by someone with expertise in this area. Symptomatic patients: Genetic counseling for symptomatic patients should be performed in the presence of the individual's legal guardian or family member."
- "DTC (direct to consumer) *APOE* testing is not advised."
- "A risk assessment should be performed by pedigree analysis to determine whether the family history is consistent with EOAD [early-onset AD] or LOAD (late-onset AD) and with autosomal dominant (with or without complete penetrance), familial or sporadic inheritance."

For families in which an autosomal dominant AD gene mutation is a possibility:

- "Testing for genes associated with early-onset autosomal dominant AD should be offered in the following situations:
  - "A symptomatic individual with EOAD in the setting of a family history of dementia or in the setting of an unknown family history (e.g., adoption).
  - "Autosomal dominant family history of dementia with one or more cases of EOAD."
  - "A relative with a mutation consistent with EOAD (currently *PSEN1/2* or *APP*)."
- "Ideally, an affected family member should be tested first. If no affected family member is available for testing and an asymptomatic individual remains interested in testing despite counseling about the low likelihood of an informative result (a positive result for a pathogenic mutation), he/she should be counseled according to the recommended protocol. If the affected relative, or their next of kin, is uninterested in pursuing tested, the option of DNA banking should be discussed."

For families in which an autosomal dominant AD is unlikely:

- "Discuss that both sporadic and familial cases can be due to a genetic susceptibility. Risk estimates are only available for first-degree relatives of an affected individual in sporadic or familial cases."
- "Genetic testing for susceptibility loci (e.g., *APOE*) is not clinically recommended due to limited clinical utility and poor predictive value. If a patient wishes to pursue testing despite genetic counseling and recommendations to the contrary, testing may be considered at the clinician's discretion."

Finally, the authors comment that "in general, clear genotype-phenotype correlations cannot typically be made for the three causative genes, and age of onset can vary more than 20 years within the same family" (Goldman et al., 2011).

In 2019, an addendum was published for the 2011 guidelines. The ACMB board of directors reaffirmed these guidelines (as of June 25, 2018) with two changes:

- "To use the phrase "pathogenic variant" rather than the word "mutation" in discussing pathogenic variants related to autosomal dominant early-onset Alzheimer disease. This would be consistent with current ACMG/AMP Guidelines for Variant Interpretation and Reporting.
- Because this document no longer meets the criteria for an evidence-based practice guideline by either the American College of Medical Genetics and Genomics (ACMG) or National Society of Genetic Counselors (NSGC), NSGC reclassified this document as a Practice Resource in 2016, and ACMG is also classifying it as a Practice Resource as of this reaffirmation" (Goldman et al., 2019).

American College of Medical Genetics and Genomics (ACMG)

In the Choosing Wisely Initiative, the ACMG recommended "Don't order *APOE* genetic testing as a predictive test for Alzheimer's disease." The rationale for the recommendation is that "*APOE* is a susceptibility gene for later-onset Alzheimer disease (AD), the most common cause of dementia. The presence of an ε4 allele is neither necessary nor sufficient to cause AD. The relative risk conferred by the ε4 allele is confounded by the presence of other risk alleles, gender, environment and possibly ethnicity. *APOE* genotyping for AD risk prediction has limited clinical utility and poor predictive value" (ACMG, 2016).

American Academy of Neurology (AAN)

In 2001 (reaffirmed in 2004), AAN made the following recommendation on the use of genetic testing for Alzheimer's disease:

- Routine use of *APOE* genotyping in patients with suspected AD is not recommended at this time (Guideline).
- There are no other genetic markers recommended for routine use in the diagnosis of AD (Guideline) (Knopman et al., 2001).

National Institute on Aging (NIA)

In 2011, Alzheimer's Disease diagnostic guidelines were revised including latest research results and better scientific understanding of the disease. The development of

the new guidelines was led by the National Institute of Health and the Alzheimer's Association. Diagnostic criteria for Alzheimer's disease were re-defined. In respect to genetic testing, NIA issued following guidance and recommendations: "A rare type of familial Alzheimer's disease, called Early-Onset Alzheimer's Disease (EOAD), is caused by mutations in the amyloid precursor protein, presenilin 1, or presenilin 2 genes. A person who inherits any of these mutations from a parent will almost surely develop Alzheimer's dementia before age 65. Genetic testing for the disease is common in families with a history of EOAD"; "The major genetic risk factor for the more common, sporadic form of the disease, or Late-Onset Alzheimer's disease (LOAD), is the ε4 allele of the APOE gene. But carrying this allele by itself does not mean a person has or will develop Alzheimer's dementia, so genetic testing for APOE ε4 is not recommended outside of a research setting" (NIH, 2022).

The NIA and Alzheimer's Association released a joint research framework in 2018. In that framework, they state that "Genetics is not formally included in the research framework because our concept of disease rests on neuropathologic change (that can be detected by biomarkers). In contrast, gene variants do not measure pathologic change but rather indicate an individual's risk for developing pathologic change" (Jack et al., 2018).

European Federation of Neurological Societies (EFNS) and European Neurological Society (ENS)

The EFNS and ENS have developed guidelines for the diagnosis and management of disorders associated with dementia. Regarding genetic testing, these guidelines state that "No studies have addressed the value of genetic counselling for patients with dementia or their families when autosomal-dominant disease is suspected. Because the genetics of dementing illnesses is a very young field, expertise in genetic counselling for the dementias of the elderly is likely to be found only in specialized dementia research centres (Good Practice Point). Screening for known pathogenic mutations can be undertaken in patients with appropriate phenotype or a family history of an autosomal-dominant dementia. This should only be undertaken in specialist centres with appropriate counselling of the patient and family caregivers, and with consent (Good Practice Point). Pre-symptomatic testing may be performed in adults where there is a clear family history, and when there is a known mutation in an affected individual to ensure that a negative result is clinically significant. (Good Practice Point)" (Sorbi et al., 2012).

European Federation of Neurological Sciences (EFNS)

In 2010, EFNS published revised recommendations on the diagnosis and management of Alzheimer disease. It stated that "the ApoE 4 allele is the only genetic factor

consistently implicated in late-onset AD, but it is neither necessary nor sufficient for development of the disease. Hence, there is no evidence to suggest ApoE testing is useful in a diagnostic setting." The EFNS recommended that "screening for known pathogenic mutations can be undertaken in patients with appropriate phenotype or a family history of an autosomal dominant dementia. Routine Apo E genotyping is not recommended" (Hort et al., 2010).

United States Preventive Services Task Force (USPSTF)

The USPSTF has concluded that "the current evidence is insufficient to assess the balance of benefits and harms of screening for cognitive impairment in older adults" (Owens et al., 2020).

Alzheimer's Disease and Related Disorders Therapeutics Work Group

In 2023, a workgroup developed and published information on Lecanemab (Leqembi®) as an approved treatment for Alzheimer disease (AD). The drug can be initiated in early Alzheimer disease for those with confirmed brain amyloid pathology. The working group recommends that patients requiring anticoagulants should not receive lecanemab until more data regarding the interaction with anticoagulants is available. This is because adverse events of amyloid related imaging abnormalities (ARIA) can result with lecanemab and these may involve microhemorrhages and rare macrohemorrhages; in other words, anticoagulation may increase the risk of hemorrhage.

Other recommendations:

- "We recommend that all patients being considered for lecanemab therapy meet diagnostic criteria for mild cognitive impairment (MCI) due to AD or probable mild AD dementia with biomarker evidence (amyloid PET or CSF) of the AD pathophysiological process."
- "Individuals with depression who scored >8 on the Geriatric Depression Scale or had a body mass index (BMI) greater than 35 or less than 17 were excluded from both the phase 2 and 3 studies. We recommend adopting these same criteria while allowing medical judgment for individual circumstances when the impact of these modifications has been considered."
- "Patients who are apolipoprotein E ε4 (*APOE4*) gene carriers, especially *APOE4* homozygotes, are at higher risk for ARIA, and the AUR recommends *APOE* genotyping to better inform risk discussions with patients who are lecanemab candidates."
- "We recommend excluding patients with any history of seizures until additional data are available."

- "Cerebral amyloid angiopathy-related inflammation/amyloid beta-related angiitis (CAA-ri/ABRA) increase the risk for ARIA (discussed below) and should exclude patients as treatment candidates."
- "Patients should not be given lecanemab if they are receiving aducanumab or had severe or recurrent ARIA with use of aducanumab."
- "Participants with clotting disorders should be excluded."
- "Evidence of cerebral contusion, encephalomalacia, brain aneurysms or other vascular malformations, central nervous system (CNS) infection, and brain tumors other than meningioma or arachnoid cysts excluded patients from phase 3 trial participation. These same restrictions should apply when considering patients for treatment with lecanemab" (Cummings et al., 2023).

International Working Group (IWG)

The IWG released recommendations for the clinical diagnosis of AD in their "Personal View" article responding to the National Institute of Aging and the Alzheimer Association biologically defining AD based on biomarkers. The IWG contests this definition, stating that some cognitively unimpaired people with AD biomarkers may never develop clinical symptoms of AD, and that AD can develop as a co-morbidity of other brain diseases. The IWG goes on to recommend how biomarkers should and should not be used to clinically diagnose AD. "We recommend that AD diagnosis be restricted to the occurrence of positive biomarkers together with specific AD phenotypes, whereas biomarker positive cognitively unimpaired individuals should be considered only at-risk for progression to AD" (Dubois et al., 2021). The IWG recommends:

- A "clinical-biological" diagnosis of AD requiring the presence of both a clinical phenotype and a biomarker.
- The common clinical phenotypes for AD are "the amnestic syndrome of the hippocampal type (typical), the posterior cortical atrophy variant, and the logopenic variant primary progressive aphasia." Less common phenotypes include "behavioural/dysexecutive variant7, the cortico-basal variant, and the other variants of primary progressive aphasia."
- Both positive amyloid and tau biomarkers must both be present, with the common phenotypes, for AD diagnosis. Uncommon phenotypes with positive AD markers do not ensure an AD diagnosis, a clinician must determine that AD is the dominant pathology.
- "Recommended biomarker measures for amyloid pathology are low CSF Aβ42, increased CSF Aβ40/42 ratio, or increased tracer retention in amyloid PET; for tau pathology, we recommend high CSF p-tau (not total tau [t-tau] due to its lack of specificity) or increased ligand retention in tau PET."

- The diagnosing clinician must be an expert in critically assessing both clinical and biomarker results.
- "CSF investigation is prioritized as it provides simultaneous information on the 2 types of biomarkers (amyloid and tau) and is less expensive than amyloid-PET and/or tau-PET. Where lumbar puncture is contraindicated, PET investigations are an alternative consideration."
- Clinical pathological biomarker investigation is not recommended for cognitively unimpaired individuals. This may change in the future with prevention programs.
- When biomarker investigation has been performed on cognitively unimpaired individuals, the IWG proposed a risk stratification system to distinguish an absolute risk group, a high-risk group, and an undefined risk group. Individuals should be counselled before AD biomarker investigation and if they are at-risk for progression to prodromal AD or AD dementia.
- Isolated subjective memory complaints or cognitive decline that are not supported by cognitive impairment are not enough to be part an AD phenotype.
- When AD is co-morbid with other brain pathologies, it is recommended that physicians rely more on the phenotype and follow-up for the diagnosis.
- Physicians should objectively evaluate the added-value of biomarker investigation in symptomatic patients based on the clinical situation, life context, patient wishes, the possibility of participating in disease-modifying trials, and the current global appreciation of how this information can change patient management.
- When pathophysiological biomarkers are unavailable, patients should have a clinical syndrome diagnosis and more attention should be given to rule out non-degenerative causes (Dubois et al., 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On April 6, 2017 the FDA approved the 23andMe PGS Genetic Health Risk Report for Late-onset Alzheimer Disease, indicated for reporting of the ε4 variant in the *APOE*

gene. The report describes if a person's genetic result is associated with an increased risk of developing Late-onset Alzheimer Disease, but it does not describe a person's overall risk of developing Alzheimer Disease. The ε4 variant included in this report is found and has been studied in many ethnicities. Detailed risk estimates have been studied the most in people of European descent (FDA, 2017a).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
S3852	DNA analysis for APOE epsilon 4 allele for susceptibility to alzheimer's disease

Current Procedural Terminology© American Medical Association. All Rights reserved.
Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Familial Hypercholesterolemia

Policy Number: AHS – M2137 – Genetic Testing for Familial Hypercholesterolemia	Prior Policy Name and Number, as applicable: • AHS-M2137-Genetic Testing for Heterozygous Familial Hypercholesterolemia
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Familial hypercholesterolemia (FH) is a genetic condition that results in premature atherosclerotic cardiovascular disease due to lifelong exposure to elevated low-density lipoprotein cholesterol (LDL-C) levels (Sturm et al., 2018). FH encompasses multiple clinical phenotypes associated with distinct molecular etiologies. The most common is an autosomal dominant disorder caused by mutations in one of three genes, low-density lipoprotein receptor (*LDLR*), *apolipoprotein B-100* (*APOB*), and proprotein convertase subtilisin-like kexin type 9 (*PCSK9*) (Ahmad et al., 2016; Goldberg et al., 2011). Rare autosomal recessive disease results from mutation in low-density lipoprotein receptor adaptor protein (*LDLRAP*) (Garcia et al., 2001).

Genetic counseling is strongly recommended for individuals pursuing genetic testing for familial hypercholesterolemia.

II. Related Policies

Policy Number	Policy Title
AHS-M2180	Genetic Markers for Assessing Risk of Cardiovascular Disease

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic testing to establish a molecular diagnosis of familial hypercholesterolemia (FH) **MEETS COVERAGE CRITERIA** when **both** of the following criteria are met:

   a) When FH is clinically suspected (based on clinical features, family history, physical exam, lipid levels, etc.) and a definitive diagnosis is required;

   b) When the result of the test will directly impact the treatment being delivered to the individual.

2) For asymptomatic close blood relatives (see Note 1) of an individual affected with FH, genetic testing for a known familial mutation associated with FH **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For all other situations not described above, genetic testing to confirm a diagnosis of FH **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Close blood relatives include 1st-degree relatives (e.g., parents, siblings, and children), 2nd-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings), and 3rd-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins), all of whom are on the same side of the family.

Note 2: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AACE	American Association of Clinical Endocrinology
ACC	American College of Cardiology
ACE	American College of Endocrinology
AHA	American Heart Association
APOB	*Apolipoprotein B-100*
ASCVD	Atherosclerotic cardiovascular disease
CAD	Coronary artery disease
CCS	Canadian Cardiovascular Society

CHD	Coronary heart disease
CMS	Centers for Medicare and Medicaid Services
DLCN	Dutch Lipid Clinic Network
EAS	European Atherosclerosis Society
ESC	European Society of Cardiology
FH	Familial hypercholesterolemia
HEART UK	Hyperlipidaemia Education and Atherosclerosis Research Trust United Kingdom
HoFH	Homozygous hypercholesterolemia
IMT	Intima-media thickness
LDL-C	Low-density lipoprotein cholesterol
LDLR	*Low-density lipoprotein receptor*
LDLRAP	Low-density lipoprotein receptor adaptor protein
MEDPED	Make early diagnosis to prevent early death
NICE	National Institute for Health and Care Excellence
NLA	National lipid association
PCSK9	*Proprotein convertase subtilisin-like kexin type 9*
USPSTF	United States Preventive Services Task Force

V. Scientific Background

Familial Hypercholesterolemia (FH) is considered the most common inherited cardiovascular disease, affecting up to one in 200 people. FH's signature clinical sign is extremely elevated levels of low-density lipoprotein (LDL) cholesterol, which often leads to early-onset atherosclerotic cardiovascular disease (ASCVD) (Rosenson & Durrington, 2023). FH likely accounts for up to 3% of myocardial infarctions for individuals under 60 (Youngblom et al., 2016). Although affected individuals have a 20-fold increased risk of premature ASCVD (Austin et al., 2004), early diagnosis and treatment with lipid-lowering drugs can reduce the risk of coronary heart disease (CHD) to rates comparable to the general population (Ahmad et al., 2016; Knowles et al., 2014; Versmissen et al., 2008).

The primary pathogenic mechanism of FH is the impairment of LDL-receptor mediated catabolism of LDL. Mutations in any of the three main genes (*APOB*, *LDLR*, *PCSK9*) typically cause this impairment, and mutations can be detected in up to 80% of patients with "definite" FH and up to 30% with "possible" FH. Of the three mutations, *LDLR* is the most common, composing 85-90% of the total mutations. *PCSK9* consists of 2-4% of the total, and *APOB* consists of 1-12%. The severity of clinical phenotype depends on the extent to which LDL metabolism is affected. *LDLR* mutations reduce the efficacy of LDL receptors to clear LDL particles, *APOB* mutations impair binding of

LDL particles to the LDL receptor, and *PCSK9* mutations lead to decreased *LDLR* expression (fewer LDL receptors). Other factors (unrelated genetic conditions, diet, et al.) may affect LDL levels as well (Rosenson & Durrington, 2023). Several proprietary gene panels exist for assessment of FH. These typically include the three primary genes, but they may also include rarer genes, such as *LDLRAP* (Ambry, 2020; Invitae, 2020). Some panels intended for broader conditions, such as hyperlipidemia, may also include FH-related genes, such as BluePrint Genetics' 20 gene panel (BluePrint, 2022).

At least three current diagnostic criteria have been developed (Simon Broome, Dutch Lipid Clinic Network (DLCN), and the US Make Early Diagnosis to Prevent Early Death [MEDPED]). These criteria have been able to identify patients with FH-causing mutations with >80% sensitivity or specificity (Civeira, 2004; Marks et al., 2003; Williams et al., 1993). The Simon Broome and DLCN diagnostic criteria consider DNA-based evidence of mutations in any of *APOB, LDLR,* or *PCSK9* to be suitable evidence for a "definite" diagnosis of FH (Rosenson & Durrington, 2023).

However, <10% of FH cases are identified (O'Brien et al., 2014), despite an estimated prevalence of 1:200 to 1:500 (Ahmad et al., 2016; De Backer et al., 2015; Do et al., 2015; Nordestgaard et al., 2013). Ahmad et al. noted the heterogeneity of clinical application of FH diagnostic criteria, observing that the most commonly used formal criteria was Simon–Broome only (21%), followed by multiple diagnostic criteria (16%), MEDPED only (7%), DLCN only (1%), and other (0.5%) (Ahmad et al., 2016).

Clinical Utility and Validity

Wald et al. (2016) assessed the efficacy and feasibility of child-parent screening for familial hypercholesterolemia in primary care practice. 10095 children provided capillary blood samples, and the authors measured their cholesterol. Children were considered positive for FH if their levels were at or above the 99.2% percentile (1.53 times the median level). 28 (0.3%) children were considered positive for FH, and 20 children were classified as carriers of an FH mutation. Another 17 children with levels under the 1.53 median were found to have an FH mutation. Overall, the mutation prevalence was 1/273 children (37/10095). The authors concluded that "Child-parent screening was feasible in primary care practices at routine child immunization visits. For every 1000 children screened, 8 persons (4 children and 4 parents) were identified as having positive screening results for familial hypercholesterolemia and were consequently at high risk for cardiovascular disease" (Wald et al., 2016).

Khera et al. (2016) evaluated the prevalence of an FH mutation among those with "severe" hypercholesterolemia and determined whether coronary artery disease (CAD) risk varies with mutation status. Three genes causative of FH (*LDLR*, *APOB*, and *PCSK9*) were sequenced in 26025 patients from seven case-control studies (5540 with CAD,

8577 controls without) and five prospective cohort studies (n = 11908). Out of the 20485 prospective cohort and CAD-free patients, 1386 were found to have LDL cholesterol levels of ≥190 mg/dL, and only 24 of these carried an FH mutation. Patients with LDL cholesterol ≥190 mg/dL and no FH mutation were found to have a 6-fold higher risk for CAD compared to patients with LDL <130 mg/dL, but patients with both LDL cholesterol ≥190 mg/dL and an FH mutation were found to have a 22-fold higher risk (Khera et al., 2016).

Braamskamp et al. (2017) performed a study assessing the effect of two-year treatment with rosuvastatin on carotid intima-media thickness (IMT) in children with heterozygous familial hypercholesterolemia (HeFH). 197 children with HeFH were provided rosuvastatin for two years, and carotid IMT was assessed at baseline, one year, and two years. The authors noted that at baseline, carotid IMT was greater in HeFH than affected siblings, but rosuvastatin treatment resulted in "significantly less progression of increased carotid IMT in children with HeFH than untreated unaffected siblings", even suggesting that "no difference in carotid IMT could be detected between the 2 groups after 2 years of rosuvastatin." The authors concluded that "these findings support the value of early initiation of statin treatment for low-density lipoprotein cholesterol reduction in children with HeFH" (Braamskamp et al., 2017).

Elbitar et al. (2018) showed the identification new mutations in FH through use of exome sequencing of *LDLR*, *APOB*, *PCSK9,* and *APOE*. 13 French families with "autosomal dominant hypercholesterolemia" had an exome sequencing performed. Several new mutations were identified, such as "p.Arg50Gln mutation in the *APOB* gene, a p.Ala3396Thr mutation of *APOB*, and one patient with a severe phenotype carrying also a mutation in *PCSK9*: p.Arg96Cys." The authors stated that this study provided the first known case of a compound heterozygote with a mutation in *APOB* and *PCSK9* and suggested that identifying these new mutations "lead to better diagnosis and treatment of ADH" (Elbitar et al., 2018).

Lee et al. (2019) performed a meta-analysis on the impact of genetic testing for FH on "1) diagnosis of 'definite familial hypercholesterolemia', 2) initiation and adherence of lipid-lowering therapy and 3) risk of ASCVD." The authors included 56 studies. Genetic testing was found to have provided confirmation of FH in 28-80% of cases over clinical criteria alone. The authors also identified a 76751-individual cohort that indicated that an FH-causing variant was found in only 1.7%-2.5% of subjects with LDL >190 mg/dL. Molecular diagnosis was found to increase lipid-lowering therapy adherence (4181 definite FH subjects). A loss-of-function *LDLR* variant was found to increase risk of myocardial infarction by 6.77-fold, and even a milder pathogenic *LDLR* variant still increased risk by 4.4-fold. The authors concluded that "DNA sequencing confirms the diagnosis of FH but has a poor yield in unselected patients whose sole criterion is an

elevated LDL-C. Initiation and adherence to treatment is improved. The risk of ASCVD is 4.4- to 6.8-fold increased in patients with an FH-causing variant compared with controls, depending on the severity of the DNA change" (Lee et al., 2019).

Trinder et al. (2019) evaluated the risk of premature (defined as <55 years old) cardiovascular events in patients with clinically diagnosed familial hypercholesterolemia. Monogenic (defined as mutations in *LDLR, APOB,* or *PCSK9,* comprising up to 80% of cases) and polygenic causes of FH were compared. 626 patients were included, and both targeted sequencing and genetic variant analysis were performed to identify patients for both cohorts. Patients with polygenic scores above the 80th percentile were considered to have polygenic FH. Risk of several cardiovascular events (unstable angina, myocardial infarction, coronary revascularization, or stroke) were assessed. Monogenic causes of FH were associated with a 1.96-fold increase of CVD, whereas the polygenic cohort saw no significant increase compared to patients without any genetic cause of FH at all. The authors also found that an elevated low-density lipoprotein polygenic risk score increased the CVD risk for monogenic patients to 3.06-fold. The authors concluded that "genetic testing for FH provides important prognostic information that is independent of LDL-C levels" (Trinder et al., 2019).

Trinder et al. (2020) compared the risk of CVD events between three cohorts; monogenic FH (277 patients), polygenic FH (2379), and hypercholesterolemia with "undetermined cause" (2232). The authors defined polygenic FH as a "polygenic score >95th percentile based on 223 single-nucleotide variants." The authors found that patients with monogenic FH were three times more likely than polygenic FH to experience a CVD event before age 55 (6.1% vs 2.0%) and that both genetically-based types of FH were more likely to experience a CVD event compared to patients with hypercholesterolemia of unknown cause. The authors concluded that "genetic determinants of LDL-C levels may impose additional risk of CVD" and that "understanding the possible genetic cause of hypercholesterolemia may provide important prognostic information to treat patients" (Trinder et al., 2020).

Sturm et al. (2021) conducted a cross-sectional study comparing limited-variant screening and comprehensive next-generation (NGS) genetic testing for diagnosing FH. In the patient cohort, the researchers found that the limited-variant screen would have only yielded a positive detection rate of 8.4%, compared to the 27.0% positive detection rate with the comprehensive test, meaning that 68.9% of individuals with a FH-associated gene would've been missed by the limited screen. Individuals of self-reported Black/African American and Hispanic descent were more likely to be missed by the limited-variant screen. This demonstrates the need to conduct a full evaluation

via genetic screening, and how it is a useful modality for diagnosing FH (Sturm et al., 2021).

Reeskamp et al. (2020) performed a study that investigated the role of NGS in clinical FH. For the diagnostic yield of NGS, the researchers stated that "a FH-causing genetic variant was identified in only 14.9% of FH patients with LDL-cholesterol levels of 5 mmol/L or greater;" the mutations being considered were from *LDLR* (80.2%), APOB (14.5%), or PCSK9 (5.3%). "This percentage increased to more than 50% when patients were stratified according to either higher LDL-cholesterol levels or more stringent diagnostic FH criteria ascertained by the DLCN [Dutch Lipid Clinic Network] criteria; 4.8% of FH-mutation negative patients were heterozygous carriers of a pathogenic variant in a minor FH gene." Though this study overall had a lower diagnostic yield using NGS in comparison to other studies, the researchers propose that "stringent use of clinical criteria algorithms is warranted to increase this yield" and thus maximize the clinical utility of NGS (Reeskamp et al., 2020).

Vallejo et al. (2021) conducted a cross-sectional assessment of 42,617 adults 18 years and older with a clinical or genetic diagnosis of heterozygous familial hypercholesterolaemia. The European Atherosclerosis Society Familial Hypercholesterolaemia Studies Collaboration provided a global registry of individuals with FH in World Health Organization regions. Cardiovascular risk factors varied by age and World Health Organization region. The authors found that, "among patients taking lipid-lowering medications, 2.7% had LDL cholesterol lower than 1.8 mmol/L; the use of combination therapy, particularly with three drugs and with proprotein convertase subtilisin-kexin type 9 inhibitors, was associated with a higher proportion and greater odds of having LDL cholesterol lower than 1·8 mmol/L." In addition, the authors advocated for earlier detection and the use of combination therapies (as opposed to single-drug therapy) to achieve guideline-recommended LDL concentrations.

VI. Guidelines and Recommendations

European Atherosclerosis Society (EAS)

Cuchel et al. (2014) published a position paper from the Consensus Panel on Familial Hypercholesterolemia of the EAS that stated that the diagnosis of homozygous familial hypercholesterolemia (HoFH) can be made on clinical or genetic criteria. The authors recommended genetic analysis should be considered to:

- Confirm the clinical diagnosis
- Facilitate testing of family members (reverse cascade screening) – still endorsed in 2023

- Assist in diagnosis where clinical presentation is borderline between that of HoFH and heterozygous FH

In 2023, the EAS provided updates to their clinical guidance for homozygous familial hypercholesterolaemia. In terms of the updated genetic criteria, EAS stated the following:

- "Genetic confirmation of bi-allelic pathogenic/likely pathogenic variants on different chromosomes at the *LDLR, APOB, PCSK9, or LDLRAP1* genes or ≥2 such variants at different loci"
- "Consider only variants reported as 'pathogenic/likely pathogenic' according to recognized criteria as a confirmed genetic diagnosis of HoFH."

Despite these recommendations, the EAS acknowledges that "genetic results can be potentially misunderstood or miscommunicated." When there are privacy concerns for probands or parents, or limited access to testing, the EAS also states that screening of lipid levels is "acceptable" to identify family members with FH, as the LDL-C level/phenotype is what ultimately determines therapy (Cuchel et al., 2023).

Wiegman et al. (2015) published a position paper from the EAS regarding FH in children. In it, they state that "DNA testing establishes the diagnosis," and that "detection of a pathogenic mutation, usually in the *LDLR* gene, is the gold standard for diagnosis of FH." The EAS also observes that "It is best practice to first genetically test a phenotypically affected parent or a second-degree relative in the absence of a parent. If a mutation is identified, genetic testing and counselling should be offered to all family members" (Wiegman et al., 2015).

European Society of Cardiology and European Atherosclerosis Society (ESC/EAS)

The Task Force for the management of dyslipidaemias of the European Society of Cardiology (ESC) and European Atherosclerosis Society (EAS) published an update in 2019. In it, they recommend that genetic testing should be performed to confirm clinically suspicious cases of FH. The EAS lists the following criteria as evidence for FH:

- "TC ≥8 mmol/L (≥310 mg/dL) without treatment in an adult or adult family member (or >95th percentile by age and gender for country);
- Premature CHD in the patient or a family member;
- Tendon xanthomas in the patient or a family member; or
- Sudden premature cardiac death in a family member."

The EAS also recommends that cascade testing be performed when a causative mutation is known in an index case of heterozygous FH. Moreover, "To improve risk

assessment, the use of imaging techniques to detect asymptomatic atherosclerosis is recommended" (Mach et al., 2019).

American Heart Association (AHA)

In 2015, the AHA released a scientific statement on FH that stated that "identification of all patients with FH is critical, but the optimal screening strategy has not been determined, and the complementary roles of genetic testing, family history, and LDL-C need to be further defined, particularly for children." AHA noted that "In healthcare systems that are less cohesive such as the US system, genetic testing is controversial for individuals in confirming diagnosis, and implementing cascade screening will be more difficult. In most countries, genetic testing remains relatively expensive and has limited availability. A reduction in costs and improved efficiency of genetic testing is likely to increase its broader application in screening families for FH." Regarding testing for family members of patients with FH, AHA stated that "Consenting family members should be offered a standard plasma lipid profile and a genetic test if the family mutation is known, and DNA testing is available." The AHA also recommended that "Genetic counseling for FH can help patients and their families complete their pedigree and understand the inheritance of FH and the personal and familial implications of the diagnosis" (Gidding et al., 2015).

For diagnosing FH, the AHA states that "genetic testing may offer additional insight regarding cardiac risk and diagnosis" and can confirm diagnosis, but "cannot be excluded in the absence of a causative mutation" (McGowan et al., 2019).

The American Heart Association also proposed new diagnostic criteria shown below (Gidding et al., 2015):

***ICD-10* Category**	**Clinical Criteria**	**With Genetic Testing Performed**
Heterozygous FH	LDL-C ≥160 mg/dL (4 mmol/L) for children and ≥190 mg/dL (5 mmol/L) for adults and with one first-degree relative similarly affected or with premature CAD or with positive genetic testing for an LDL-C–raising gene defect (LDL receptor, *APOB*, or *PCSK9*)	Presence of one abnormal LDL-C–raising (LDL receptor, *APOB* or *PCSK9*) gene defect Diagnosed as heterozygous FH if LDL-C–raising

		defect positive and LDL-C <160 mg/dL (4 mmol/L) Occasionally, heterozygotes will have LDL-C >400 mg/dL (10 mmol/L); they should be treated similarly to homozygotes Presence of both abnormal LDL-C–raising (LDL receptor, *APOB* or *PCSK9*) gene defect(s) and LDL-C–lowering gene variant(s) with LDL-C <160 mg/dL (4 mmol/L)
Homozygous FH	LDL-C ≥400 mg/dL (10 mmol/L) and one or both parents having clinically diagnosed familial hypercholesterolemia, positive genetic testing for an LDL-C–raising (LDL receptor, *APOB*, or *PCSK9*) gene defect, or autosomal-recessive FH	Presence of two identical (true homozygous FH) or nonidentical (compound heterozygous FH) abnormal LDL-C–raising (LDL receptor, *APOB* or *PCSK9*) gene defects; includes the rare autosomal-recessive type
	If LDL-C >560 mg/dL (14 mmol/L) or LDL-C >400 mg/dL (10 mmol/L) with	Occasionally, homozygotes will

	aortic valve disease or xanthomata at <20 y of age, homozygous FH highly likely	have LDL-C <400 mg/dL (10 mmol/L)
Family history of FH	LDL-C level not a criterion; presence of a first-degree relative with confirmed FH	Genetic testing not performed

-
-

American College of Cardiology/American Heart Association (ACC/AHA)

The 2018 statement (Sturm et al., 2018) on clinical genetic testing for familial hypercholesterolemia recommends:

Proband (index case)

Genetic testing for FH should be offered to individuals of any age in whom a strong clinical index of suspicion for FH exists based on examination of the patient's clinical and/or family histories. This index of suspicion includes the following:

- "Children with persistent∗ LDL-C levels ≥160 mg/dl or adults with persistent LDL-C levels ≥190 mg/dl without an apparent secondary cause of hypercholesterolemia and with at least 1 first-degree relative similarly affected or with premature CAD‡ or where family history is not available (e.g., adoption)"
- "Children with persistent∗ LDL-C levels ≥190 mg/dl or adults with persistent LDL-C levels ≥250 mg/dl without an apparent secondary cause of hypercholesterolemia, even in the absence of a positive family history"

Genetic testing for FH may be considered in the following clinical scenarios:

- "Children with persistent∗ LDL-C levels ≥160 mg/dl (without an apparent secondary cause of hypercholesterolemia†) with an LDL-C level ≥190 mg/dl in at least 1 parent or a family history of hypercholesterolemia and premature CAD"
- "Adults with no pre-treatment LDL-C levels available but with a personal history of premature CAD and family history of both hypercholesterolemia and premature CAD"
- "Adults with persistent LDL-C levels ≥160 mg/dl (without an apparent secondary cause of hypercholesterolemia) in the setting of a family history of

hypercholesterolemia and either a personal history or a family history of premature CAD"

*Two or more measurements, including assessment after intensive lifestyle modification

†Hypothyroidism, diabetes, renal disease, nephrotic syndrome, liver disease, medications.

If LDL-C values are unavailable, total cholesterol values ≥320, 260, and 230 mg/dl (corresponding to LDL-C levels ≥250, 190, and 160 mg/dl, respectively) could be used.

At-risk relatives

Cascade genetic testing for the specific variant(s) identified in the FH proband (known familial variant testing) should be offered to all first-degree relatives. If first-degree relatives are unavailable, or do not wish to undergo testing, known familial variant testing should be offered to second-degree relatives. Cascade genetic testing should commence throughout the entire extended family until all at-risk individuals have been tested and all known relatives with FH have been identified.

They recommend that "Genetic testing for patients with suspected FH should, at a minimum, include analysis of *LDLR, APOB,* and *PCSK9*. This analysis should include for *LDLR* and *PCSK9* sequencing of all exons and exon/ intron boundaries, as well as *LDLR* deletion/duplication analysis, and for *APOB* the exons encoding the *LDLR* ligand-binding region… Larger, more inclusive, lipid disorder NGS panels are also available that provide evaluation of not only the main FH genes but also the genes causing conditions with phenotypic overlap previously described. These expanded panels should be considered to improve the diagnosis of patients with these 'phenocopy' conditions that may require specific therapies, and they should include the following genes: *LDLR, APOB, PCSK9, LDLRAP1, LIPA, ABCG5, ABCG8,* and *APOE*" (Sturm et al., 2018).

National Lipid Association (NLA)

In 2011, the NLA released guidelines for screening, diagnosing, and managing familial hypercholesterolemia among pediatric and adult patients. This was last reaffirmed in August 2020. With regards to genetic testing/screening, the NLA stated the following:

- "Genetic screening for FH is generally not needed for diagnosis or clinical management but may be useful when the diagnosis is uncertain.
- Identification of a causal mutation may provide additional motivation for some patients to implement appropriate treatment.

- Importantly, a negative genetic test does not exclude FH, since approximately 20% of clinically definite FH patients will not be found to have a mutation despite an exhaustive search using current methods."

On cascade screening, the NLA stated the following:

- "Cascade screening involves testing lipid levels in all first-degree relatives of diagnosed FH patients.
- As cascade screening proceeds, newly identified FH cases provide additional relatives who should be considered for screening.
- Cascade screening is the most cost-effective means of finding previously undiagnosed FH patients and is also cost-effective in terms of cost per year of life saved. General population screening of a young population (before age 16) is similarly cost-effective in terms of cost per year of life saved, given that effective cholesterol-lowering treatment is begun in all those identified."

However, in terms of diagnosis of FH, the NLA states:

- "Untreated fasting lipid levels at which FH may be suspected in children, adolescents and young adults (<20 years) are LDL cholesterol concentration ≥160 mg/dL or non-HDL cholesterol ≥190 mg/dL. These levels are supported by family studies of affected individuals.
- A second lipid profile should be performed to assess response to diet management, to account for regression to the mean, and to accurately classify those with levels close to classification thresholds" (Goldberg et al., 2011).

In 2015, the NLA published guidelines for the management of dyslipidemia (Jacobson et al., 2015) which was reaffirmed in August 2020:

"If LDL-C is ≥190 mg/dL, consider severe hypercholesterolemia phenotype, which includes familial hypercholesterolemia."

The NLA also published a statement on genetic testing for dyslipidemia in 2020. This statement has been reaffirmed in June 2021. The FH-related recommendations are listed below:

- "Genetic testing is reasonable when heterozygous familial hypercholesterolemia is suspected but not definitively diagnosed based on clinical criteria alone."
- "Cascade screening for FH either by lipid profile or genetic testing is recommended in all first-degree relatives (children and siblings) of an individual who has tested genetically positive for FH."

- "Cascade testing [for general genetic dyslipidemias] should begin with first-degree relatives (parents, siblings, and children) and then extend to second- and third-degree relatives."

The Association also remarks that genetic testing for FH can predict clinical outcomes and that identifying specific mutations (such as *LDLR*) may guide targeted therapy in the future. No "polygenic risk scores" have been identified as a "gold standard" (Brown et al., 2020).

American Association of Clinical Endocrinologists (AACE) and American College of Endocrinology (ACE)

The 2017 American Association of Clinical Endocrinologists and American College of Endocrinology Guidelines for Management of Dyslipidemia and Prevention of Cardiovascular Disease include some items regarding FH. These guidelines include the following (Jellinger et al., 2017):

- For children at risk (such as family history) for FH,
  - screening should be at three years of age
  - repeated once between ages nine and 11 years
  - repeated again at age 18
- "Individuals should be screened for familial hypercholesterolemia (FH) when there is a family history of premature ASCVD. . ."
- Individuals should be screened if they have "Elevated cholesterol levels (total, non-HDL and/ or LDL) consistent with FH"
- The authors note, "While genetic testing may identify FH, it is not commonly used in the U.S. due to cost and lack of payer coverage" (Jellinger et al., 2017).

United States Preventive Services Task Force (USPSTF)

According to the 2016 USPSTF guidelines, "Screening can detect FH in children, and lipid-lowering treatment in childhood can reduce lipid concentrations in the short term, with little evidence of harm. There is no evidence for the effect of screening for FH in childhood on lipid concentrations or cardiovascular outcomes in adulthood, or on the long-term benefits or harms of beginning lipid-lowering treatment in childhood" (Lozano et al., 2016).

In a 2023 screening recommendation, "The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for lipid disorders in children and adolescents 20 years or younger" (Barry et al., 2023).

National Institute for Health and Care Excellence (NICE)

NICE published an update on FH in 2019, and their relevant recommendations include the following:

- "Carry out cascade testing using DNA testing to identify affected first- and second- and, when possible, third-degree biological relatives of people with a genetic diagnosis of FH."
- "Healthcare professionals should consider a clinical diagnosis of homozygous FH in adults with a low-density lipoprotein cholesterol (LDL-C) concentration greater than 13 mmol/l and in children/young people with an LDL-C concentration greater than 11 mmol/l."
- "Use the Simon Broome or Dutch Lipid Clinic Network (DLCN) criteria to make a clinical diagnosis of FH in primary care settings."
- "Refer the person to an FH specialist service for DNA testing if they meet the Simon Broome criteria for possible or definite FH, or they have a DLCN score greater than 5" (NICE, 2019).

Hyperlipidaemia Education and Atherosclerosis Research Trust United Kingdom (HEART UK)

This guideline focuses on homozygous FH. For diagnosis of homozygous FH, HEART-UK recommends that mutation analysis "should be by comprehensive DNA sequencing of introns and exons of the *LDLR, APOB, PCSK9* and *LDLRAP1* gene loci [in an accredited laboratory]" (France et al., 2016).

International Atherosclerosis Society Severe Familial Hypercholesterolemia Panel (IAS)

The panel notes that in addition to the main three genes, mutations in *APOE* or *STAP1* may result in the heterozygous FH phenotype. However, the panel remarks that "…identification of a causative gene variant is not essential for either diagnosis or treatment decisions, since as mentioned these are more appropriately guided by the LDL-C and not by the genotype" (Santos et al., 2016).

New guidance from this society asserts that "Early detection of FH is fundamental to all models of care for FH… However, the best approach to detecting FH in primary care remains uncertain." Nonetheless, they offer the following recommendations for the screening of FH:

Clinical recommendations	Class	Level
1. Multiple screening strategies (for example, selective, opportunistic and/or universal) should ideally be used to detect index cases with FH	1	B
2. Age-specific, sex-specific and country-specific LDL-cholesterol concentrations (estimated in plasma or serum) above the corresponding 95th percentiles for the population should preferably be used to screen for index cases with FH	1	B
3. Selective screening should be used to detect index cases among adults with premature ASCVD, mainly coronary artery disease, and a family history of premature ASCVD and/or hypercholesterolaemia	1	A
4. Opportunistic screening, such as an LDL-cholesterol concentration >4.9 mmol/l (≥190 mg/dl), should be used to detect cases in the community	1	B
5. Universal screening using age-specific and sex-specific criteria for LDL-cholesterol concentration should be considered initially to detect children and adolescents with FH, after which the diagnosis should be formally confirmed and reverse cascade testing offered to parents, as indicated	2	B
6. Cascade testing should be offered to all close relatives of an index case with definite FH and be carried out using phenotypic and genetic methods; if genetic testing is not feasible, LDL-cholesterol testing (based on appropriate age-specific and gender-specific thresholds) should be used	1	A
7. Genome-based population screening of adults may be considered for wider and more accurate detection of FH, but requires careful implementation	3	C
8. After initial detection of potential index cases, the diagnosis of FH should be formally confirmed using country-specific (or internationally accepted) phenotypic criteria and ideally with genetic testing	1	A
9. Children with suspected HoFH (for example, with physical stigmata), or at risk of FH (both parents known to have FH), should be tested as early as possible (at the newborn stage or by 2 years of age), with measurement of LDL-cholesterol concentrations, followed by genetic confirmation	1	B
10. Screening of children at risk of HeFH should be considered using LDL-cholesterol concentrations at or after the age of 5 years, or as early as 2 years in those with a strong family history of premature ASCVD, with confirmation of the diagnosis genetically, as indicated	2	B
11. Non-fasting samples may be considered when screening for FH; the Friedewald equation should be used with caution owing to the confounding effect of hypertriglyceridaemia on the estimation of LDL-cholesterol concentration	3	B
12. Patients with hypertriglyceridaemia > 4.5 mmol/l (>400 mg/dl), in whom FH is strongly suspected, should be re-screened for FH with a 12-h fasting sample and LDL-cholesterol concentration measured using a direct assay	1	A
13. In the absence of a direct assay for LDL-cholesterol concentration, the probability of FH should be reconsidered in patients with very severe hypertriglyceridaemia after therapeutic lowering of triglyceride concentrations to <4.5 mmol/l (<400 mg/dl), or by calculating LDL-cholesterol using a novel equation, if triglycerides are between 4.5 mmol/l and 10.0 mmol/l (400–850 mg/dl)	2	C
14. The effects of cholesterol-lowering medications and acute illness should be accounted for when phenotypically screening for FH; LDL-cholesterol concentrations should be adjusted for the use of statins, ezetimibe, PCSK9 inhibitors and other therapies, particularly if a reliable pretreatment value is unavailable; if the diagnosis of FH is in doubt, LDL-cholesterol measurement should be repeated after full recovery from acute illness	1	B

(Watts et al., 2023).

For the diagnosis of FH, IAS offers the recommendations below.

Clinical recommendations	Class	Level
1. A diagnosis of HeFH or HoFH should be made, whenever possible, using genetic testing that identifies pathogenic variants (such as in *LDLR*, *APOB*, *PCSK9* or *LDLRAP1*) that impair the LDL-receptor pathway; such testing is particularly important when phenotypic features are less obvious, such as in children, and for planning long-term care and cascade testing of family members. Conversely, if the phenotype strongly suggests FH and a pathogenic or likely pathogenic variant is not detected, FH should not be excluded	1	A
2. If genetic testing is not feasible, a clinical diagnosis of FH in adults should be made using country-specific or recognized phenotypic criteria (such as the Dutch Lipid Clinic Network, Simon Broome criteria, MED-PED, AHA, Canadian or Japanese criteria) for index cases (Supplementary Material 2)	1	A
3. A phenotypic diagnosis of FH in adults and children requires exclusion of, or correction for secondary causes of, high LDL-cholesterol concentrations (Supplementary Material 3); in the absence of an untreated value, LDL-cholesterol concentration should be adjusted for concurrent use of cholesterol-lowering medication; LDL-cholesterol concentrations should ideally be measured after fasting and on two occasions	1	A
4. Use of imaging-based detection of subclinical Achilles tendon xanthomas may be considered to increase the specificity and accuracy of the phenotypic diagnosis of FH in adults	3	B
5. A clinical diagnosis of FH in children and adolescents should be considered as highly probable in the presence of an untreated LDL-cholesterol concentration >4.9 mmol/l (>190 mg/dl), recorded on at least two occasions (fasting lipid profile, >2 weeks but <3 months apart), and a parental history of high LDL-cholesterol levels, premature ASCVD or a positive genetic test for FH	2	B
6. After exclusion of secondary causes of high LDL-cholesterol levels (Supplementary Material 3), a clinical diagnosis of FH in children and adolescents should be considered as probable in the presence of an untreated (a) LDL-cholesterol concentration > 4.9 mmol/l (>190 mg/dl; recorded on at least two occasions), even in the absence of a parental history of high LDL-cholesterol concentrations or premature ASCVD; (b) LDL-cholesterol concentration > 4.0 mmol/l (>160 mg/dl; recorded on at least two occasions), with a parental history of high LDL-cholesterol concentrations or premature ASCVD; (c) LDL-cholesterol concentration > 3.5 mmol/l (>135 mg/dl; recorded on at least two occasions), with a parent having a pathogenic gene variant for FH; (d) LDL-cholesterol concentration (recorded on at least two occasions) exceeding a country-specific LDL-cholesterol threshold (lower than the above) and a parental history of elevated LDL-cholesterol concentrations or premature ASCVD	2	B
7. Phenotypic criteria developed for making a diagnosis of HeFH in adult index cases (such as the Dutch Lipid Clinic Network criteria) should not be used in children or adolescents, or when undertaking cascade testing	1	A
8. After excluding secondary causes of high LDL-cholesterol levels (Supplementary Material 3), a clinical diagnosis of HoFH (that is, phenotypic HoFH) should be made in children and adults with an untreated LDL-cholesterol concentration > 10 mmol/l (>400 mg/dl; recorded on two occasions) in the presence of (a) physical stigmata (tendon or cutaneous xanthomas, arcus cornealis) before the age of 10 years and/or (b) untreated LDL-cholesterol concentrations consistent with HeFH in both parents; in the absence of genetic testing and a clear history of FH in both parents, sitosterolaemia and hypercholesterolaemia (cerebrotendinous xanthomatosis) should also be excluded	1	C
9. If cascade testing in the family is recommended, the diagnosis of FH in the proband or index case should ideally be confirmed genetically	1	A
10. The diagnosis of FH during phenotypic cascade testing should be made using age-specific, sex-specific and country-specific LDL-cholesterol concentrations, ideally measured after fasting and on two occasions	1	A

(Watts et al., 2023)

Finally, in asserting that "Genetic testing procedures should be standardized, including informed consent, pre-test and post-test genetic counselling, classification of variants,

reporting and return of results, follow-up of family members for cascade testing, and shared decision-making", IAS created the following table of recommendations:

Clinical recommendations	Class	Level
1. Genetic testing for FH should be offered to all individuals in whom there is a strong suspicion of FH based on clinical and/or family history (for example, phenotypic HoFH, definite or highly probable phenotypic HeFH in an adult, child or adolescent)	1	B
2. Genetic testing should be considered in individuals with a probable phenotypic diagnosis of HeFH	2	B
3. Genetic testing may be considered in individuals with a phenotypic diagnosis of possible HeFH, especially when there is incomplete information to establish a diagnosis and the genetic result affects clinical management	3	C
4. Genetic testing for FH should be carried out using an accredited method in a certified laboratory, using targeted next-generation sequencing of all exons and exon–intron boundaries of *LDLR*, *APOB*, *PCSK9* and *LDLRAP1*, and the exons in *APOB* that encode the LDLR ligand-binding region, as well as analysis for deletions and duplications in *LDLR*	1	A
5. Variants detected by genetic testing should be classified and reported according to contemporary standardized guidelines, for example, those of the ACMG, AMP or ClinGen FH Variant Curation Expert Panel	1	A
6. If a pathogenic or likely pathogenic variant is not detected, FH should not be excluded, particularly if the clinical phenotype is strongly suggestive of FH, because the condition may result from undetected genetic variants	1	A
7. Genetic counselling should be offered, before and after genetic testing, to all individuals suspected of having FH	1	B
8. Genetic counselling should at a minimum include obtaining a three-generation family medical history, risk and psychological assessment, family-based care, enabling of cascade testing, anticipatory guidance and psychological assessment	1	A
9. Pre-conception counselling should be offered to all couples, especially if both partners/parents are known, or suspected, to have FH	1	B
10. Prenatal or pre-implantation genetic testing should be offered if both partners/parents are known to have FH, counselling being particularly important in parents with HeFH who have previously had a child with HoFH	1	C
11. Polygenic scores for hypercholesterolaemia may be useful but are not yet fully standardized, so that they should be used with caution when assessing the differential diagnosis of FH in clinical practice	3	B
12. Cascade genetic testing is highly cost-effective and should be used after a disease-causing variant has been identified in the proband or index case	1	A
13. Pre-test and post-test genetic counselling should be offered to all at-risk relatives as an integral component of cascade testing	1	A
14. Cascade testing should be undertaken using both phenotypic and genotypic approaches (Fig. 1); if genetic testing is not available, a phenotypic approach (that is, a plasma or serum lipid profile, including the LDL-cholesterol concentration) should be used	1	A
15. Cascade genetic testing for the specific variant (variants) identified in the proband (that is, known familial variant testing) should initially be offered to all first-degree relatives; if first-degree relatives are unavailable, or do not wish to undergo testing, known familial variant testing should be offered to at-risk second-degree and then third-degree relatives, with sequential extension to the entire family until all at-risk individuals have been offered testing (Fig. 1)	1	A
16. At-risk children should be offered cascade genetic testing at the earliest opportunity (and more than once if not pursued at the first offer) if an FH-causing variant has been identified in a parent or other first-degree relative	1	A
17. When genetic testing is not feasible, the diagnosis of FH in at-risk relatives should be made phenotypically using age-specific, sex-specific and country-specific LDL-cholesterol concentrations (Fig. 1; Supplementary Material 4); clinical tools for diagnosing FH probands (such as the Dutch Lipid Clinic Network criteria and Simon Broome criteria) are not valid for this purpose. Phenotypic cascade testing should initially be offered to all first-degree relatives. If first-degree relatives are unavailable, or decline testing, phenotypic testing should next be offered to second-degree and then third-degree relatives, with sequential extension to the entire family until all at-risk individuals have been offered testing	1	A
18. 'Reverse' cascade testing (from child to parents) should be offered to parents after a child is identified as a proband with FH, such as after making a diagnosis following a clinical presentation or via a universal or newborn screening programme	1	B

(Watts et al., 2023).

Canadian Cardiovascular Society (CCS)

In 2018, the CCS released a position statement on FH. With regards to genetic testing, screening and diagnosis of FH, the CCS included the following relevant recommendations:

- Diagnosis of FH
  - "We recommend that FH be defined using the DLCNC [Dutch Lipid Clinic Network Criteria], Simon Broome Registry, or FH Canada definition (Strong Recommendation, High-Quality Evidence)."
- Screening for FH
  - "We recommend that cascade screening (lipid profile) protocols be implemented at the local, provincial, and national level in Canada and offered to first-degree relatives of patients with FH (Strong Recommendation, Moderate-Quality Evidence)."
- Genetics
  - "We recommend that genetic testing be offered, when available, to complement a diagnosis of FH and enable cascade screening (Strong Recommendation, High Quality Evidence). The decision to request genetic screening should be made by the treating physician after discussion with the patient."
- ASCVD [atherosclerotic cardiovascular disease] and FH
  - "We suggest that if available, genetic testing should be used to stratify the ASCVD risk in patients with FH (Weak Recommendation, Moderate-Quality Evidence).
    - Values and preferences. An FH-causing genetic variant increases ASCVD risk, beyond that associated with an elevated LDL-C level. Patients should be informed on the high lifetime risk of ASCVD associated with FH."
- Homozygous FH
  - "We recommend that patients with HoFH be referred to a specialized lipid clinic and undergo complete evaluation for genetic analysis, presence of ASCVD, and aggressive lipid-lowering therapies, including consideration for extracorporeal LDL-C removal, lomitapide, and PCSK9 inhibitors (Strong Recommendation, Moderate-Quality Evidence)" (Brunham et al., 2018).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for

Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81407	Molecular pathology procedure, Level 8 (eg, analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Fanconi Anemia

Policy Number: AHS – M2077 – Genetic Testing for Fanconi Anemia	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Fanconi anemia (FA) is an inherited disorder in which cells cannot correctly repair inter-strand crosslinks (ICLs), a specific type of DNA damage that results in genomic instability. This can lead to bone marrow failure (such as aplastic anemia), leukemia, and/or solid tumors. FA is rare, occurring in one in 100,000 to 250,000 births, with an increased incidence in populations such as Ashkenazi Jews and South African Afrikaner populations (Olson, 2022).

For guidance on prenatal or preconception screening for FA, please see AHS-M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title
AHS-M2145	General Genetic Testing, Germline Mutations
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have received genetic counseling and who have clinical signs and symptoms of Fanconi anemia (FA), chromosome breakage testing or gene sequencing (single gene or multi-gene panel testing) for the diagnosis of FA **MEETS COVERAGE CRITERIA**.

2) For all other situations not discussed above, genetic testing for the diagnosis of FA **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For two or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics and Genomics
ACOG	American College of Obstetricians and Gynecologists
AML	Acute myeloid leukemia
ATM	Ataxia-telangiectasia mutated
ATR	Ataxia-telangiectasia mutated and Rad3-related protein
BRCA2	*Breast cancer 2 gene*
CBT	Chromosome breakage test
CCO	Cancer Care Ontario
CDK	Cyclin-dependent kinase
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CNV	Copy number variants
DEB	Diepoxybutane
DNA	Deoxyribonucleic acid
FA	Fanconi anemia
FA-A	Fanconi anemia complementation group A
FA-C	Fanconi anemia complementation group C
FA-D1	Fanconi anemia complementation group D1 (breast cancer 2 gene related)
FANCA	Fanconi anemia complementation group A
FANCC	Fanconi anemia complementation group C
FANCD1	Fanconi anemia complementation group D1
FANCD2	Fanconi anemia complementation group D2
FANCF	Fanconi anemia complementation group F
FANCG	Fanconi anemia complementation group G
FANCI	Fanconi anemia complementation group I
FANCM	Fanconi anemia complementation group M
FANCP	Fanconi anemia complementation group P

FARF	Fanconi Anemia Research Fund
FDA	Food and Drug Administration
FISH	Fluorescence in situ hybridization
G2	Second growth phase of the cell
HCT	Hematopoietic cell transplant
HSC	Hematopoietic stem cell
ICLs	Inter-strand cross links
IFAR	The International Fanconi Anemia Registry
LDTs	Laboratory-developed tests
MDS	Myelodysplastic syndrome
MMC	Mitomycin C
NCCN	The National Comprehensive Cancer Network
NGS	Next-generation sequencing
NORD	The National Organization for Rare Disorders
ROS	Reactive oxygen species
SLX4	*SLX4 structure-specific endonuclease subunit*
USPSTF	U.S. Preventive Services Task Force
VACTERL-H	Vertebral anomalies, anal atresia, congenital heart disease, tracheoesophageal fistula, esophageal atresia, renal anomalies, limb anomalies, and hydrocephalus
WES	Whole exome sequencing
WGS	Whole-genome sequencing

V. Scientific Background

Primarily inherited as an autosomal recessive disorder, Fanconi anemia (FA) is associated with known mutations in at least 22 FA identified genes (Jung et al., 2020). It is found equally in males and females, as well as in different ethnic groups; approximately 50% of FA patients are diagnosed by age ten (NORD, 2020). Jung et al. (2020) also noted that siblings with FA often have similar hematological courses, potentially attributed to similarity in causative variants and environmental factors but have different presentations of congenital anomalies (except for kidney abnormalities and microcephaly to a moderate degree). The three most mutated genes in FA are *FANCA*, *FANCC*, and *FANCG*; these comprise up to 80-90% of all FA cases, with *FANCA* mutations accounting for approximately 60% of cases worldwide (Bogliolo et al., 2019; Olson, 2022). The main function of this set of proteins is to repair the inter-strand crosslinks (ICL) that typically form during DNA replication and transcription (Olson, 2022). A cell is estimated to repair about 10 ICLs per day, but as few as 20-40 unresolved ICLs can lead to cell death (Sumpter & Levine, 2017).

The FA pathway may also play a role in other functions, such as metabolizing alcohol, ensuring the stability of the replication fork during DNA replication, managing oxidative stress as in providing defense from reactive oxygen species (ROS)-induced cell death, and repairing double strand breaks (Kottemann & Smogorzewska, 2013; Longerich et al., 2014; Milletti et al., 2020; Olson, 2022). For example, a mutation in the *FANCC* gene was found to impede the cell's ability to clear out damaged mitochondria and viruses, which could eventually lower immunity to viral infection and contribute to the characteristic bone marrow failure (Cheung & Taniguchi, 2017; Sumpter et al., 2016).

Fanconi anemia may manifest in several ways with symptoms including short stature, skin findings such as hyper- or hypo- pigmentation and café-au-lait skin lesions, microcephaly, and abnormalities in the thumb, eye, axial skeleton, ear, renal system, or urinary tract. There is also a potential connection between FA and the VACTERL-H association (three or more of the following: vertebral anomalies, anal atresia, congenital heart disease, tracheoesophageal fistula, esophageal atresia, renal anomalies, limb anomalies, and hydrocephalus) as the percentage of FA patients also meeting the criteria for VACTERL-H was much higher than previously found (Alter & Giri, 2016). However, up to 25-40% of FA patients look physically normal (D'Andrea, 2010). At the physiological level, the most common symptoms are bone marrow failure and cytopenias, such as pancytopenia, macrocytic anemia, or thrombocytopenia (Olson, 2022). Bone marrow failure is reportedly the most common primary symptom in FA and presents itself in 70-80% of patients by age ten (Bogliolo et al., 2019). Though the exact mechanism of premature hematopoietic stem cell (HSC) loss in FA remains unclear, it is thought to be impacted by defective DNA repair, causing increased damage and cell cycle arrest, increased levels of reactive oxygen species and inflammatory cytokines, and damage caused by reactive aldehydes in the absence of intact repair pathways (Olson, 2022).

Aplastic anemia, another common FA side effect which causes the body to halt the production of red blood cells, also typically occurs early, either leading to death or to a HSC transplant. Endocrine issues, such as growth hormone deficiency, abnormal glucose/insulin metabolism, dyslipidemia, pubertal delay, and hypothyroidism are also commonly associated with an FA diagnosis (about 80% of FA children and adults have at least one endocrine defect) and often lead to a worsening life quality in FA patients (Milletti et al., 2020; Shimamura & Alter, 2010).

Screening for Fanconi Anemia

The most common screening assay for Fanconi anemia is the chromosome breakage test. A DNA crosslinking agent, such as mitomycin C (MMC) or diepoxybutane (DEB), is

used to induce chromosome breakage, and the cells are evaluated at their respective stages in the cell cycle. FA cells typically have more DNA damage and are forced to arrest in the G2 phase when these cells can be observed. Tests may be positive, negative, or inconclusive; a positive test typically shows about 90% of lymphocytes with increased breakage, a negative test shows no increased breakage, and an inconclusive test cannot provide any definitive answer (Hays, 2014). Normal cells have a mean baseline of <.05 breaks per cell while FA cells may range from 0.02 – 0.85 breaks per cell. DEB (the more sensitive and specific agent) typically has a mean baseline of <.10 breaks per normal cell and from 1.06 to 23.9 breaks per FA cell (Auerbach, 2015). The International Fanconi Anemia Registry (IFAR) found the mean standard error of breaks per cell of 104 FA patients to be 8.96 ± 0.448 and the mean standard error of percentage of cells with breaks to be 85.15% ± 1.99%, compared to 0.06 ± 0.004 breaks and 5.12% ± 0.28% of 224 non-FA patients (Kook et al., 1998).

Inconclusive results are typically due to one of two possibilities—one is "mosaicism," where two separate populations of lymphocytes in the blood occur, and the other is where the patient has another underlying condition causing chromosome breakage. However, a mutation analysis can corroborate a diagnosis or provide further information. This can be particularly helpful in assessing the patient's family members, such as potential carriers, asymptomatic family members, or members who may develop clinical symptoms (FARF, 2020).

More recently, researchers have utilized whole exome sequencing as a diagnostic method for FA. Historically, molecular diagnostics regarding FA have been challenging for the medical community because the disease is caused by hereditary patterns featuring point mutations and large genomic deletions in an estimated 22 genes (Rio et al., 2019). Nonetheless, the whole exome sequencing method used in this study identified 93.3% of deletions and mutated alleles when compared to a previously validated method, leading the researchers to the conclusion that whole exome sequencing is efficient enough to characterize patients with FA (Rio et al., 2019).

Clinical Utility and Validity

Due to the increased instability of an FA patient's genome, it is common to see an increased risk of cancer in patients with FA, particularly bone marrow cancers such as leukemia. A study found the observed to expected ratio of all cancers to be as high as 48 (i.e., the observed rate was 48 times higher than expected after controlling for factors such as age and sex) (Alter, 2014). The same study found the likelihood that an FA patient would develop acute myeloid leukemia (AML) to be 700 times higher than normal and the likelihood to develop any myelodysplastic syndrome (MDS) to be 6000 times higher (Alter, 2014). Underlying FA disease mechanisms may also be causing

patients to develop cancers at a much earlier age than typically observed. A study focusing on 35 FA patients found that when compared to the general population, those afflicted by FA were, on average, diagnosed with head and neck squamous cell carcinoma 31 years earlier than controls (32 years for FA patients, 63 years for general population). FA mutation type may also play a factor in cancer development as another study found that FA patients with *FANCA* mutations developed cancer at a significantly older age than those with other mutations; however, mutation type did not seem to affect the overall survival rates of FA cancer patients (Steinberg-Shemer et al., 2019). Furthermore, the common risk factors, such as tobacco or alcohol consumption, were typically not a factor for the FA patients as is usually seen in the general population (Kutler et al., 2016).

Another example of how intertwined the FA proteins and pathway is with cancer is found in the *FANCD1* (Fanconi anemia complementation group D1) gene. The *FANCD1* gene, also known as *BRCA2*, is a gene whose mutations often lead to a higher risk of breast cancer. The *BRCA2* (-/-) cell reacts the same way an FA cell does when treated with the crosslinking agents and *BRCA2* co-localizes with *FANCD2* at damaged sections of DNA. The patients with heterozygous genotypes of *BRCA2* are historically more likely to have a higher risk of breast and ovarian cancer (D'Andrea, 2010).

Novel studies have further demonstrated the risk of germline mutations in FA complementation group (FANC) of the FA pathway in cancer. *FANCD2* (Fanconi anemia complementation group D2) was found to confer a malignant phenotype in esophageal squamous cell carcinoma, and cyclin-cyclin-dependent kinase (CDK) and ataxia-telangiectasia RAD3-related/ataxia-telangiectasia mutated (ATR/ATM) signaling was shown to help in depletion of FANCD2 protein expression and suppress cancer cell proliferation (Lei et al., 2020). In a different study done on a Han Chinese population, Yu et al. (2020) identified that Fanconi anemia complement group F (*FANCF*), though already known to impact cell proliferation and DNA repair, can increase risk of colorectal cancer if hypomethylated. Aberrant methylation of *FANCF* was also observed in ovarian tumors, non-small-cell lung cancer, cervical cancer, and oral cancer previously in general populations (Yu et al., 2020). This conveys the markedly increased predisposition to cancer via mutations in FA and FA pathway components.

Chang et al. (2021) discusses novel diagnostic approaches for FA by single-cell sequencing and capillary nano-immunoassay. Next-generation sequencing (NGS) has been widely utilized for FA diagnosis but has limitations that may lead to unconfirmed genetic subtypes. Chang et al. (2021) studies one FA cause with *FANCM* mutation by conducting the capillary-nano-immunoassay to analyze the expression profile of FA-associated proteins. This assay is designed to detect 417 blood disease genes, including the 17 known FA-related genes. In this case, Chang et al. (2021) observed

two homozygous mutations of the *FANCM* and *FANCD1* genes and abnormal expression of both genes simultaneously existed, diagnosing the patient as a FA-D1/FA-M dual subtype. According to the author, "compared with mixed cell sequencing, single-cell sequencing data shows more accuracy for the FA subtype evaluation, while the capillary nano-immunoassay is a good method to detect the expression profile of abnormal or modified FA protein" (Chang et al., 2021).

Chan et al. (2021) studied the genetic spectrum of FA-associated genes across populations of varying ancestries to explore potential genotype-phenotype associations in cancer. A total of 3,523 subjects in Singapore, of varying ancestry, were assessed for carrier frequency and variant spectrum of potentially pathogenic variants in 17 FA genes. The data suggested higher germline and somatic mutation burden between *FANCA* and *FANCC* with head and neck and lung squamous cell carcinomas and *FANCI* and *SLX4/FANCP* with uterine cancer. Additionally, Chan et al. (2021) highlighted the differences in carrier frequencies in non-European populations, considering the fact that our knowledge about the clinical and genetic spectrum of FA is derived predominantly from populations of European ancestry. Consequently, "Given the variable distribution of germline pathogenic variant carriers across different ancestries, genetic testing for molecular diagnosis should not be restricted to *FANCA*, *FANCC*, and *FANCG*, which are reported more frequently in FA patients of European descent, but should include all known FA genes."

Alter et al. (2022) classified patients by age of diagnosis as part of a National Cancer Institute IBMFS cohort that included 178 pediatric patients and 26 adult patients. The authors were investigating whether FA cases could be distinguished and placed into subgroups by age diagnosed. The various features that were compared included the cumulative incidences of first adverse events (severe BMF leading to hematopoietic cell transplant or death, leukemia, or solid tumors) between an adult cohort and the pediatric cohort. The adult group did not consistently have the traditional FA features of birth defects, early-onset bone marrow failure or leukemia, and the group had more patients with the *FANCA* genotype. This adult group developed more head and neck squamous cell carcinoma and/or gynecological cancers (as compared to the pediatric group). The overall conclusion is Hematology and Oncology providers should investigate an FA diagnosis in adult patients that present with early-onset head and neck squamous cell carcinoma or gynecological cancer (with or without hematologic issues) (Alter et al., 2022).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG)

The guidelines for clinical genetics laboratories are specified in the 2018 (revised January 2021) edition of the ***Standards and Guidelines for Clinical Genetics Laboratories*** by the ACMG. The guidelines on FA state that:

- A cytogenetic evaluation for FA should include an induction of breakage with a crosslinking agent such as MMC or DEB (in addition to a baseline chromosome breakage).
- A well-established negative and positive control should be present and multiple cultures are recommended (if there is enough specimen available).
- At least 50 different cells (banded or unbanded) in the metaphase stage of the cell cycle should be analyzed, and the percentage of cells with aberration should reported (Kaiser-Rogers et al., 2021).

In 2021, ACMG released an updated guideline for screening for autosomal recessive and X-linked conditions during pregnancy and preconception. Their practice resource reviews aim to recommend "a consistent and equitable approach for offering carrier screening to all individuals during pregnancy and preconception" and replaces any earlier ACMG position statements on prenatal/preconception expanded carrier screening and provide the following recommendations:

- "Analytical validity of carrier screening is to be established by a laboratory in compliance with CLIA/CAP regulations and adhering to ACMG Laboratory Standards and Guidelines."
- "As evidence evolves, ClinVar and ClinGen continually update pathogenicity of variants and the association between genes and conditions, respectively."
- "Carrier screening enables those screened to consider their reproductive risks, reproductive options, and to make informed decisions."
- "Published evidence supports clinical utility for carrier screening of multiple conditions simultaneously."
- "The phrase 'expanded carrier screening' be replaced by 'carrier screening.'"
- "Adopting a more precise tiered system based on carrier frequency:
  - Tier 4: <1/200 carrier frequency (includes Tier 3) genes/condition will vary by lab
  - Tier 3: ≥ 1/200 carrier frequency (includes Tier 2) includes X-linked conditions
  - Tier 2: ≥1/100 carrier frequency (includes Tier 1)
  - Tier 1: CF [Cystic Fibrosis] + SMA [spinal muscular atrophy] + Risk Based Screening"

Fanconi anemia falls into Tier 2 carrier screening, according to the ACMG recommendation. For purposes of Fanconi anemia screening, this policy focuses on Tier 2 and Tier 3 carrier screening (as Tier 3 is inclusive of Tier 2). ACMG recommends

that

- "Tier 2 carrier screening stems from an ACOG recommendation for conditions that have a severe or moderate phenotype and a carrier frequency of at least 1/100." However, "data demonstrate that carrier screening for two common conditions using a carrier frequency threshold of 1/100 may not be equitable across diverse populations. Others have shown that limiting the carrier frequency to ≥1/100 creates missed opportunities to identify couples at risk for serious conditions."
- "We define Tier 3 screening as carrier screening for conditions with a carrier frequency ≥1/200 . . . Tier 2 and Tier 3 screening prioritize carrier frequency as a way to think about conditions most appropriate for screening in the general population. However, when ACOG proposed this level, they did not specify whether it was thinking about carrier frequency in terms of the global population or subpopulations. We use "carrier frequency" to mean in any ethnic group with reasonable representation in the United States."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening."
- ACMG does NOT recommend:
  - Offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups.
  - Routine offering of Tier 4 panels.
- "Carrier screening paradigms should be ethnic and population neutral and more inclusive of diverse populations to promote equity and inclusion."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening for autosomal recessive (Tables 1–5) and X-linked (Table 6) conditions."
- "Reproductive partners of pregnant patients and those planning a pregnancy may be offered Tier 3 carrier screening for autosomal recessive conditions (Tables 1–5) when carrier screening is performed simultaneously with their partner."
- "All XX patients should be offered screening for only those X-linked genes listed in Table 6 as part of Tier 3 screening."
- "When Tier 1 or Tier 2 carrier screening was performed in a prior pregnancy, Tier 3 screening should be offered" (Gregg et al., 2021).

ACMG table 2 lists autosomal recessive genes for screening with carrier frequency and includes Fanconi anemia, complementation C , as reported below.

Table 2. Autosomal recessive genes for screening with carrier frequency <1/50 to ≥1/100.

OMIM gene	OMIM gene name	Maximum carrier frequency[a]	OMIM phenotype	Conditions

American College of Obstetricians and Gynecologists (ACOG) Committee Opinion on Carrier Screening for Genetic Conditions

In March 2017, ACOG issued a Committee Opinion on Carrier Screening for Genetic Conditions. Regarding Fanconi anemia, ACOG asserts the following:

"Fanconi anemia can be caused by mutations in at least 15 different genes, but 80–90% of cases are due to mutation in one of three genes: 1) *FANCA*, 2) *FANCC*, and 3) *FANCG*. Affected individuals can experience bone marrow failure; increased risk of cancer, including leukemia and solid tumors; and structural defects such as short stature, skin pigment changes, nervous system abnormalities (including central nervous system malformations), eye and ear malformations and hearing loss, skeletal abnormalities in particular affecting the thumb or forearms, gastrointestinal abnormalities (including effects on the oral cavity), and others. Of note, 25–40% of affected individuals do not have any physical abnormalities" (ACOG, 2017).

These ACOG guidelines were reaffirmed in 2023.

Second Pediatric Blood and Marrow Transplant Consortium International Conference on Late Effects after Pediatric HCT

Due to recent increase in survival following a hematopoietic cell transplant (HCT), the conference recommends continued screening and follow up with a wide variety of specialists, with focus on the late side-effects of HCT. The conference emphasizes the importance of screening for cancer due to the increased cumulative risk (Dietz et al., 2017).

The National Organization for Rare Disorders (NORD)

The National Organization for Rare Disorders has published several recommendations for testing patients with suspected FA. These recommendations state that "FA should be suspected and tested for in any infant born with the thumb and arm abnormalities described previously. Anyone developing aplastic anemia at any age should be tested for FA, even if no other defects are present. Any patient who develops squamous cell carcinoma of the head and neck, gastrointestinal or gynecologic system at an early age with or without a history of tobacco or alcohol use, should be tested for FA. Many FA patients show no other abnormalities. It is essential to test for FA before contemplating stem cell transplantation for aplastic anemia or treatment for cancer, as standard chemotherapy and radiation protocols may prove toxic to FA patients" (NORD, 2020).

"Complementation testing is usually done first in order to identify which FA gene is mutated. Sequence analysis of the appropriate gene can then be done to determine the specific mutation in that gene. If a mutation is not identified, deletion/duplication analysis is available clinically for the genes associated with FA. Targeted mutation analysis is available for the common Ashkenazi Jewish FANCC mutation" (NORD, 2020).

Cancer Care Ontario (CCO)

In December 2016, the CCO published recommendations for malignant hematology conditions. It is stated that patients aged <50 years with suspected aplastic anemia may be tested for FA via a peripheral blood chromosomal breakage analysis, such as the diepoxybutane test (DEB Test). However, "it would also be indicated to screen older patients if FA is clinically suspected. It is difficult to set an upper age limit for FA screening, as anecdotal cases have been diagnosed in the fifth decade (unpublished observations). Screen all patients who are transplant candidates and siblings of FA patients". An abdominal ultrasound scan and echocardiogram is also indicated in some instances as "an enlarged spleen and/or lymph nodes raise the possibility of a malignant haematological disorder as the cause of the pancytopenia. In younger patients, abnormal or anatomically displaced kidneys are features of FA" (CCO, 2016).

The National Comprehensive Cancer Network (NCCN)

As FA often results in higher incidence of cancers, the NCCN has noted some observations regarding this condition. In the guideline for Esophageal and Esophagogastric Junction Cancers, the NCCN stated that

"The genes involved in Fanconi anemia (FA) include FA complementation groups A–E, with FA-A (FANCA) located at 16q24.3; FA-B (FANCB), unknown; FA-C (FANCC) at 9q22.3; FA-D (FANCD) at 3p26–p22; and FA-E (FANCE), unknown. Mutations in FANCA and FANCC have been identified. Individuals are identified by pancytopenia and chromosome breakage and hematologic abnormalities, including anemia, bleeding, and easy bruising. Increased frequency of SCC of the esophagus as well as other squamous epithelium is observed. Karyotyping does not identify individuals with FA, but enhanced chromosome breakage with mitomycin C can identify homozygotes but not heterozygotes" (NCCN, 2024).

United Kingdom National Multidisciplinary Guidelines

These recommendations were specifically made in the context of head and neck cancers. The recommendations for Fanconi anemia (FA) are as follows:

- "FA patients should receive prophylactic vaccination against high-risk HPV virus.
- FA patients should have quarterly screening for head and neck squamous cell carcinoma and an aggressive biopsy policy…treatment for head and neck squamous cell carcinoma with surgery alone where possible".
- FA patients should follow up with a specialty Fanconi clinic (Shaw & Beasley, 2016).

U.S. Preventive Services Task Force (USPSTF)

No U.S. Preventive Services Task Force recommendations for genetic testing for FA have been identified. A search for "Fanconi" on the USPSTF website turned up no results on October 15, 2024.

Fanconi Anemia Research Fund (FARF)

In 2023, the Fanconi Anemia Research Fund updated their recommendations on testing and genetic counseling. For a patient suspected of having FA (FARF, 2023):

- "Any patient suspected of having FA should be referred to a hematologist and/or clinical geneticist or genetic counselor, who can arrange for diagnostic testing. As FA testing is highly specialized, particularly the evaluation of chromosome breakage in response to DNA damage, only laboratories with extensive

experience should undertake this testing."

- "The recommended testing procedures are outlined in the flow chart in Figure 1. The flow chart presents one potential algorithm for testing, starting with chromosome breakage testing and ending with genotyping. However, genetic testing has become increasingly utilized as a first-line diagnostic test, especially for newborns and pediatric patients with multiple congenital anomalies. Regardless of the order of testing, it is important that both chromosome breakage and germline genetic testing be performed to obtain a precise diagnosis in all persons with suspected FA."
- The gold-standard test for diagnosing Fanconi anemia (FA) is the chromosome breakage test using DNA crosslinking agents, specifically diepoxybutane (DEB). Mitomycin C (MMC) may also be used, but it has a higher potential for false-positive results. Dotted line: If chromosome breakage testing is unavailable, a diagnosis of FA can be directly confirmed by genetic testing. If peripheral blood testing is negative but clinical suspicion for FA remains high, the negative result may be a false negative because of somatic mosaicism in the peripheral blood. Therefore, repeat testing on fibroblasts cultured from a skin biopsy should be performed. If the chromosome breakage testing is positive, FA panel testing should be performed. If FA panel testing is negative, whole exome sequencing (WES) and/or research testing should be considered. In cases where chromosome breakage testing on both blood and skin cells is negative, referral for evaluation of conditions that overlap clinically with FA should be considered."
- "Following a positive chromosome breakage test, NGS panel testing for clinically relevant FANC genes should be offered as the next step. Clinical laboratories have evolved to offer two types of panel tests: dedicated panels (laboratory pre-selected genes associated with a patient's phenotype) and custom panels (self-selection of relevant genes from a large list of genes). When selecting a panel, it is important to consider whether the test has been designed to address variant hotspots and/or gene regions known to present reporting challenges. As an example, the FANCD2 gene has two pseudogenes that can complicate the accuracy and interpretation of test results. Because of rapidly evolving knowledge of FA, many laboratories have not yet added the more recently discovered FANC genes to their panels. Thus, most currently available panels evaluate only a subset of the 22 known FANC genes."
- "Following the diagnosis of FA, cytogenetic analysis of chromosomes in bone marrow cells should be performed using standard G-banding methodology. The goal of this analysis is to investigate for the presence of a clone with acquired chromosome abnormalities and, if present, to characterize the observed abnormalities. Identification of a clone, which involves the presence of the same numerical and/or structural chromosomal abnormalities in multiple cells, is an

indication of an abnormal hematologic process. The significance of cytogenetic findings must be interpreted within the context of the clinical findings, bone marrow morphologic findings from hematopathology examination, and immunophenotyping results."

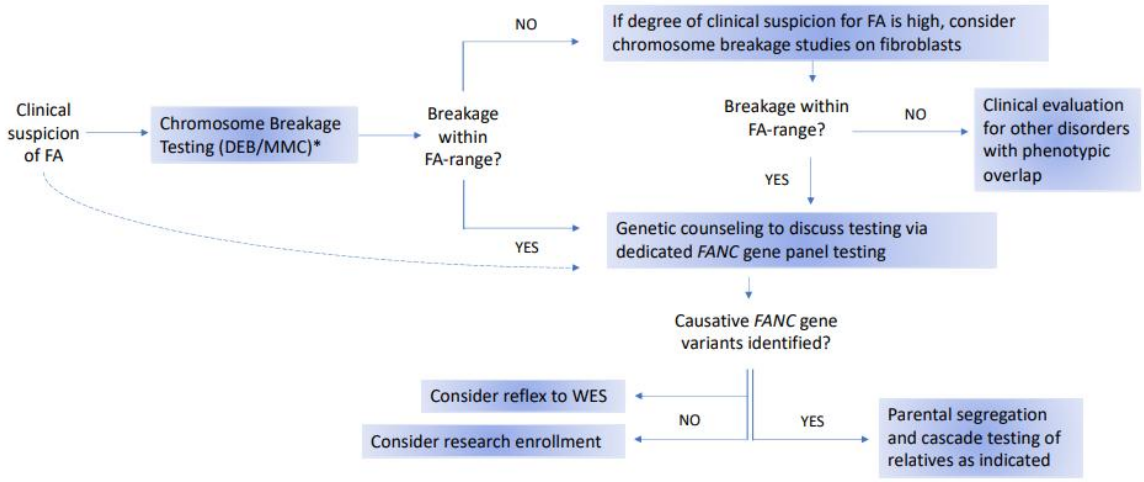

Figure 1: *Schematic representing a suggested algorithm for Fanconi anemia testing* (FARF, 2023).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81242	FANCC (Fanconi Anemia, complementation group C) (e.g.: Fanconi Anemia, type C) gene analysis, common variant (e.g.: IVS4+4A>T)
81412	Ashkenazi Jewish associated disorders (eg, Bloom syndrome, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia group C, Gaucher disease, Tay-Sachs disease), genomic sequence analysis panel, must include sequencing of at least 9 genes, including ASPA, BLM, CFTR, FANCC, GBA, HEXA, IKBKAP, MCOLN1, and SMPD1
81443	Genetic testing for severe inherited conditions (eg, cystic fibrosis, Ashkenazi Jewish-associated disorders [eg, Bloom syndrome, Canavan disease, Fanconi anemia type C, mucolipidosis type VI, Gaucher disease, Tay-Sachs disease], beta hemoglobinopathies, phenylketonuria, galactosemia), genomic sequence analysis panel, must include sequencing of at least 15 genes (eg, ACADM, ARSA, ASPA, ATP7B, BCKDHA, BCKDHB, BLM, CFTR, DHCR7, FANCC, G6PC, GAA, GALT, GBA, GBE1, HBB, HEXA, IKBKAP, MCOLN1, PAH)
88230	Tissue culture for non-neoplastic disorders; lymphocyte
88248	Chromosome analysis for breakage syndromes; baseline breakage, score 50-100 cells, count 20 cells, 2 karyotypes (eg, for ataxia telangiectasia, Fanconi anemia, fragile X)
88249	Chromosome analysis for breakage syndromes; score 100 cells, clastogen stress (eg, diepoxybutane, mitomycin C, ionizing radiation, UV radiation
88291	Cytogenetics and molecular cytogenetics, interpretation and report

Genetic Testing for *FMR1* Mutations

Policy Number: AHS – M2028 – Genetic Testing for *FMR1* Mutations	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Fragile X syndrome (FXS) is an X-linked disorder resulting from a loss of function mutation of the Fragile X Mental Retardation-1 (*FMR1*) gene (Saul & Tarleton, 1993); FXS is the most common cause of heritable intellectual disability (Coffee et al., 2009). *FMR1*-related disorders include FXS, fragile X-associated tremor/ataxia syndrome (FXTAS), and *FMR1*-related primary ovarian insufficiency (FRPOI). FXS results in a range of physical, cognitive, and behavioral effects of variable severity (Mila et al., 2016), generally characterized by moderate intellectual disability and autistic characteristics in affected males and mild intellectual disability and emotional and/or psychiatric problems in affected females (Mila et al., 2016; Monaghan et al., 2013).

Terms such as male and female are used when necessary to refer to sex assigned at birth. For guidance on prenatal or pre-conception screening for FXS, please see AHS-M2179-Prenatal Screening (Genetic).

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have received genetic counseling, diagnostic genetic testing for *FMR1* gene CGG repeats (including AGG interruption testing) and methylation status **MEETS COVERAGE CRITERIA** for any of the following conditions:
   a) For individuals with unexplained mental retardation, developmental delay, or autism spectrum disorder.
   b) For symptomatic individuals with features of Fragile X syndrome or a family history of Fragile X syndrome.
   c) For females with unexplained ovarian insufficiency, unexplained ovarian failure, or unexplained elevated FSH prior to 40 years of age.
   d) For individuals with unexplained late-onset tremor-ataxia.
   e) For fetuses and offspring of known *FMR1* premutation or full mutation carriers.
2) Genetic screening for *FMR1* gene CGG repeat length more than once per lifetime **DOES NOT MEET COVERAGE CRITERIA.**
3) Determination of *FMR1* gene point mutations **DOES NOT MEET COVERAGE CRITERIA**.
4) Determination of *FMR1* gene deletion **DOES NOT MEET COVERAGE CRITERIA**.
5) General population screening for Fragile X syndrome **DOES NOT MEET COVERAGE CRITERIA**.
6) Cytogenetic testing for Fragile X syndrome **DOES NOT MEET COVERAGE CRITERIA**.
7) Testing for the FMRP protein **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics and Genomics
ACOG	The American College of Obstetricians and Gynecologists
CCMG	Canadian College of Medical Geneticists
CI	Confidence interval
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid
CNS	Central nervous system
DBS	Dried blood spots
dTP-PCR	Triplet-primed polymerase chain reaction

EMQN	European Molecular Genetics Quality Network
FDA	Food and Drug Administration
FMR1	*Fragile X mental retardation-1*
FMRP	Protein encoded by *Fragile X mental retardation-1*
FRPOI	*Fragile X mental retardation-1*-Related Primary Ovarian Insufficiency
FSH	Follicle stimulating hormone
FXS	Fragile X syndrome
FXTAS	Fragile X-associated tremor/ataxia syndrome
LDT	Laboratory-developed test
mGluR	Metabotropic glutamate receptor 2
mRNA	Messenger ribonucleic acid
miRNA	Micro ribonucleic acid
MoMe	Methylation mosaic
MoMN	Mosaicism for full mutation and normal alleles
MoMP	Mosaic premutation and full mutation
mRNA	Messenger ribonucleic acid
NORD	National Organization for Rare Disorders\
PCR	Polymerase chain reaction
RNA	Ribonucleic acid
SB	Southern blotting
SNP	Single nucleotide polymorphisms
SOGC	Society of Obstetricians and Gynecologists of Canada

V. Scientific Background

Fragile X Syndrome (FXS) and related disorders affects about one in 4,000 males and one in 6,000 to 8,000 females in America (NORD, 2022). Transmitted as an X-linked dominant trait with reduced penetrance, FXS is associated with a fragile site on the X chromosome (Yu et al., 1991) identified as the *Fragile X Mental Retardation-1* (*FMR1*) gene (Santoro et al., 2012). More than 99% of patients with FXS have a mutation in this gene with over 200 CGG repeats and atypical methylation (NORD, 2022). The protein encoded by *FMR1* (FMRP) is a multifunctional RNA-binding protein that regulates the translation of a subset of dendritic mRNAs and plays a central role in neuronal development and synaptic plasticity (Antar et al., 2006; Ascano et al., 2012; Bechara et al., 2009; Castagnola et al., 2018; Didiot et al., 2008; Kenny et al., 2014; Parvin et al., 2018; Yang et al., 2018). The absence of FMRP results in excessive and persistent mGluR-mediated protein synthesis in postsynaptic dendrites, dysregulation of ion homeostasis, and disruption of calcium ion homeostasis leading to abnormal synaptic signaling and dendritic development (Bear et al., 2004; Castagnola et al., 2018;

Finucane et al., 2012). The typical clinical phenotype includes intellectual disability, social impairment, autism spectrum disorder, speech and language delay, neurological dysfunction (seizures and abnormal sleep patterns), sensory hypersensitivity (Rais et al., 2018), and a characteristic physical appearance that typically develops in the second decade of life (Hersh & Saul, 2011). Autism disorders are seen in approximately one third of FXS patients, affecting males more frequently than females (Ormazabal et al., 2019). Between 55 and 90% of patients with autism and FXS report gaze aversion, hand flapping, repetitive behaviors, reduced social interaction, anxiety, speech preservations, and aggressive behaviors (Reisinger et al., 2020).

Any genetic alteration that results in a lack of functional FMRP can cause FXS symptoms. The most common type of mutation of *FMR1* is the expansion of a CGG trinucleotide repeat in the 5′ untranslated region of the gene (Jin & Warren, 2000). Normally, this ranges in size from seven to about 60 repeats, with 30 being most common (Peprah, 2012). The full mutation consists of expansions of over 200 repeats which become abnormally hypermethylated, silencing the *FMR1* gene and expression of FMRP (Maurin et al., 2014; Oberle et al., 1991). Molecular clinical correlations have shown that the resulting phenotype is related to the degree of methylation and mosaicism rather than the number of repeats (Hersh & Saul, 2011).

Alleles with 55 to 200 CGG repeats are generally unmethylated with normal transcript and FMRP level; however, they are extremely unstable during transmission to the next generation and are referred to as premutations (Zafarullah et al., 2020). Although premutation carriers produce normal levels of FMRP, mRNA levels are elevated, causing toxic effects such as protein sequestration and mitochondrial dysfunction (Garcia-Arocena & Hagerman, 2010; Tassone et al., 2000). As a consequence, RNA toxicity leads to neuronal toxicity and a spectrum of premutation associated disorders such as primary ovarian insufficiency (FXPOI) (Rosario & Anderson, 2020) and tremor ataxia syndrome (FXTAS) (Zafarullah et al., 2020). An increased frequency of neurological, psychological, endocrine, and immune-related characteristics has been documented in premutation carriers (Hagerman & Hagerman, 2013; Raspa et al., 2018). Those with the premutation have higher rates of anxiety, depression, autistic traits, and physical health symptoms such as chronic fatigue and pain, fibromyalgia, and sleep disorders (Johnson et al., 2020).

It has been found that AGG interruptions (when an error in DNA replication results in an AGG interrupting the CGG repeat tract with *FMR1*) may affect the stability of the fragile X triplet repeat in a positive manner. The presence of an AGG interruption has been found to substantially impact the risk of a full mutation expansion from a given repeat length. There is an emerging role for AGG genotyping to "clarify the course of fragile X genetic diagnosis, counseling, and patient management" (Latham et al., 2014).

Others have also noted that the risk of unstable transmissions should be based on the presence or absence of AGG interruptions, not on the classical cutoffs which define the risk categories of *FMR1* alleles (Villate et al., 2020).

Analytical Validity

While many fragile X testing methods have been developed, no single approach can characterize all aspects of *FMR1* mutations and expansions, especially when mosaicism is taken into consideration (Monaghan et al., 2013). In a diagnostic setting, it is important to not only detect presence of the CGG expansion, but to also determine its size and methylation status (Lim et al., 2017). Molecular diagnostic testing of *FMR1* currently relies on a combination of polymerase chain reaction (PCR) and Southern blot (the gold standard) for the CGG repeat expansion and methylation analyses (Cai et al., 2019; Rajan-Babu & Chong, 2016). Detection of rare point mutations and deletions requires sequence analysis (Sitzmann et al., 2018; Suhl & Warren, 2015). This has limited the ability to implement any type of population screening (Riley & Wheeler, 2017).

CGG repeat-primed PCR designed to detect the full range of fragile X expanded alleles followed by analysis via capillary electrophoresis (Chen et al., 2010; Lyon et al., 2010) and melt curve techniques (Rajan-Babu et al., 2015; Teo et al., 2012) minimizes the need for Southern blot analysis. The FastFraX *FMR1* test was evaluated in 198 archived clinical samples, yielding results of 100% sensitivity (95% CI, 91.03% to 100%) and 100% specificity (95% CI, 97.64% to 100%) in categorizing patient samples into the respective normal, intermediate, premutation, and full mutation genotypes (Lim et al., 2017).

The triplet-primed PCR method (dTP-PCR) has been validated by comparison to Southern blot analysis for use in determining mutations in the *FMR1* gene; clinical performance was confirmed with 40 samples resulting in 100% sensitivity and 90.48% specificity in the detection of CGG repeats greater than 30 (Skrlec et al., 2018). This testing method may be utilized to screen a general population by quickly determining specific allelic changes in the *FMR1* gene (Skrlec et al., 2018).

Immunohistochemical detection of FMRP has been validated in lymphocytes and chorionic villi samples as an alternative prenatal diagnostic method for detection of full mutations in male fetuses; however, staining is more complex in female fetuses due to X-inactivation and is insufficient for diagnostic use (Oostra & Willemsen, 2001; Willemsen et al., 2002). Clinical and analytical specificity and sensitivity of cytogenetic analysis for FXS are both insufficient (Monaghan et al., 2013).

In a retrospective design, Ramos et al. (2020) studied the performance of the commercial FragileEase PCR kit for FXS diagnosis and compared it to Southern blotting (SB), PCR, and AmplideX FMR1 PCR. Ninety DNA samples were analyzed using FragileEase from patients with a clinical suspicion of FXS or a family history and was compare with the results from the other methods. Overall, FragileEase PCR kit had high concordance with the results from PCR, SB, and AmplideX. FragileEase was able to detect normal, intermediate/gray zone, premutation, and full mutation alleles along with female homozygosity and mosaicism. The authors conclude that "FragileEase™ PCR, as well as other commercially available kits, efficiently detect *FMR1* mutations and simplify the workflow in laboratories that performing FXS diagnoses" (Ramos et al., 2020).

Clinical Utility and Validity

As the clinical phenotype of FMR-related diseases can be subtle, its detection, especially in the prepubertal period, can be difficult. Although phenotypic symptoms are not obvious at birth, both animal and neuroimaging studies suggest that the effects of FXS begin in the prenatal period (Riley & Wheeler, 2017). Families report significant delays in diagnosis of FXS with 24% of families reporting that they had seen a healthcare provider more than ten times before testing. On average, caregivers or other individuals first report concern in regard to the child's development by 13 months; however, professional confirmation of a developmental delay did not occur until an average age of 21 months, and the FXS diagnosis did not occur until an average age of nearly 32 months. Meanwhile, many families had additional children with FXS before becoming aware of the reproductive risk (Bailey et al., 2003). Establishing a diagnosis of FXS allows for an understanding of the disorder and education on appropriate management strategies. Psychopharmacologic intervention to modify behavioral problems, such as attentional deficits, impulse control, anxiety, and emotional lability in a child with FXS can be important in addition to speech therapy, occupational therapy, special educational services, and behavioral interventions (Hersh & Saul, 2011). A recent pilot of allopregnanolone in six males with FXTAS showed significant improvement in GABA metabolism, oxidative stress, and some of the mitochondria-related outcomes (Napoli et al., 2018).

Huang et al. (2019) utilized a GC-rich PCR method to detect *FMR1* gene mutations in 30 pregnant woman who were known carriers of *FMR1* mutations or who contained *FMR1* gene deletion mosaicism; samples utilized chorionic villus, amniotic fluid, or umbilical blood samples. Southern blotting was used as a confirmatory measure. PCR results showed that 18 fetuses were normal, while others presented with full *FMR1* gene mutations, premutations, and/or mosaicism. Even with successful results, the

authors state that the use of a single detention method may not be sufficient in determining *FMR1* genetic mutations (Huang et al., 2019).

Lee et al. (2020) utilized a customized PCR and software system to detect the *FMR1* gene expansions from dried blood spots (DBS) and performed analytical validity studies to determine its accuracy, specificity, sensitivity, and precision to be used for newborn screening. The study investigated 963 newborn dried blood spots, which were studied by DNA extraction, *FMR1* PCR amplification, and capillary electrophoresis for automated CGG repeat analysis. While previous *FMR1* newborn screening assays were unsuitable for a routine laboratory setting, this fit-for-purpose FMR1 screening method provides a reliable method for newborn screening that is both cost effective and compatible with simple DBS elution methods already used in newborn screening laboratories. From the 963 DBS samples tested, 957 samples (99.4%) samples were classified as normal and six samples (0.6%) had premutation alleles with 55-76 CGG repeat expansions. Five out of the six premutation samples had one normal allele in addition to the premutation allele, while one out of the six had only one allele. Accuracy testing results were 100% concordance with reference genotypes with no false positive or false negative test results found. CGG expansions were consistently within six CGG repeats for larger expansions up to 200, within three CGG repeats for expansions up to 137, and within a single repeat for CGG expansions less than 80. However, the authors wrote that "further studies are required to identify if early screening of Fragile X syndrome would lead to better outcomes for the children, families, and society" (Lee et al., 2020).

Approximately twenty individuals have been reported with rare missense or nonsense mutations in the *FMR1* gene; also reported were other coding disturbances of the same gene resulting in physical, cognitive, and behavioral features similarly seen in FXS (Sitzmann et al., 2018). Studies of other FMR mutations that can affect the level and function of the protein include analysis of SNPs showing that 31.66 % of the *FMR1* gene SNPs were disease-related and that 50% of SNPs from online databases had a pathogenic effect (Tekcan, 2016). Screening of 508 males with clinical signs of mental retardation and developmental delay, but without CGG and GCC repeat expansions in the *FMR1* gene, revealed two missense mutations in the *FMR1* gene that would have not been diagnosed with standard molecular testing for FXS (Handt et al., 2014).

Cao et al. (2021) studied the clinical utility of screening *FMR1* gene mutations during early and middle pregnancy for those carrying high-risk CGG trinucleotide expansions. DNA samples from, 316 pregnant women at 12-21 gestational weeks were collected and analyzed for CGG repeats using fluorescence PCR and capillary electrophoresis. The carrier rate of CGG repeats was one in 178 for the intermediate type and one in

772 for the premutation types. The highest frequency allele of CGG was 29 repeats, which accounted for 49.29%, followed by 30 repeats (28.56%) and 36 repeats (8.83%). In one case of a premutation type of CGG expansion, the couple chose to terminate the pregnancy. The authors conclude that "pregnant women should be screened for *FMR1* gene mutations during early and middle pregnancy, and those with high-risk CGG expansions should undergo prenatal diagnosis, genetic counseling and family study" (Cao et al., 2021). Ramos et al. (2021) conducted a cross-sectional study on *FMR1* gene mutations in 52 Brazilian women diagnosed with primary ovarian insufficiency. The authors extracted genomic DNA and used FragileEase PCR kits to analyze CGG trinucleotide repeat expansions in the *FMR1* gene. In total, 3.8% of participants had *FMR1* mutations. The authors further concluded that "the most frequent CGG-repeat sizes were 28 and 30" (Ramos et al., 2021).

Fisher et al. (2021) studied the predisposition of carriers to a neurodegenerative disease called Fragile X-associated tremor/ataxia syndrome (FXTAS). FXTAS is caused by "expansions of the CGG repeats in the 5' upstream region of the FMR1 gene from the normal range" (Fisher et al., 2021) The authors noted that individuals in the premutation group showed CGG expansion sizes with a peak in the 80-99 repeat size range. The two groups in the study included 33 participants who were controls and 41 participants who were FMR1 premutation carriers. The authors were interested in the role of mitochondrial dysfunction and associated cellular-stress signaling in carriers versus healthy control subjects. Results confirmed "the elevation of AMPK and mitochondrial respiratory activities and reduction in reactive O_2 species (ROS) levels in premutation cells and revealed for the first time that target of rapamycin complex I (TORC1) activities are reduced" (Fisher et al., 2021). This study also confirmed findings of a previous study in which they reported significant elevation of mitochondrial respiratory functions in FMR1 premutation carriers.

Lindstrand et al. (2022) conducted a study comparing diagnostic methods in patients with intellectual disability and neurodevelopmental disorders using genome sequencing or chromosomal microarray with or without *FMR1* analysis. From the genomic sequencing tests, when using it first, the diagnostic yield was 35%, 26% for when genomic sequencing was second, and 11% for CMA with or without FMR1 analysis. They also identified that costs were higher with CMA/FMR1, and that the majority (91%) of those with a negative result from the CMA/FMR1 analysis remain undiagnosed of definitive intellectual disability or neurodevelopmental disorder. This demonstrated that genome testing may be superior to traditional CMA and FMR1 analysis as a first-line test for those with neurocognitive difficulties, thus rendering it a faster and more cost effective method that is worth further investigating (Lindstrand et al., 2022).

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG)

The American College of Medical Genetics and Genomics (ACMG) recommends FXS molecular genetic testing for:

"Fragile X syndrome:

- Individuals of either sex with mental retardation, developmental delay, or autism, especially if they have (a) any physical or behavioral characteristics of fragile X syndrome, (b) a family history of fragile X syndrome, or (c) male or female relatives with undiagnosed mental retardation.
- Individuals seeking reproductive counseling who have (a) a family history of fragile X syndrome or (b) a family history of undiagnosed mental retardation.
- Fetuses of known carrier mothers.
- Affected individuals or their relatives in the context of a positive cytogenetic fragile X test result who are seeking further counseling related to the risk of carrier status among themselves or their relatives. The cytogenetic test was used prior to the identification of the FMR1 gene and is significantly less accurate than the current DNA test. DNA testing on such individuals is warranted to accurately identify premutation carriers and to distinguish premutation from full mutation carrier women.

Ovarian dysfunction:

- Women who are experiencing reproductive or fertility problems associated with elevated follicle stimulating hormone (FSH) levels, especially if they have (a) a family history of premature ovarian failure, (b) a family history of fragile X syndrome, or (c) male or female relatives with undiagnosed mental retardation.

Tremor/ataxia syndrome:

- Men and women who are experiencing late onset intention tremor and cerebellar ataxia of unknown origin, especially if they have (a) a family history of movement disorders, (b) a family history of fragile X syndrome, or (c) male or female relatives with undiagnosed mental retardation" (Sherman et al., 2005).

The 2013 ACMG Fragile X testing standards and guidelines, with the American Congress of Obstetricians and Gynecologists, published the following indications for fragile X diagnostic testing and carrier detection:

- "The identification of a full mutation in a male is considered diagnostic rather than predictive, inasmuch as penetrance of fragile X syndrome is virtually 100% in males and the age of onset is not variable.
- The identification of a full mutation in a female may be diagnostic, but [over] 50% of females with full mutations have intellectual disability. They may, however, have some manifestations of the disease such as avoidance personality, mood, or stereotypic disorders. Nonrandom X inactivation may explain the milder phenotype in females, although the extent of symptoms cannot be determined by X-inactivation patterns from diagnostic tests that determine the expansion and methylation in blood.
- The identification of a premutation in an asymptomatic male or female undergoing carrier testing (e.g., due to a family history of intellectual disability) is predictive because FXPOI and FXTAS are not fully penetrant and are dependent on both age and allele size.
- All positive results should state that genetic counseling is recommended and testing is available for at-risk family members" (Monaghan et al., 2013).

In 2021, ACMG released an updated guideline for screening for autosomal recessive and X-linked conditions during pregnancy and pre-conception. Their practice resource aims to recommend "a consistent and equitable approach for offering carrier screening to all individuals during pregnancy and preconception" and replaces any earlier ACMG position statements on prenatal/preconception expanded carrier screening and provide the following recommendations:

- "Carrier screening enables those screened to consider their reproductive risks, reproductive options, and to make informed decisions."
- "The phrase "expanded carrier screening" be replaced by "carrier screening"."
- "Adopting a more precise tiered system based on carrier frequency:
  - Tier 4: <1/200 carrier frequency (includes Tier 3) genes/condition will vary by lab
  - Tier 3: ≥ 1/200 carrier frequency (includes Tier 2) includes X-linked conditions
  - Tier 2: ≥1/100 carrier frequency (includes Tier 1)
  - Tier 1: *CF* [Cystic Fibrosis] + *SMA* [spinal muscular atrophy] + Risk Based Screening
    - "Tier 1 screening conveys the recommendations previously adopted by ACMG and ACOG" and "adopts an ethnic and population neutral approach when screening for cystic fibrosis and spinal muscular atrophy. Beyond

these two conditions, additional carrier screening is determined after risk assessment, which incorporates personal medical and family history as well as laboratory and imaging information where appropriate".
    - "Tier 2 carrier screening stems from an ACOG recommendation for conditions that have a severe or moderate phenotype and a carrier frequency of at least 1/100." However, "data demonstrate that carrier screening for two common conditions using a carrier frequency threshold of 1/100 may not be equitable across diverse populations. Others have shown that limiting the carrier frequency to ≥1/100 creates missed opportunities to identify couples at risk for serious conditions."
    - "We define Tier 3 screening as carrier screening for conditions with a carrier frequency ≥1/200 . . . Tier 2 and Tier 3 screening prioritize carrier frequency as a way to think about conditions most appropriate for screening in the general population. However, when ACOG proposed this level, they did not specify whether it was thinking about carrier frequency in terms of the global population or subpopulations. We use "carrier frequency" to mean in any ethnic group with reasonable representation in the United States."
    - "Tier 4 includes genes less common than those in Tier 3 and can identify additional at-risk couples. Tier 4 has no lower limit carrier screening frequency and can greatly extend the number of conditions screened . . . the clinical validity at this level of carrier screening may be less compelling, therefore we suggest reserving this level of screening for consanguineous pregnancies (second cousins or closer) and in couples where family or medical history suggests Tier 4 screening might be beneficial . . . Importantly, patients should understand that their chance of being a carrier for one or more conditions increases as the number of conditions screened is increased."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening."
- Tier 4 screening should be considered:
    - When a pregnancy stems from a known or possible consanguineous relationship (second cousins or closer);
    - When a family or personal medical history warrants.
- ACMG does NOT recommend:
    - Offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups.
    - Routine offering of Tier 4 panels.
- "Carrier screening paradigms should be ethnic and population neutral and more inclusive of diverse populations to promote equity and inclusion."

- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening for … X-linked (Table 6) conditions."
- "All XX patients should be offered screening for only those X-linked genes listed in Table 6 as part of Tier 3 screening."
- "When Tier 1 or Tier 2 carrier screening was performed in a prior pregnancy, Tier 3 screening should be offered" (Gregg et al., 2021).

Table 6. X-linked genes recommended for carrier screening.

OMIM gene	OMIM gene name	OMIM phenotype	Phenotype
300371	*ABCD1*	300100	Adrenoleukodystrophy (ALD)
300806	*AFF2*	309548	Mental retardation, X-linked, associated with fragile site FRAXE
300382	*ARX*	308350	Developmental and epileptic encephalopathy 1 (DEE1)
300377	*DMD*	300376	Muscular dystrophy, Becker type (BMD)
		310200	Muscular dystrophy, Duchenne type (DMD)
306700	*F8*	300841	Hemophilia A (HEMA)
300746	*F9*	306900	Hemophilia B (HEMB)
309550	*FMR1*	300624	Fragile X syndrome (FXS)
300644	*GLA*	301500	Fabry disease
308840	*L1CAM*	307000	Hydrocephalus due to congenital stenosis of aqueduct of Sylvius (HSAS)
300552	*MID1*	300000	Opitz GBBB syndrome, type I (GBBB1)
300473	*NR0B1*	300200	Adrenal hypoplasia, congenital (AHC)
300461	*OTC*	311250	Ornithine transcarbamylase deficiency
300401	*PLP1*	312920	Spastic paraplegia 2, X-linked (SPG2)
312610	*RPGR*	300029	Retinitis pigmentosa 3 (RP3; RP)
		300455	Retinitis pigmentosa, X-linked, and sinorespiratory
		300834	Infections, with or without deafness
			Macular degeneration, X-linked atrophic
300839	*RS1*	312700	Retinoschisis 1, X-linked, juvenile (RS1)
300036	*SLC6A8*	300352	Cerebral creatine deficiency syndrome 1 (CCDS1)

Table six from (Gregg et al., 2021)

The American College of Obstetricians and Gynecologists (ACOG)

The American College of Obstetricians and Gynecologists (ACOG) published committee opinion 691 in 2017, that was reaffirmed in 2023 which recommends Fragile X premutation carrier screening for women with a family history of fragile X-related disorders or intellectual disability suggestive of fragile X syndrome and who are considering pregnancy or are currently pregnant (ACOG, 2017).

If a woman has unexplained ovarian insufficiency or failure or an elevated follicle stimulating hormone level before age 40 years, fragile X carrier screening is recommended to determine whether she has an *FMR1* premutation.

All identified individuals with intermediate results and carriers of a fragile X premutation or full mutation should be provided follow-up genetic counseling to

discuss the risk to their offspring of inheriting an expanded full mutation fragile X allele and to discuss fragile X-associated disorders (premature ovarian insufficiency and fragile X tremor/ataxia syndrome).

Prenatal diagnostic testing for FXS should be offered to known carriers of the fragile X premutation or full mutation (ACOG, 2017).

Society of Obstetricians and Gynecologists of Canada (SOGC) and Canadian College of Medical Geneticists (CCMG) Guidelines

Guidelines for FXS genetic testing were given in a joint statement from the SOGC and CCMG. It is stated that "Any woman with a personal or family history of Fragile X- or Fragile X mental retardation 1–related disorders; unexplained intellectual disability or developmental delay; autism; ovarian insufficiency with elevated follicle stimulating hormone at age < 40 years of unknown etiology; or any woman with a family history of male relatives with developmental delay, autism, or isolated cerebellar ataxia and tremor should be offered screening for this condition (II-2A) (GRADE moderate/moderate)" (Wilson et al., 2016). It is also stated that "Population carrier screening for Fragile X syndrome in all women of reproductive age cannot be recommended at this time (II-2D) (GRADE moderate/moderate)" and "Fragile X carrier testing must only occur after detailed genetic counselling and informed consent from the woman to be tested has been obtained (III-A) (GRADE low/moderate)" (Wilson et al., 2016). This statement has since been retired as of 2023. The most updated guidelines regarding prenatal screening for fetal aneuploidy, fetal anomalies, and adverse pregnancy outcomes as well as guidelines for using chromosomal microarray analysis for prenatal diagnosis and assessment of fetal loss from SOGC and CCMG do not make a direct mention of FXS genetic testing (Armour et al., 2018; Audibert et al., 2017)..

National Society of Genetic Counselors (NSGC)

The National Society of Genetic Counselors published guidelines, which recommend: "Centers offering population screening should ensure that they have the resources available to provide pre- and post-test genetic counseling that supports the psychosocial and clinical needs of the patient and family. In light of widespread *FMR1* testing among women without known risk factors, genetic counselors should anticipate seeing patients who did not receive any pre-test information, have no prior knowledge of *FMR1*-associated disorders, and are unprepared to learn that they have an *FMR1* mutation. Prenatal diagnosis should be offered to women with pre- or full mutations. Males with premutation alleles should receive genetic counseling about potential

phenotypic risks to their daughters, all of whom will inherit premutations" (Finucane et al., 2012).

American Academy of Pediatrics Committee on Genetics (AAP)

The American Academy of Pediatrics recommends testing for FXS in children with any of the following, particularly when associated with physical and behavioral characteristics of FXS or a relative with undiagnosed intellectual disability: developmental delay, borderline intellectual abilities or intellectual disability, or diagnosis of autism without a specific etiology (Hersh & Saul, 2011).

European Molecular Genetics Quality Network (EMQN)

The EMQN published their best practice guidelines concerning FXS and fragile X-associated disorders in 2015. They state, "Prenatal testing is not indicated for the pregnant partner of a male with a premutation." but they do recommend offering prenatal diagnosis to any woman with 55 or more CGG repeats; "Prenatal testing may be considered for a female fetus of a full mutation father as a cautionary measure (full mutation or MoMP [mosaic premutation and full mutation] or MoMe [methylation mosaic])." Concerning molecular diagnostic analysis in FXS and fragile X-associated disorders, they state the following:

"It is best practice to use a method which detects the whole range of expansions when testing relatives (including prenatal diagnosis) in a family with any known fragile X disorder due to expansion. When testing the FMR1 gene in population screening, the report must specify that rare cases of point mutation or deletion cannot be detected, nor rare cases of CGG expansion mosaicism (MoMN) if the method used cannot detect the whole range of expansions. It could be useful to confirm results by an independent method when detecting an expansion in an index case depending on specific pitfalls of each method" (Biancalana et al., 2015).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81243	FMR1 (fragile X mental retardation 1) (e.g., fragile X mental retardation) gene analysis; evaluation to detect abnormal (e.g., expanded) alleles
81244	FMR1 (fragile X mental retardation 1) (e.g., fragile X mental retardation) gene analysis; characterization of alleles (e.g., expanded size and promoter methylation status)

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Germline Variants of the RET Proto-Oncogene

Policy Number: AHS – M2078 – Genetic Testing for Germline Variants of the RET Proto-Oncogene	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

The rearranged during transfection (Elisei et al.) proto-oncogene encodes a transmembrane receptor tyrosine kinase (Takahashi et al., 1985) that regulates a complex network of signal transduction pathways during development, survival, proliferation, differentiation, and migration of the enteric nervous system progenitor cells (Hedayati et al., 2016). Disruption of RET signaling by mutation, gene rearrangement, overexpression or transcriptional up-regulation of the *RET* gene is implicated in several human cancers (Plaza-Menacho et al., 2014), most commonly thyroid cancer, but also chronic myelomonocytic leukemia, acute myeloid leukemia, and lung, breast, pancreatic, and colon cancers (Gordon et al., 2018). Mutation of the *RET* gene in a germline cell results in an autosomal dominant hereditary cancer syndrome, multiple endocrine neoplasia type 2 (MEN2). characterized by medullary thyroid carcinoma (MTC), pheochromocytoma (PHEO), and primary parathyroid hyperplasia (PPTH) (Figlioli et al., 2013).

This policy covers genetic testing for germline variants in the *RET* gene. For information on testing of tumors for *RET* variants for guiding chemotherapy, see AHS-M2030 Testing for Targeted Therapy of Non-Small-Cell Lung Cancer, AHS-M2108 Molecular Markers in Fine Needle Aspirates of the Thyroid, and AHS-M2171 Esophageal Pathology Testing.

II. Related Policies

Policy Number	Policy Title
AHS-M2030	Testing for Targeted Therapy of Non-Small-Cell Lung Cancer
AHS-M2108	Molecular Markers in Fine Needle Aspirates of the Thyroid
AHS-M2171	Esophageal Pathology Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic testing for *RET* proto-oncogene variants **MEETS COVERAGE CRITERIA** when any of the following conditions are met:
   a) For individuals who are a member of a family with defined *RET* gene mutations.
   b) For individuals who are a member of a family that is known to be affected by inherited medullary thyroid cancer but whose family has not previously been evaluated for *RET* mutations.
   c) For individuals who are a first-degree relative (see Note 1) of individuals with MTC.
   d) For individuals with a diagnosis of MTC, a clinical diagnosis of multiple endocrine neoplasia type 2 (MEN2), or primary C-cell hyperplasia.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For all other situations not discussed above, genetic testing for germline variants in the *RET* gene **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: First-degree relatives include parents, full siblings, and children of the individual.

IV. Table of Terminology

Term	Definition
A750T	Alanine-750-threonine
A883F	Alanine-883-phenylalanine
AKT	*AKT serine/threonine kinase 1*
ALK	*ALK receptor tyrosine kinase*
AMP	Association for Molecular Pathology
ATA	American Thyroid Association
BTA	British Thyroid Association
C634R	Cysteine-634-arginine

C634Y	Cystine-634-tyrosine
CAP	College of American Pathologists
CDKN2A	*Cyclin dependent kinase inhibitor 2A*
CLA	Cutaneous lichen amyloidosis
CLIA'88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
DNA	Deoxyribonucleic acid
EGFR	*Epidermal growth factor receptor*
ESMO	European Society for Medical Oncology
ETA	European Thyroid Association
FDA	Food and Drug Administration
FFPE	Formalin-fixed, paraffin-embedded
FISH	Fluorescent in situ hybridization
FLT3	*Fms related receptor tyrosine kinase 3*
FMTC	Familial medullary thyroid carcinoma
HD	Hirschsprung disease
HPTH	Primary hyperparathyroidism
HSCR	Hirschsprung's disease
IASLC	International Association for the Study of Lung Cancer
IHC	Immunohistochemistry
L790F	Leucine-790-phenylalanine
LDTs	Laboratory developed tests
M918T	Methionine-918-threonine
MAPK	*Mitogen-activated protein kinase*
MEN	Multiple endocrine neoplasia
MEN2	Multiple endocrine neoplasia type 2
MEN2A	Multiple endocrine neoplasia type 2A
MEN2B	Multiple endocrine neoplasia type 2B
MTC	Medullary thyroid carcinoma
NAT2	*N-acetyltransferase 2*
NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
NHS	National Health Services
NSCLC	Non-small cell lung cancer
PTH	Parathyroid hyperplasia
PHEO	Pheochromocytoma
PPTH	Primary parathyroid hyperplasia
QOE	Quality of evidence
Q-PCR	Quantitative polymerase chain reaction

R387Q	Arginine-387-glutamine
R693H	Arginine-693-histidine
RET	Rearranged during transfection
ROS1	*ROS proto-oncogene 1, receptor tyrosine kinase*
RT-PCR	Real-time polymerase chain reaction
SNP	Single nucleotide polymorphism
SOR	Strength of recommendation
V292M	Valine-292-methionine
V804M	Valine-804-methionine
VUS	Variants of unknown significance

V. Scientific Background

The *RET* gene encodes a receptor tyrosine kinase that transduces growth and differentiation signals from the glial cell-derived neurotrophic factor family of ligands (Saarma, 2001). *RET* is expressed in the neuroendocrine parafollicular C-cells of the thyroid gland, adrenal medulla, neurons, and other tissues (Takaya et al., 1996). Unlike loss of function mutations that inactivate tumor suppressor proteins, oncogenic *RET* mutations result in a gain-of-function, inducing ligand-independent autophosphorylation of the RET receptor (Santoro et al., 1995), uncontrolled activation of MAPK and phosphoinositide 3-kinase pathways, and ultimately uncontrolled growth and cell dedifferentiation (Hansford & Mulligan, 2000; Raue & Frank-Raue, 2018).

Oncogenic activation of the *RET* gene can result from either somatic or germline alterations. Activating germline point mutations in *RET* with autosomal dominant heritability have been identified as the primary initiating events causative of malignancy in C-cells of the thyroid gland (MTC) and other clinical presentations of MEN2 (Hansford & Mulligan, 2000; Mulligan, 2014). These mutations are identified in 98-100% of MEN2 cases (Raue & Frank-Raue, 2018; Romei et al., 2016), which are responsible for 25% of MTC cases overall (Raue & Frank-Raue, 2015). An estimated 64,000 individuals are diagnosed with thyroid cancer in the United States annually, and 1-2% of these cases are due to MTC. The most common alterations in the *RET* proto-oncogene are missense gain-of-function mutations mainly located in the extracellular domain of the *RET* gene (exons 10 or 11) and in the *RET* tyrosine kinase domain (exons 13, 14, 15 and 16) (ATA, 2016).

Germline *RET* mutations are associated with clear genotype-phenotype correlations (Plaza-Menacho et al., 2014). These clinical phenotypes can be divided into two subclasses of MEN2: multiple endocrine neoplasia type 2A (MEN2A) including familial medullary thyroid carcinoma (FMTC) and MEN type 2B (MEN2B) (Jasim et al., 2011). Over 100 *RET* point mutations, duplications, insertions, deletions, and fusions have

been identified in individuals with MEN2A, with the C634R mutation in exon 11 being the most common mutation, whereas only two *RET* mutations have been identified in individuals with MEN2B (mainly M918T, and rarely A883F) (Giani et al., 2020; Romei et al., 2018). New variants continue to be reported (Paragliola et al., 2018; Qi et al., 2018). For example, in a case study of a 7-year-old girl in Italy, a "de novo" new germline *RET* deletion in exon 11 was found to cause features of both MEN2B without PHEO (pheochromocytoma), but "with a pelvic plexiform neurofibroma and with HPTH (primary hyperparathyroidism), which is typical of MEN2A" (Giani et al., 2020).

The MEN2A subclass is characterized by MTC and variable rates of PHEO, PPTH or both, with *RET* mutations in codons 609, 611, 618, or 620 of exon 10 and codon 634 of exon 11. Subtypes of classical MEN2A include development of cutaneous lichen amyloidosis and Hirschsprung disease. Absence of any clinical finding other than MTC in at least four family members is classified as FMTC (Wells et al., 2015).

The MEN2B subclass is characterized by highly aggressive MTC, usually PHEO, but not PPTH, and may exhibit musculoskeletal abnormalities and developmental defects with *RET* mutations in codons 918 and 883 of exon 15 (Wells et al., 2015).

Figure 1: *RET* point mutations in MEN2A, MEN2B, and FMTC (Wells et al., 2013).

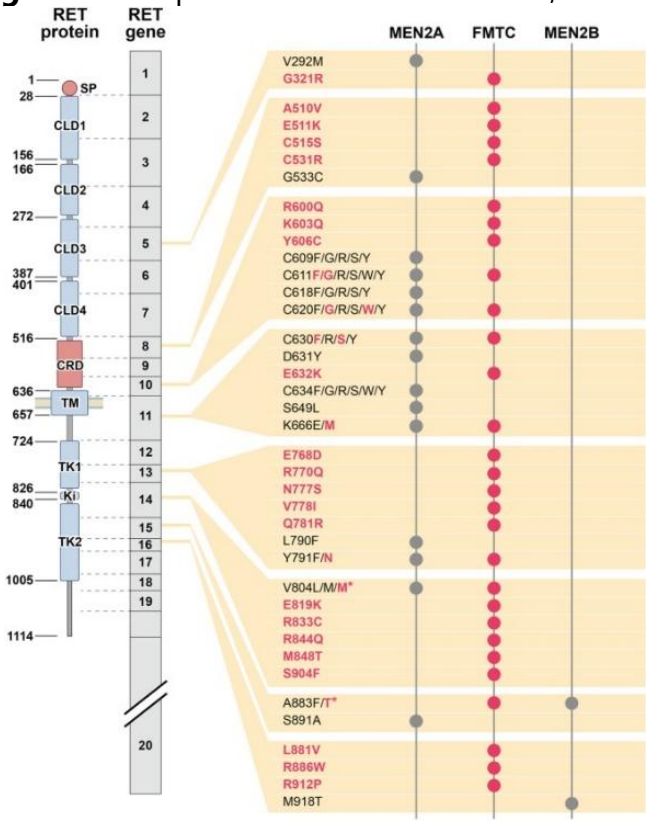

Table 1: Clinical expression of familial MTC-associated syndromes (Links et al., 2015).

	FMTC (%)	MEN2A (%)	MEN2B (%)
MTC	100	100	100
Pheochromocytoma	0	10-60	50
Hyperparathyroidism	0	10-30	0
Marfanoid habitus	0	0	100
Intestinal ganglioneuromatosis	0	0	60-90
Mucosal neuromas	0	0	70-100

Clinical Utility and Validity

The development of tyrosine kinase inhibitors that specifically target *RET* (Suyama & Iwase, 2018) has allowed for genetic analysis of *RET* germline mutations to become the standard of care in the initial workup for detecting germline mutations and familial risk and identifying targeted therapy in MTC (Ernani et al., 2016; Wells et al., 2015). Further, somatic *RET* rearrangements have recently been implicated in a variety of cancers, including chronic myelomonocytic leukemia; acute myeloid leukemia; and lung, breast, pancreatic, and colon cancers; an individual previously diagnosed with lung cancer underwent genomic profiling, and the identification of a *RET* point mutation associated with MTC allowed researchers to determine that this lung cancer diagnosis was incorrect (Gordon et al., 2018). A change in treatments proved to be very helpful for this individual. Other researchers have reported *RET* translocations in lung cancer cases, but they state that this is extremely rare (Zhao et al., 2016).

Guan et al. (2020) identified *RET* mutations in human epithelial ovarian cancer, providing another area of benefit from genetic testing of the *RET* gene for developing targeted therapies. Results showed that R693H and A750T mutants, in the juxtamembrane region and intracellular kinase domain, respectively, could promote the MAPK and AKT signaling pathway in ovarian cancer, and that the RET inhibitor vandetanib could decrease signal transduction and inhibit cancer growth (Guan et al., 2020).

Though activating variants in the receptor tyrosine kinase rearranged during transfection are known to be associated with MEN 2, not all variants are created equal. Hansen et al. (2021) explored the pathogenic role of the variant c.166C>A, p.Leu56Met in *RET*, which was identified in individuals presenting short segment HSCR and more recently in two individuals with MTC. Seven unrelated *RET* Leu56Met carriers from a Danish cohort were evaluated in the study, none of whom displayed evidence of MEN 2 or MTC based on the authors' predefined criteria for MEN2B ("(i) the individual demonstrates more than one MEN 2 manifestation, including histologically verified MTC, histologically verified pheochromocytoma, histologically verified gastrointestinal

or mucosal neuromas, histologically verified HSCR, biochemically verified PHPT, and clinically or histologically verified cutaneous lichen amyloidosis, or (Martins-Costa et al.) the individual has one MEN 2 manifestation and a relative with MTC and the RET Leu56Met variant"). Moreover, while known causative variants of MEN 2 such as p.Cys634Tyr and p.Met918Thr boast allele frequencies below 0.001%, the allele frequency for the Leu56Met variant computed from the in-house diagnostic cohort was much higher at 0.59%. These considerations, combined with the lack of family history for MEN 2, suggest that Leu56Met is "a common variant without clinical significance in the Danish population" and "is most likely a benign variant" (Hansen et al., 2021).

Researchers have also found in two *RET* L790F index individuals that somatic *RET* variants were not responsible for the early onset and aggressiveness of MTC in a *RET* germline mutation carrier. Normally, variations in MTC presentation could be attributed to *RET* germline variants (Mathiesen et al., 2020). However, Mathiesen et al. (2020) found an *FLT3* R387Q variant - FLT3 being a protein commonly found in hematopoietic malignancies - that could have been a genetic modifier instead.

The strong genotype-phenotype correlation of *RET* mutations makes genetic screening of significant value in diagnosis, prognosis, and management of MEN2 (Eng et al., 1996; Frank-Raue et al., 2010; Romei et al., 2015) and resultant MTC (Machens, Lorenz, et al., 2018), PHEO (Kimura et al., 2018), and PPTH. Each specific *RET* mutation correlates with MEN2 presentation, age at onset of MTC, and MTC aggressiveness (Brandi et al., 2001). Screening and early treatment of the manifestations of MEN2 can prevent metastasis of MTC and the morbidity and mortality caused by PHEO (Gagel et al., 1988; Makri et al., 2018). Moreover, screening has been associated with improved survivorship and outcomes (Raue et al., 2018). Based upon these genotype-phenotype correlations, *RET* mutations have been stratified into three risk levels based on the penetrance and aggressiveness of the MTC (Brandi et al., 2001; Wells et al., 2015). Consequently, mutation type should guide major management decisions, such as whether and when to perform thyroidectomy (Machens, Elwerr, et al., 2018; Machens, Lorenz, et al., 2018). Children in the highest risk category should undergo thyroidectomy in their first year of life, and perhaps even in their first months of life (Machens, Elwerr, et al., 2018; Machens, Lorenz, et al., 2018). Those with mutations in the high-risk category (codon 634 mutations) "should undergo thyroidectomy before reaching the age of 5 years" (Larouche et al., 2019). Annual biochemical screening in individuals with a family history of FMTC or MEN2 can also be stopped in those individuals who test negative for mutations (Wells et al., 2015).

Martins-Costa et al. (2018) performed *RET* genetic sequencing on exons 8, 10, 11, and 13-16 in 247 individuals with MTC or who are at risk of developing MTC due to family

history. Before genetic testing, 54 of the individuals were diagnosed with sporadic disease and six were diagnosed with hereditary disease; after genetic testing, 31 individuals were diagnosed with sporadic disease and 29 with hereditary disease (Martins-Costa et al., 2018). *RET* screening allowed several individuals to be classified as hereditary who were initially diagnosed with sporadic MTC; 73 at-risk relatives were identified as mutation carriers, which will assist in long-term life and reproductive decisions (Martins-Costa et al., 2018).

A meta-analysis consisting of 438 Indian individuals with MTC and 489 healthy controls of similar ages and genders was completed; all participants received molecular genetic testing including *RET* gene sequencing and SNP genotyping (Mishra et al., 2019). This study identified *RET* SNPs as a significant risk factor for developing hereditary MTC; *CDKN2A* and *NAT2* SNPs with a significant risk of developing sporadic MTC (Mishra et al., 2019).

Genetic screening for *RET* was also provided to a total of 2031 Italian subjects; this included 1264 individuals with sporadic MTC symptoms, 117 individuals with hereditary MTC symptoms, and 650 relatives (Elisei et al., 2019). The researchers state, "A *RET* germline mutation was found in 115/117 (98.3%) hereditary and in 78/1264 (6.2%) apparently sporadic cases: in total, 42 distinct germline variants were found" (Elisei et al., 2019). This thereby underscores the significance of genetic screening in unsuspected MEN2 families. Sporadic MTC cases were present most commonly with a V804M mutation, and all M918T mutations were *de novo* "and exclusively associated with MEN2B" (Elisei et al., 2019). These researchers also identified several variants of unknown significance (VUS).

A paper by Milićević et al. (2021) focused on examining the crude annual incidence rate of MTC and *RET* mutation frequency. The study involved Slovenian individuals at the Institute of Oncology Ljubljana from 1995 to 2015 and involved their family members who participated in genetic counseling and testing there. It was found that among 143 individuals with MTC, 37 (25.9%) harbored a germline *RET* mutation, and said mutations were uncovered in exons 10, 11, 13, 14, and 16. Also, the researchers noted that "*RET* germline mutations are quite commonly discovered even in the apparently sporadic form of the disease", such that 14.2% of individuals with a negative family history were presented with them. It was also reported that the most frequent *RET* germline mutations were found on codons 634 and 618 (30.0%) and exon 11 was the most frequently altered, though mutations of codons 790, 804, and 918 were observed in smaller but noticeable percentages (25.0%, 10.0%, and 5.0%, respectively). However, despite the low compliance of family members resulting in a smaller pool of participants, the authors extol the use of genetic counseling in this case, as "Annual incidence increase and nation-specific frequency of discovered *RET*

mutations justify the continuation of gene counseling and testing of MTC individuals in Slovenia" (Milićević et al., 2021).

A study by Fussey et al. (2021) aimed to lend their perspective on the diagnostic potential of *RET* genetic testing. Between 1997 and 2018, the Exeter Genomics Laboratory at the Royal Devon and Exeter NHS Foundation Trust collected information on 1058 index individuals with MTC and other MEN2-related clinical features. They found that in total, 92 of the 766 UK individuals with MTC were harboring a germline *RET* pathogenic variant, and that variants in 10, 11, and 14 comprised its bulk, with codons 634 in exon 11 and 804 in exon 14 being most often affected. As such, the researchers believe that "the use of somatic *RET* analysis to confirm the diagnosis of sporadic MTC in individuals with no identified germline RET variants may be a useful adjunct both in terms of reassuring family members about the lack of a heritable pathogenic germline variant, and risk-stratifying sporadic tumours based on somatic variants" (Fussey et al., 2021).

Genetic screening for *RET* could also disclose new variants with their respective phenotypes. Yang et al. (2020) described a compound C634Y/V292M transmutation in a northern Chinese family that was associated with a more aggressive clinical presentation. Carriers of this variant had bilateral MTC with PHEO or lymph node metastasis with faster cell growth (cell growth speed identified *in vitro*). On the other hand, carriers of the V292M variant were asymptomatic, and carriers of the C634Y mutation only had elevated calcitonin (Yang et al., 2020). This has demonstrated the striking variability in MTC clinical presentation based on *RET* gene variants, making it critical to aid in any future potential treatment regimen.

Though activating variants in the receptor tyrosine kinase rearranged during transfection are known to be associated with MEN 2, not all variants are created equal. Hansen et al. (2021) explored the pathogenic role of the variant c.166C>A, p.Leu56Met in *RET*, which was identified in individuals presenting short segment HSCR and more recently in two individuals with MTC. Seven unrelated *RET* Leu56Met carriers from a Danish cohort were evaluated in the study, none of whom displayed evidence of MEN 2 or MTC based on the authors' predefined criteria for MEN2B ("(i) the individual demonstrates more than one MEN 2 manifestation, including histologically verified MTC, histologically verified pheochromocytoma, histologically verified gastrointestinal or mucosal neuromas, histologically verified HSCR, biochemically verified PHPT, and clinically or histologically verified cutaneous lichen amyloidosis, or (Martins-Costa et al.) the individual has one MEN 2 manifestation and a relative with MTC and the RET Leu56Met variant"). Moreover, while known causative variants of MEN 2 such as p.Cys634Tyr and p.Met918Thr boast allele frequencies below 0.001%, the allele frequency for the Leu56Met variant computed from the in-house diagnostic cohort

was much higher at 0.59%. These considerations, combined with the lack of family history for MEN 2, suggest that Leu56Met is "a common variant without clinical significance in the Danish population" and "is most likely a benign variant" (Hansen et al., 2021).

Bhandari et al. (2023) studied the testing patterns for *RET* in the United States for people with advanced or metastatic medullary thyroid cancer. The authors completed a retrospective analysis of 203 individuals being cared for by 75 oncologists. Here, "A total of 59.6% (121 of 203) of patients underwent testing for RET, and 37.2% (45 of 121) had a RET mutation, of which 55.6% were identified as RET mutation-positive before initial diagnosis." The authors also note that "90 (44.3%) patients were tested for biomarkers on or after initial diagnosis, with RET being the most tested (95.6%) biomarker." The authors conclude that there is opportunity to improve testing rates (Bhandari et al., 2023).

VI. Guidelines and Recommendations

European Society for Medical Oncology (ESMO)

The ESMO has published clinical practice guidelines on diagnosis, treatment, and follow-up of thyroid cancer, stating that "All patients with MTC should be offered genetic counselling and screened for germline *RET* mutations" (Filetti et al., 2020). Filetti et al. (2020) also stated that "screening for somatic *RET* mutations is only recommended if *RET* inhibitor therapy is planned."

In 2021, ESMO Translational Research and Precision Medicine Working Group expanded upon the algorithm to identify individuals eligible for anti-RET therapy across three scenarios based on the malignancies. The recommendations are captured below:

"Scenario A: Patients affected by NSCLC, non-MTC or other solid tumours, with available formalin-fixed, paraffin-embedded (FFPE) specimen need to be screened for detection of RET fusion. If NGS is not available, FISH or RT-PCR is indicated in NSCLC and non-MTC, depending on local availability, cost and/or amount of tumour cells. In case of a negative test result, it is recommended to perform an NGS panel. It should be noted, however, that the recent ESMO recommendations suggest using multigene NGS to assess NSCLC level I alterations, including *RET* fusions.

In addition to *RET* fusion testing, patients affected by other solid tumours may need to be tested also for *RET* mutation according to the results of pending clinical trials. This

can be done preferably by NGS; if this is not available, Q-PCR can be used. In none of the above cases is RET IHC testing recommended.

Scenario B: For patients affected by NSCLC, non-MTC or other solid tumours whose FFPE specimens are not available or are exhausted, we suggest performing a liquid biopsy (cell-free nucleic acid NGS panel) to test for *RET* alteration.

It is important to notice that if an *RET* alteration is not detected by liquid biopsy, then tumour tissue testing is still required to definitively exclude the possibility of an RET fusion.

Scenario C: Patients affected by MTC need to be screened for detection of *RET* mutation. They should be referred to genetic counselling in order to study the presence of MEN syndrome or FMTC. Mutations in the RET gene, in fact, are canonical in hereditary MTC, but can be found also in sporadic MTC. A Q-PCR or NGS can be carried out on sputum or blood of the patient. In case of known familial *RET* mutation, a simple Sanger test can be carried out on blood leukocyte DNA. If a germline *RET* mutation is present, family counselling is indicated. In case of absence of germline *RET* mutations, if the patient with MTC becomes metastatic, a Q-PCR of NGS analysis on FFPE tissue specimens from metastatic site of disease should be carried out in order to confirm or reject the presence of this alteration.

In none of the above cases is RET IHC testing recommended" (Belli et al., 2021).

American Thyroid Association (ATA)

The ATA published revised guidelines (Wells et al., 2015) which state that:

- "Initial testing for patients with MEN2A phenotype is either a single or multi-tiered analysis to detect *RET* mutations in exon 10 (codons 609, 611, 618, and 620), exon 11 (codons 630 and 634), and exons 8, 13, 14, 15, and 16. Grade B Recommendation"
- Initial testing for patients with MEN2B phenotype should be tested for the *RET* codon M918T mutation (exon 16), and if negative, the *RET* codon A883F mutation (exon 15).
- "Sequencing of the entire coding region should be reserved for situations in which no *RET* mutation is identified or there is a discrepancy between the MEN2 phenotype and the expected genotype. Grade B Recommendation
- Patients with the MEN2B phenotype should be tested for the *RET* codon M918T mutation (exon 16), and if negative, the *RET* codon A883F mutation (exon 15). If

there are no mutations identified in these two exons the entire RET coding region should be sequenced. Grade B Recommendation

- Patients with presumed sporadic MTC should have genetic testing to detect a germline *RET* mutation. If a *RET* mutation is found the patient should have genetic testing. Grade B Recommendation
- In very rare families who meet the clinical criteria for MEN2A or 2B, despite negative sequencing of the entire *RET* coding region, the relatives at risk should be periodically screened by conventional methods for MTC, PHEO, and HPTH. After the initial evaluation, screening should continue at 1- to 3-year intervals. Grade C Recommendation
- Genetic counseling and genetic testing for *RET* germline mutations should be offered to
    - First-degree relatives of patients with proven hereditary MTC,
    - Parents whose infants or young children have the classic phenotype of MEN2B,
    - Patients with CLA [cutaneous lichen amyloidosis], and
    - Infants or young children with HD and exon 10 *RET* germline mutations, and adults with MEN2A and exon 10 mutations who have symptoms suggestive of HD" (Wells et al., 2015).

National Comprehensive Cancer Network (NCCN)

NCCN guidelines for neuroendocrine and adrenal tumors (NCCN, 2024b) recommends that for diagnosis of or clinical suspicion of MEN2, genetic counseling and *RET* genetic testing should be offered in the following cases:

- "Individuals with MTC or primary C-cell hyperplasia or a clinical diagnosis of MEN2."
- "At-risk relative of an individual with a known germline *RET* mutation at a very young age."
- "All patients with MTC should be tested for germline mutation of the *RET* oncogene even if the family history is not suggestive of a hereditary syndrome, because about 50% of patients with presumed sporadic MTC have a *de novo* germline mutation" (NCCN, 2024b).

NCCN Guidelines for Thyroid Carcinoma (NCCN, 2024c) stated that as part of the additional workup after medullary thyroid carcinoma is identified by initial thyroid surgery, a "Screen for germline *RET PV* (exons 10, 11, 13-16); genetic counseling may be indicated" and "Germline mutation should prompt specific mutation testing in subsequent family members and genetic counseling" (NCCN, 2024c).

The FDA has approved several targeted therapeutic agents for use in esophageal and EGJ cancers. NCCN guidelines for Esophageal and Esophagogastric Junction Cancers (NCCN, 2024a) lists *RET* gene fusion as a targeted biomarker for NGS. "Immunohistochemistry/in situ hybridization/targeted PCR should be considered first for the identification of biomarkers, followed by NGS testing" (NCCN, 2024a).

The College of American Pathologists (CAP), the International Association for the Study of Lung Cancer (IASLC), and the Association for Molecular Pathology (AMP)

The 2013 guidelines from CAP, IASLC and AMP for molecular testing in lung cancer individuals have been updated in 2018; new recommendations state that *RET* testing is approved in lung cancer specimens "as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative" because "*RET* molecular testing is not recommended as a routine stand-alone assay outside the context of a clinical trial" (Lindeman et al., 2018).

The British Thyroid Association (BTA)

Regarding MTC, the BTA has stated that "In all confirmed cased of MTC, *RET* mutation analysis to establish the possible genetic basis for the disease within an individual or kindred, should be performed even in the absence of a positive family history." Other key recommendations to consider before genetic testing are listed below.

- "Because of the possibility of heritable disease, every case of MTC should be offered genetic testing"
- "Testing should always begin with the affected individual, if they are available"
- "If the affected individual is not available, the decision and strategy for testing should be discussed with the clinical genetics service"
- "Before blood is taken, a clear explanation must be given of the nature of the test, the possible outcomes, and of the implications of a positive or negative result for the individual and the family. This explanation should be recorded in the case notes for each individual" (Perros et al., 2014).

European Thyroid Association (Giani et al.)

The ETA Executive Committee in 2012 issued guidelines specifically devoted to *RET* genetic screening for individuals affected by MTC with reference to three different phenotypes: multiple endocrine neoplasia types 2A and 2B and familial MTC (FMTC) (Elisei et al., 2013). In their attempt to improve the quality of care for individuals and

families with MTC, they made recommendations with varying valences, grading their own recommendations by the quality of evidence (QOE), which is indicated by plus signs at three levels, and the strength of recommendation (SOR) score, indicated by a 1 (strong recommendation for or against) or a 2 (" weak recommendation or a suggestion that may not be appropriate for every patient, depending on the context, patient values, and preferences"). The relevant parts of the guidelines are

From Recommendation 4:

> "(a) Exons 5, 8, 10, 11, 13, 14, 15, and 16 should always be analyzed starting from the most likely involved in the presenting syndrome (i.e. exon 10 in MEN 2A, exon 16 in MEN 2B, etc.). DNA from MTC individuals with a strong suggestion of familial disease should also be analyzed for all other uncommonly mutated exons when those listed above are negative… (QOE = +++; SOR = score 1)."
> (b) Subjects belonging to the few families (2–5% of all MEN 2/FMTC families) with clinically evident MEN 2/FMTC features but lacking evidence of an associated germline *RET* mutation should be followed up annually by measurement of basal serum Ct, metanephrines, calcium, and PTH. Neck and abdomen ultrasound could also be useful although not absolutely required if biochemical tests are still negative (QOE = ++; SOR = score 1).
> (c) Once a germline *RET* mutation has been identified, all first-degree relatives and other relevant family members should be screened for the specific causative mutation (QOE = +++; SOR = score 1).
> (d) Once a germline *RET* mutation has been discovered, further sequencing adds little, although some cases of double or triple RET mutations have been reported. These peculiar cases would likely be missed if RET screening was stopped when the first mutation was identified. The completeness of RET gene analysis is particularly indicated when the first identified mutation is rare and with a low or null transforming ability. These rare cases should be referred to specialized tertiary centers for a complete characterization of the mutation and its relationship with the disease (QOE = ++; SOR = score 2).
> (e) Family members negative for the mutation are not at risk for the development of MTC and their children are not at risk either. Such individuals should be reassured and do not require further investigation or follow-up (QOE = +++; SOR = score 1)" (Elisei et al., 2013).

From Recommendation 5:

"(a) All patients with either apparently sporadic or familial MTC should be screened for germline *RET* mutations (QOE = +++; SOR = score 1)."

From Recommendation 6:

"(a) Patients with bilateral PHEO [pheochromocytoma] should be considered for RET genetic screening when other MEN 2A endocrinopathies (MTC and/or PHPT [primary hyperparathyroidism]) or CLA are present in the same subject or if a family history of MEN 2A or 2B is present. The screening becomes mandatory if the basal serum Ct is above the normal range, independently of the presence of other MEN 2A endocrinopathies (QOE = ++; SOR = score 1).
(b) Patients with multiple adenomatosis of the parathyroid glands and PHPT should be considered for RET genetic screening if other MEN 2A endocrinopathies (MTC and/or PHEO) or CLA are present in the same subject or if a family history of MEN 2A is present. Also in this case, RET genetic screening must be performed if basal serum Ct levels are above the normal range, even if no other MEN 2A endocrinopathies are diagnosed (QOE = ++; SOR = score 1).
(c) Subjects with CLA should be investigated clinically and should undergo genetic testing for MEN 2A. In particular RET codon 634 in exon 11 should be analyzed (QOE = +++; SOR = score 1).
(d) Patients with Hirschsprung disease should have RET genetic screening for mutations involved in Hirschsprung disease, but analyses performed specifically to investigate an association with MEN 2 should be limited to exon 10 (QOE = +++; SOR = score 1)" (Elisei et al., 2013).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and

Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81404	Molecular pathology procedure, Level 5 Gene: ***RET*** (ret proto-oncogene) (eg, multiple endocrine neoplasia, type 2B and familial medullary thyroid carcinoma), common variants (eg, M918T, 2647_2648delinsTT, A883F)
81405	Molecular pathology procedure, Level 6 Gene: ***RET*** (ret proto-oncogene) (eg, multiple endocrine neoplasia, type 2A and familial medullary thyroid carcinoma), targeted sequence analysis (eg, exons 10, 11, 13-16)
81406	Molecular pathology procedure, Level 7 Gene: ***MUTYH*** (mutY homolog [E.coli]) (eg, MYH-associated polyposis), full gene sequence
S3840	DNA analysis for germline mutations of the ret proto-oncogene for susceptibility to multiple endocrine neoplasia type 2

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Hereditary Hearing Loss

Policy Number: AHS - G2148 – Genetic Testing for Hereditary Hearing Loss	Prior Policy Name and Number, as applicable: • AHS-G2148 Genetic Testing for Nonsyndromic Hereditary Hearing Loss
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Hearing loss is among the most etiologically heterogeneous disorders. More than 400 genetic syndromes include hearing loss as a feature; additionally, more than 100 genes are associated with nonsyndromic genetic hearing loss, and several non-genetic causes can also result in hearing loss. Genes associated with syndromic and nonsyndromic genetic hearing loss encode a variety of proteins involved in the development and function of the auditory system, including transcription factors, structural proteins, gap junction proteins, and ion channel (Alford et al., 2014). The genes may be associated with an autosomal dominant, autosomal recessive, X-linked, or mitochondrial inheritance pattern (A Eliot Shearer, 2017). Genetic counseling is strongly recommended for individuals pursuing genetic testing for nonsyndromic hereditary hearing loss.

For guidance on prenatal screening and preconception screening for hereditary hearing loss, please see AHS-M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who are in a family with a deleterious familial hearing loss gene mutation, the following genetic testing **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial mutation.
   b) Comprehensive genetic testing using multi-gene panel testing when the specific familial mutation is unknown.

2) For individuals diagnosed with hearing loss (when hearing loss due to nonhereditary causes [e.g., infection, injury, age-related] has been excluded), multi-gene panel testing (panel must include *GJB2* and *GJB6*) **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) Genetic testing for hereditary hearing loss-related mutations more than once per lifetime **DOES NOT MEET COVERAGE CRITERIA**.

4) For all other situations not described above, genetic testing for hearing loss **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AAO	American Academy of Otolaryngology
AAP	American Academy of Pediatrics
ACMG	American College of Medical Genetics and Genomics
ACTG1	*Actin gamma 1*
ANSD	Auditory neuropathy spectrum disorder

ASHA	American Speech-Language-Hearing Association
BSND	*Barttin CLCNK type accessory subunit beta*
CDH23	*Cadherin related 23*
CLDN14	*Claudin 14*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CLRN1	*Clarin 1*
CMS	Centers For Medicare and Medicaid
CMV	Cytomegalovirus
CNV	Contingent negative variation
COCH	*Cochlin*
COL11A2	*Collagen type Xl alpha 2 chain*
DFN	Different gene loci for nonsyndromic deafness
DFNA	Autosomal dominant inherited deafness
DFNA5	*Nonsyndromic hearing impairment protein 5*
DFNB	Autosomal recessive inherited deafness
DFNB1	*Nonsyndromic hearing loss and deafness*
DFNB31	*Deafness autosomal recessive 31 - Whirlin*
DFNB59	*Deafness autosomal recessive 59*
DFNX	X-linked Inheritance
DNA	*Deoxyribonucleic acid*
EKG	Electrocardiogram
ESPN	*Espin*
ESRRB	*Estrogen related receptor beta*
EYA4	*Transcriptional coactivator and phosphatase 4*
FDA	Food And Drug Administration
GJB2	Gap junction protein, beta 2
GJB6	Gap junction protein, beta 6
GPR98	*G-protein coupled receptor 98*
GRXCR1	*Glutaredoxin and cysteine rich domain containing 1*
HGF	*Hepatocyte growth factor*
IPOG	International Pediatric Otolaryngology Group

V. Scientific Background

Approximately one in every 500 children born in the United States is deaf or has a hearing loss significant enough to affect speech and language development. Ninety-five percent of newborns with hearing loss identified by newborn hearing screening programs are born to hearing parents, obscuring the fact that most newborns have a hereditary cause for their hearing loss (Alford et al., 2014). Approximately 80 percent of

cases of hereditary hearing loss are inherited in an autosomal recessive pattern, 19 percent are autosomal dominant, and the remaining cases X-linked (mainly recessive) or mitochondrial (A Eliot Shearer, 2017).

Hearing loss is typically described in terms related to its clinical presentation. In general, it is categorized as either syndromic or nonsyndromic. Syndromic hearing loss is associated with other medical or physical findings, including malformations of the external ear or other organs, or with medical problems involving other organ systems. An estimated 30% of hereditary hearing loss is syndromic. Nonsyndromic hearing loss (NSHL) is defined as hearing loss that is not associated with visible abnormalities of the external ear or any related medical problems. For NSHL, it is more difficult to determine whether the etiology is hereditary or acquired because there are no other clinical manifestations at the time of the hearing loss presentation. NSHL accounts for an estimated 70% of genetically determined hearing loss (Angeli et al., 2012), and it is frequently congenital and sensorineural (Sloan-Heggen et al., 2016).

The genetic loci where mutations associated with nonsyndromic hereditary hearing loss are commonly found are termed DFN. DFN loci are named based on their mode of inheritance: DFNA associated with autosomal dominant inheritance; DFNB with autosomal recessive inheritance; and DFNX with x-linked inheritance (A Eliot Shearer, 2017). The DFNB1 locus, which includes the *GJB2* gene encoding the gap junction protein connexin 26 and the *GJB6* gene encoding the gap junction protein connexin 30, accounts for an estimated 50% of all autosomal recessive nonsyndromic hearing loss and 15–40% of all deaf individuals in a variety of populations (Alford et al., 2014).

GJB2 is a small gene with a single coding exon, which codes for the Cx26 connexin protein (OMIM, 2016). At least 83 deafness-causing variants have been identified in *GJB2*, but a few common mutations account for a large percentage of alleles in several populations. Probands with this mutation generally have congenital hearing loss (A Eliot Shearer, 2017). Mutations in the *GJB6* gene lead to similar effects on abnormal expression of connexin protein Cx30 (OMIM, 2014). *GJB6* deletions have been observed in multiple populations, although they appear to be a relatively uncommon explanation for hearing loss in the United States (Alford et al., 2014).

In addition to mutations in the *GJB6* and *GJB2* genes, many less common pathologic mutations are found in other genes. Some of these are: *ACTG1, BSND, CDH23, CLDN14, COCH, COL11A2, DFNA5, DFNB31, DFNB59, ESPN, ESRRB, EYA4, GRXCR1, HGF, KCNQ4, LHFPL5, MARVELD2, MT-TS1, MYO15A, MYO6, MYO7A, OTOA, OTOF, PCDH15, POU3F4, PTPRQ, RDX, SLC26A4, STRC, TECTA, TMC1, TMIE, TMPRSS3, TRIOBP, USH1C, WFS1*, and *WHRN* genes (A Eliot Shearer, 2017). Several gene panels exist for assessment of hereditary hearing loss. For example, Shang et al evaluated the

"MiamiOtoGenes" panel, which consists of 180 genes. The investigators examined five unrelated probands with varying degrees of hearing loss onset and severity and found seven different genetic variants (Shang et al., 2018). Other entities offering proprietary genetic panels include BluePrint (239 genes), GeneDx (146 genes), OtoSCOPE by the University of Iowa (152 genes), Otogenetics Gx (167 genes), OtoGenome™ Test (84 genes), Hearing Loss Advanced Sequencing and CNV Evaluation by Athena Diagnostics (183 genes), Invitae Comprehensive Deaf Panel (203 genes), and AudioloGene Hereditary Hearing Loss Panel by Mayo Clinic Laboratories (160 genes) (BluePrint, 2023; GeneDx, 2024; Invitae, 2024; Iowa, 2020; Mayo Clinic, 2024; Otogenetics, 2021; Partners Healthcare, 2021).

Clinical Utility and Validity

Shearer and Smith (2015) performed a meta-analysis focusing on the current genetic tests used to evaluate hearing loss. A total of 20 studies were included, containing 426 controls and 603 patients with idiopathic hearing loss. Several genetic panels such as OtoGenetics Deafness Test and OtoGenome™ were used. Overall, the controls showed good sensitivity and specificity (over 99%), and the diagnostic rate was found to be 41% (with a range of 10%-83%). The authors concluded that "comprehensive genetic testing should form the cornerstone of a tiered approach to clinical evaluation of patients with hearing loss along with history, physical exam, and audiometry and can determine further testing that may be required, if any" (Shearer & Smith, 2015).

Sloan-Heggen et al. (2016) performed parallel sequencing on 1119 "sequentially accrued" patients. A total of 440 (39%) of these patients were found to have a genetic etiology for hearing loss. Pathogenic variants were found in 49 genes, and various alterations such as missense variants (49% of the alterations), copy number variants (18%), insertions or deletions (13%), and nonsense variants (8%) were found. The authors noted the wide variety of the genetic spectrum of hearing loss (Sloan-Heggen et al., 2016).

D'Aguillo et al. (2019) examined the role of genetic screening as an adjunct to universal newborn hearing screening. The authors evaluated 16 studies and identified the rate of children that passed the universal newborn hearing screening but who also tested positive on a genetic screening. Of the 137895 infants included in the studies, pathogenic mutations were detected in 8.66% of them. Of this cohort, 545 infants passed the universal screening, but also tested positive on a genetic screening (1.4%) (D'Aguillo et al., 2019).

Costales et al. (2020) studied the application of Otogenetics, a Next Generation Sequencing panel, in 27 patients diagnosed with sensorineural hearing loss (SNL) within a childhood hearing loss unit. A genetic diagnosis of SNL was made in 56%

(15/27) of the patients whereas 44% (12/27) had pathogenic variants in genes associated with isolated SNL, syndromic SNL, and non-syndromic SNL. According to the authors, this study demonstrated that "it is possible to implement genetic diagnosis in the daily routine" (Costales et al., 2020).

Yang et al. (2021) developed a multiplex PCR sequencing assay to sequence the *GJB2*, *SLC26A4*, and *MT-RNR1* genes and demonstrated that genetic screening can play an important role in newborn hearing screening. To validate the assay, 103 samples with known genotypes were analyzed using the multiplex PCR, which accurately identified all the variants with a 100% sensitivity and specificity. In the pilot study, 300 samples were analyzed and 12.3% were found to carry at least one pathogenic variant in the *GJB2, SLC26A4*, and *MT-RNR1* genes. The study also revealed that pathogenic variants in the *GJB2* gene had an 8% carrier rate in the newborn population. The authors concluded that "the assay is an accurate and reliable test and can be used to screen genetic hearing loss in newborns" (Yang et al., 2021).

Liao et al. (2022) put together a retrospective cohort study of 2075 patients who were seen at the Children's Communications Clinic; 517 patients completed a hearing loss testing with a GeneDx panel. Researchers gathered sociodemographic characteristics, hearing loss characteristics, and medical variables of hearing loss. On univariable analysis, those who received a genetic diagnosis were younger than those who did not receive a genetic diagnosis (OR, 0.92; 95% CI, 0.88-0.96). Twenty-four diagnostic genes were found in the study cohort, the most common diagnostic gene being *GJB2*, which encodes for connexin 26, a major protein found in gap junction protein in the cochlea. Additionally, the most prevalent diagnostic variant was different across races and ethnicities, that is, Asian patients were more likely to have the C.109 G>A variant and white patients were more likely to have the C.35del, and Hispanic patients were "almost equally" likely to have the c.35del variant as any other variant (aside from c.109 G>A) (Liao et al., 2022).

VI. Guidelines and Recommendations

The American College of Medical Genetics and Genomics (ACMG)

In 2014, the ACMG issued the following guidelines for the clinical evaluation and diagnosis of hearing loss. For individuals lacking physical findings suggestive of a known syndrome and having medical and birth histories that do not suggest an environmental cause of hearing loss, ACMG recommends that a tiered diagnostic approach should be implemented.

- "Pretest genetic counseling should be provided, and, with patient's informed consent, genetic testing should be ordered."

- "Single-gene testing may be warranted in cases in which the medical or family history, or presentation of the hearing loss, suggests a specific etiology. For example, testing for mitochondrial DNA mutations associated with aminoglycoside ototoxicity may be considered for individuals with a history of use of aminoglycoside antibiotics."
- "In the absence of any specific clinical indications and for singleton cases and cases with apparent autosomal recessive inheritance, the next step should be testing for DFNB1-related hearing loss (due to mutations in *GJB2* and adjacent deletions in *GJB6*)."
- "If initial genetic testing is negative, genetic testing using gene panel tests, NGS technologies such as large sequencing panels targeted toward hearing loss–related genes, WES, or WGS may be considered. Because several tests are clinically available, the clinician must be aware of the genes included in the test (panel) chosen and the performance characteristics of the platform chosen, including coverage, analytic sensitivity, and what types of mutations will be detected. It should be noted that the cost of these new genetic sequencing technologies is decreasing so rapidly that a tiered approach to testing may soon no longer be cost effective. In particular, for large sequencing panels targeted toward hearing loss– related genes, it may, in some cases, already be more cost effective to use NGS technologies as the initial test in the evaluation of hearing loss. However, issues related to genomic testing, such as the likelihood of incidental findings, will have to be addressed."
- "If genetic testing reveals mutation(s) in a hearing loss–related gene, mutation-specific genetic counseling should be provided, followed by appropriate medical evaluations and referrals."
- "If genetic testing fails to identify an etiology for a patient's hearing loss, the possibility of a genetic or acquired etiology remains. This point must be emphasized because it can be misunderstood by clinicians and by patients and their families. For interested patients and families, further genetic testing may be pursued on a research basis."
- "CMV testing should be done at the same time as genetic testing for infants with congenital hearing loss. For later-onset or progressive hearing loss, CMV testing can be obtained, but the likelihood that a positive test is due to postnatal exposure increases with age."

For individuals with findings that suggest a syndromic genetic etiology for their hearing loss:

- "Pretest genetic counseling should be provided, and, with patient's informed consent, genetic testing, if available, should be ordered to confirm the diagnosis—this testing may include single-gene tests, hearing loss sequencing

panels, WES, WGS, chromosome analysis, or microarray-based copy-number analysis, depending on clinical findings."
- "Appropriate studies should be undertaken to determine whether other organs are involved; and
- "Appropriate near-term and long-term screening and management should be arranged, including referrals to specialists, as indicated by the associated manifestations of the particular syndrome" (Alford et al., 2014).

The ACMG also published an algorithm stating to "consider" *GJB2, GJB6* or other gene specific testing if familial or nonsyndromic hearing loss was suspected. If nonsyndromic and mitochondrial inheritance was suspected, the ACMG recommended testing for the A1555G mutation (ACMG, 2018).

In 2021, ACMG released an updated guideline for screening for autosomal recessive and X-linked conditions during pregnancy and preconception. Their practice resource aims to recommend "a consistent and equitable approach for offering carrier screening to all individuals during pregnancy and preconception" and replaces any earlier ACMG position statements on prenatal/preconception expanded carrier screening and provide the following recommendations:

- "Carrier screening enables those screened to consider their reproductive risks, reproductive options, and to make informed decisions."
- "The phrase "expanded carrier screening" be replaced by "carrier screening"."
- "Adopting a more precise tiered system based on carrier frequency:
  - Tier 4: <1/200 carrier frequency (includes Tier 3) genes/condition will vary by lab
  - Tier 3: ≥ 1/200 carrier frequency (includes Tier 2) includes X-linked conditions
  - Tier 2: ≥1/100 carrier frequency (includes Tier 1)
  - Tier 1: *CF* [Cystic Fibrosis] + *SMA* [spinal muscular atrophy] + Risk Based Screening
    - "Tier 1 screening conveys the recommendations previously adopted by ACMG and ACOG" and "adopts an ethnic and population neutral approach when screening for cystic fibrosis and spinal muscular atrophy. Beyond these two conditions, additional carrier screening is determined after risk assessment, which incorporates personal medical and family history as well as laboratory and imaging information where appropriate"
    - "Tier 2 carrier screening stems from an ACOG recommendation for conditions that have a severe or moderate phenotype and a carrier frequency of at least 1/100." However, "data demonstrate that carrier screening for two common conditions using a carrier frequency threshold of 1/100 may not be equitable across diverse populations. Others have

shown that limiting the carrier frequency to ≥1/100 creates missed opportunities to identify couples at risk for serious conditions."

    - "We define Tier 3 screening as carrier screening for conditions with a carrier frequency ≥1/200 . . . Tier 2 and Tier 3 screening prioritize carrier frequency as a way to think about conditions most appropriate for screening in the general population. However, when ACOG proposed this level, they did not specify whether it was thinking about carrier frequency in terms of the global population or subpopulations. We use "carrier frequency" to mean in any ethnic group with reasonable representation in the United States."
    - "Tier 4 includes genes less common than those in Tier 3 and can identify additional at-risk couples. Tier 4 has no lower limit carrier screening frequency and can greatly extend the number of conditions screened . . . the clinical validity at this level of carrier screening may be less compelling, therefore we suggest reserving this level of screening for consanguineous pregnancies (second cousins or closer) and in couples where family or medical history suggests Tier 4 screening might be beneficial . . . Importantly, patients should understand that their chance of being a carrier for one or more conditions increases as the number of conditions screened is increased."

- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening.
- Tier 4 screening should be considered:
    - When a pregnancy stems from a known or possible consanguineous relationship (second cousins or closer);
    - When a family or personal medical history warrants.
- ACMG does NOT recommend:
    - Offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups.
    - Routine offering of Tier 4 panels.
- "Carrier screening paradigms should be ethnic and population neutral and more inclusive of diverse populations to promote equity and inclusion."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening for autosomal recessive [Table 1] . . . conditions."
- "Reproductive partners of pregnant patients and those planning a pregnancy may be offered Tier 3 carrier screening for autosomal recessive conditions [Table 1] when carrier screening is performed simultaneously with their partner."
- "When Tier 1 or Tier 2 carrier screening was performed in a prior pregnancy, Tier 3 screening should be offered" (Gregg et al., 2021).

(Gregg et al., 2021)

In 2022, the ACMG released updated guidelines for clinical evaluation and etiologic diagnosis of hearing loss. The updated guideline suggests the following recommendations:

1. "All newborns and infants with confirmed HL should undergo a comprehensive evaluation in which patient-focused medical and birth histories, a 3-generation pedigree, and family medical history are obtained, and a physical examination that focuses on dysmorphic physical findings is performed. Evaluation of children and young adults with HL should follow a similar approach. Evaluation of deaf or hard-of-hearing adults should be customized based on the age of onset and other characteristics of HL."
    - "The medical and birth histories may be helpful in differentiating between acquired vs inherited causes of HL."
2. "For individuals with findings that suggest a syndromic genetic etiology for their HL:

- "Pretest genetic counseling should be provided, and, with patient's or caregiver's informed consent, genetic testing should be ordered to confirm the diagnosis. This testing may include single-gene tests, HL multigene panels, ES, GS, chromosome analysis, or microarray- or NGS-based copy number analysis, depending on clinical findings."
- "Appropriate studies should be undertaken to determine whether other organs are involved."
- "Appropriate near-term and long-term screening and management should be arranged, including referrals to specialists, as indicated by the associated manifestations of the syndrome."

3. "For individuals lacking physical findings suggestive of a known syndrome, a tiered diagnostic approach should be implemented."
   - "Unless clinical and/or family history suggests a specific genetic etiology, comprehensive HL gene panel testing should be initiated. If panel testing is negative, genome-wide testing, such as ES or GS, may be considered.
     - The HL panel should include the genes recommended by the HL Gene Curation Expert Panel [https://search.clinicalgenome.org/kb/affiliate/10007?page=1&size=25&search=].
     - If genetic testing reveals variant(s) in an HL-related gene, gene-specific genetic counseling should be provided, followed by appropriate medical evaluations and referrals.
     - If genetic testing fails to identify an etiology fora patient's HL, the possibility of a genetic etiology remains."
   - "Temporal bone imaging by computed tomography or magnetic resonance imaging should be considered as a complement to genetic testing, particularly if the diagnosis remains unclear; if cochlear im-plantation is being considered; if auditory neuropathy is noted, in cases of progressive HL; or if other clinical concerns exist. The anticipated clinical utility of imaging studies should be balanced against the risks associated with radiation exposure and sedation."
   - "CMV testing should be done as soon as possible after birth but within the first 3 weeks of life for infants with congenital HL. For later-onset or progressive HL, CMV testing can be obtained, but the likelihood that a positive test is caused by postnatal exposure increases with age."
4. "Referral to a multidisciplinary care center, when available, is recommended."
   - "A team approach that includes otolaryngologists, clinical geneticists, genetic counselors, audiologists, speech and language specialists, early hearing intervention and family support specialists and other appropriate specialists offers optimal opportunity to provide ongoing management and support of

deaf and hard-of-hearing individuals and their families as their needs change over time."

- "For cases in which the genetic evaluation failed to identify an underlying cause, periodic follow-up care every 3 years with a geneticist may be appropriate for several reasons. First, subtle features of syndromic forms of HL may not be apparent at birth or early in childhood but may appear as deaf or hard-of-hearing individuals grow into adulthood. These may prompt additional medical tests or referrals for specialty care. Second, follow-up visits offer the opportunity to inform individuals about new genetic tests that may have become available or changes in the interpretation of previous test results as medical knowledge advances. Finally, follow-up visits may also help identify clinical concerns unrelated to HL, for which referral for specialty care may be appropriate."

"Regardless of whether genetic test results are positive, negative, or inconclusive, results should be communicated through the process of genetic counseling and potential risks to other family members should be conveyed" (Li et al., 2022).

The Joint Committee on Infant Hearing (JCIH)

In 2007, the JCIH recommended that evaluation of infants with confirmed hearing loss should include a review of family history of specific genetic disorders or syndromes, including genetic testing for gene mutations such as GJB2 (connexin-26), and syndromes commonly associated with early-onset childhood sensorineural hearing loss (JCIH, 2007). In 2013, a supplement by the ASHA was added to the JCIH. The 2013 supplement also stated that medical providers must "understand atypical development etiologies and diagnoses, and refer for medical-genetic evaluation" and that families must be educated on the "importance of medical, genetic, ophthalmologic, and cardiac (EKG) evaluations on children with any type and degree of hearing loss" (ASHA, 2013).

In 2019, the JCIH published an updated position statement. They note that the American College of Medical Genetics and Genomics recommends offering genetic counseling and testing to all infants who are deaf or hard of hearing and their families. A geneticist's evaluation should include "a review of family history of specific genetic disorders or syndromes, genetic testing for gene mutations such as *GJB2* (connexin-26), and syndromes commonly associated with early-onset hearing loss" (JCIH, 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state

coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81252	GJB2 (gap junction protein, beta 2, 26kDa, connexin 26) (eg, nonsyndromic hearing loss) gene analysis; full gene sequence
81253	GJB2 (gap junction protein, beta 2, 26kDa, connexin 26) (eg, nonsyndromic hearing loss) gene analysis; known familial variants
81254	GJB6 (gap junction protein, beta 6, 30kDa, connexin 30) (eg, nonsyndromic hearing loss) gene analysis, common variants (eg, 309kb [del(GJB6-D13S1830)] and 232kb [del(GJB6-D13S1854)])
81430	Hearing loss (eg, nonsyndromic hearing loss, Usher syndrome, Pendred syndrome); genomic sequence analysis panel, must include sequencing of at least 60 genes, including CDH23, CLRN1, GJB2, GPR98, MTRNR1, MYO7A, MYO15A, PCDH15, OTOF, SLC26A4, TMC1, TMPRSS3, USH1C, USH1G, USH2A, and WFS1
81431	Hearing loss (eg, nonsyndromic hearing loss, Usher syndrome, Pendred syndrome); duplication/deletion analysis panel, must include copy number analyses for STRC and DFNB1 deletions in GJB2 and GJB6 genes
S3844	DNA analysis of the connexin 26 gene (GJB2) for susceptibility to congenital, profound deafness

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Hereditary Hemochromatosis

Policy Number: AHS – M2012 – Genetic Testing for Hereditary Hemochromatosis	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Hereditary hemochromatosis (HH) is a genetic disease that causes excessive absorption of dietary iron and storage in the skin, heart, liver, pancreas, and joints due to mutations of genes involved in iron metabolism and homeostasis. The genes include the *HFE* gene, and those encoding for hepcidin, hemojuvelin, transferrin receptor, ferritin, ferroportin, and ceruloplasmin (Bacon & Camaschella, 2024; Bacon & Phatak, 2024).

For policy regarding diagnostic testing of ferritin, transferrin, and hepcidin, please see AHS-G2011.

Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS-G2011	Diagnostic Testing of Iron Homeostasis & Metabolism

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with serum transferrin saturation ≥45% or elevated serum ferritin (see Note 1) **or** who have a first-degree relative (see Note 2) with confirmed hereditary hemochromatosis (HH), *homeostatic iron regulator* (*HFE)* variant genotyping (C282Y, H63D, or S65C) **MEETS COVERAGE CRITERIA**.

2) Multi-gene panel testing (see Note 3) for additional HH-related genes **MEETS COVERAGE CRITERIA** only when **all** of the following conditions are met:

   a) Individual has tested negative for common likely pathogenic or pathogenic variants in *HFE* (C282Y, H63D, and S65C);

   b) Individual presents with atypical symptoms of iron overload, such as endocrine or cardiac involvement;

   c) All other potential causes of elevated serum iron have been ruled out.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For the general population, screening for HH via genetic testing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Elevated serum ferritin is defined as >300 ng/mL in males or postmenopausal females; >200 ng/mL in premenopausal females (Bacon & Phatak, 2024).

Note 2: First-degree relatives include parents, full siblings, and children of the individual.

Note 3: For two or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
1ATD	Alpha 1-antitrypsin deficiency
AASLD	American Association for the Study of Liver Diseases
AUD	Alcohol use disorder
ACG	American College of Gastroenterology
BSH	British Society for Haematology
CASL	Canadian Association for the Study of the Liver
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CWC	Choosing Wisely Canada
DNA	Deoxyribonucleic acid
EASL	European Association for the Study of the Liver
FBC	Full blood count
FPN1	Ferroportin

FTH1	Ferritin heavy chain 1
GH	Genetic hemochromatosis
HAMP	*Hepcidin antimicrobial peptide*
HC	Hemochromatosis
HFE	*Homeostatic iron regulator*
HJV	Hemojuvelin
HH	Hereditary hemochromatosis
IPF	Idiopathic pulmonary fibrosis
LDTs	Laboratory-developed tests
LFT	Liver function test
NAFLD	Nonalcoholic fatty liver disease
NGS	Next-generation sequencing
PCR	Polymerase chain reaction
SF	Serum ferritin
SLC11A3	Previous gene name of *SLC40A1*
SLC40A1	*Solute carrier family 40-member 1 gene*
TfR/TFR	Transferrin receptor
Tsat	Transferrin saturation
USPSTF	U.S. Preventive Services Task Force

V. Scientific Background

Iron homeostasis is a complex process where the small peptide hormone hepcidin plays a major role by binding the sole mammalian iron exporter, ferroportin (FPN1), leading to FPN1 degradation by lysosomes. Hepcidin production is sensitive to extracellular iron concentrations by way of *HFE* and transferrin receptors (TfR). The HFE protein has been shown to interact with both TfR1 and TfR2 and initiate the BMP-SMAD signaling pathway upon transferrin binding. This signaling cascade ultimately increases expression of the *HAMP* gene that encodes for hepcidin (Pietrangelo, 2015; Vujić, 2014).

Hereditary hemochromatosis (HH) is an iron-storage disease caused by genetic mutations, most often in the *HFE* gene, resulting in chronic hyperabsorption of dietary iron and iron accumulation primarily in the liver, pancreas, and heart. This may cause impaired organ structure and function, and can ultimately lead to liver cirrhosis, liver cancer, diabetes, cardiac hypertrophy, congestive heart failure, and osteoarthritis, as well as other serious conditions (Adris et al., 2019; Milman et al., 2019). A diagnosis of *HFE*-associated HH is often difficult without the presence of physical features (Adris et al., 2019). Non-*HFE* hemochromatosis, which accounts for about 20% of HH diagnoses, includes genetic mutations to hepcidin, ferroportin, ferritin, TfR2, and ceruloplasmin. If

left untreated, iron overload can result in death (Bacon & Camaschella, 2024; Bacon & Phatak, 2024; Fleming & Ponka, 2012; Santos et al., 2012).

Three point mutations in *HFE* have been identified in HH: C282Y, H63D, and S65C. Homozygous C282Y mutation, according to one study in the U.S., was present in 83% of HH cases (Bacon & Camaschella, 2024; Feder et al., 1996). C282Y *HFE* mutations are relatively common, especially in Caucasians of northern European origin, particularly Nordic or Celtic ancestry; homozygosity among Caucasians was reported at 1:200-300. The frequency of the C282Y allele ranges from as high as 12.5% in Ireland to 0% in southern Europe (Pietrangelo, 2015). The prevalence of HH Type one (HFE C282Y mutation) varies by ethnicity; "0.000039% in Asian individuals, 0.012% in black, 0.027 in Hispanic to 0.44% in non-Hispanic individuals with a peak of 1.2% in Ireland" (Piperno et al., 2020). Despite the common nature of this mutation, only a proportion of these patients with the homozygous C282Y mutation will develop symptoms of HH (Piperno et al., 2020). This mutation disrupts disulfide bridge formation, preventing association with TfR1 (Vujić, 2014). The H63D mutation stabilizes the HFE-TfR1 complex and has a higher prevalence with a mean allele frequency of approximately 14%; however, phenotypically, H63D homozygosity rarely leads to HH (Pietrangelo, 2015; Vujić, 2014). A recent study by Joly et al. (2017) identified a link between the H63D mutation and patients with severe complications from alpha 1-antitrypsin deficiency (1ATD). 1ATD patients who also have the H63D *HFE* mutation have an increased risk of "developing significant chronic hepatic injuries (hepatomegaly, chronic cholestasis, elevated liver enzymes)" and are at risk of developing liver cirrhosis (Joly et al., 2017). An earlier study reported that 7.8% of HH genes, rather than containing neither the C282Y nor H63D mutations, actually had the S65C mutation, suggesting that it is associated with a more mild form of HH (Mura et al., 1999). Moreover, *HFE* gene variants are found more frequently in patients suffering from idiopathic pulmonary fibrosis (IPF), such that "The frequency of C282Y, S65C and H63D *HFE* allelic variants was markedly higher in IPF compared with controls (40.4% versus 22.4%, OR 2.35, p=0.008) and was associated with higher iron-dependent oxygen radical generation… [suggesting] iron dysregulation associated with *HFE* allelic variants may play an important role in increasing susceptibility to environmental exposures, leading to recurring injury and fibrosis in IPF" (Sangiuolo et al., 2015).

Juvenile hemochromatosis (JH) or type II hemochromatosis is caused by mutations in the gene encoding the protein hemojuvelin (*HJV/HFE2* causes Type IIA HH). This recessive, rare form of hemochromatosis is suspected of inhibiting hepcidin production by a decrease in the bone morphogenetic protein signaling pathway (Bacon & Camaschella, 2024). This condition is fully penetrant, but with varying degrees of onset depending on the mutation; *HFE2* HH can present in adult or older age instead of in juvenile years (Piperno et al., 2020). Unlike classical HH, JH typically develops before

the age of 30, progresses at a greater rate, and is associated with iron overload, leading to severe clinical complications, such as liver damage, cardiomyopathy, and hypogonadotrophic hypogonadism (Santos et al., 2012). An Italian study identified at least 17 different mutations that can cause JH (Lanzara et al., 2004). Takami et al. (2020) discovered that JH develops "in females and males at a ratio of 3:2 with no age difference in the two groups." Earlier JH onset was also seen among patients with a L101P/L101P or R385X/R385X *HJV* gene mutation and later in those with I281T/I281T *HJV* gene mutations when compared to the most common G320V/G320V mutation (Takami et al., 2020).

A second form of JH (type IIB), also autosomal recessive, is caused by mutations to the *HAMP* gene that encodes for hepcidin (Radford-Smith et al., 2018). This form also typically presents before the age of 30 with both hepatic and extrahepatic symptoms, including hypogonadism, cardiac abnormalities, and endocrine dysfunctions; however, with early treatment, symptoms can improve and iron levels can normalize (Fonseca et al., 2016; Lescano et al., 2017).

Mutations in the transferrin receptor two (*TFR2*) gene are rare; however, either homozygosity or compound heterozygosity can result in a phenotypic Type three HH (Bacon & Camaschella, 2024; Santos et al., 2012). TfR2 is typically a sensor for iron levels in the body and is involved in hepcidin synthesis (Santos et al., 2012). Typically, the first biochemical abnormality is evident when transferrin saturation (TSAT) elevation occurs in the second or third decade of life; *TFR2* HH onset is normally earlier than *HFE* HH (De Gobbi & Roetto, 2023). This form of hemochromatosis can result in liver disease due to hepatocellular iron accumulation and fibrosis and can vary in severity "depending on the phenotypic impact of the mutation" (Bardou-Jacquet et al., 2013; Pietrangelo, 2004). This phenotype can include "abnormal liver function, diabetes, hypogonadism, cardiomyopathy and arthritis" (Santos et al., 2012).

Mutations in the iron exporter ferroportin, FPN1, encoded by the gene *SLC40A1* (classified as *SLC11A3* in older literature), can result in an autosomal dominant form of HH (Moreno-Carralero et al., 2014; Politou et al., 2004). Ferroportin is normally responsible for iron transport across enterocytes and iron recycling by the reticuloendothelial system (Santos et al., 2012). This type of ferroportin disease is dictated by the nature of the mutation. For example, loss of function mutations, such as in classical ferroportin disease, result in excess iron accumulation in macrophages, ferritinemia, and mild anemia, whereas gain of function mutations, as seen in non-classical ferroportin disease or Type four HH, result in hepcidin-resistant ferroportin, leading to iron accumulation in the hepatic parenchyma (Bacon & Camaschella, 2024). These patients "hyperabsorb iron and present with high TSAT, high serum ferritin, ad tissue iron overload with evidence of toxic damage that may develop into adult age" (Piperno et al., 2020). Typically, the earliest biochemical abnormalities can begin to

appear within the first decade of life, but the clinical onset of liver disease may not appear until adulthood (patients in their 40s); unlike *HFE*-derived HH, ferroportin diseases, although rare, are pan-ethnic (Pietrangelo, 2004; Zhang et al., 2017).

Proprietary Testing

Several proprietary gene panels are available for hereditary hemochromatosis, such as Invitae's panel (six genes, *FTH1, HAMP, HFE, HJV, SLC40A1, TFR2*) (Invitae, 2024) and Blueprint Genetics' panel (five genes, *HAMP, HFE, HFE2, SLC40A1, TFR2*) (Blueprint, 2023). These panels often encompass the primary gene, *HFE*, as well as the rarer pathogenic variants that may also cause HH.

The standard of care for all forms of HH is reduction of iron via therapeutic, life-long phlebotomy with early initiation of treatment; iron chelation and modifications to diet, such as avoidance of iron, discontinuance of iron-containing supplements, and avoidance of alcohol can also be recommended (Rombout-Sestrienkova et al., 2016). Monitoring of serum ferritin and TSAT are required to manage treatment and assess disease progression where "Improvements in overall wellbeing, including fatigue, liver function (pre-cirrhosis) and skin pigmentations, are most noticeable. On the other hand, if cirrhosis is already well established, it is generally considered irreversible" (Radford-Smith et al., 2018).

Analytical Validity

Pietrangelo (2015) states that "*HFE* gene testing can be used to diagnose hemochromatosis in symptomatic patients, but analyses of liver histology and full gene sequencing are required to identify patients with rare, non-*HFE* forms of the disease. Due to the central pathogenic role of hepcidin, it is anticipated that nongenetic causes of hepcidin loss (e.g., end-stage liver disease) can cause acquired forms of hemochromatosis."

Specifically for the C282Y *HFE* mutation, Palomaki et al. (2003) found that the "analytic sensitivity for C282Y homozygosity is 98.4% (95% CI 95.9%–99.5%). The analytic specificity is 99.8% (99.4%–99.9%). At a frequency of 40 per 10,000 for the homozygous genotype, the analytic positive predictive value is 66%" after analyzing results from the Molecular Genetic Survey collected by the American College of Medical Genetics/College of American Pathologists between 1998 and 2002. The authors noted these results as a critical part of any confirmatory testing for identifying false-positive C282Y mutation test results in any potential population-based HH screening program.

A comprehensive German study researching the technical performance and clinical relevance of *HFE* C282Y testing found that 1.7% of the patients tested for this specific point mutation were homozygous for C282Y; although, it should be noted that 42.6%

of these patients had already been clinically diagnosed with hemochromatosis. Regarding the technical performance of the genetic test, it had an accuracy of 99.6% with an overall error rate of 0.24%. The analytic specificity "with respect to the detection of homozygosity for C282Y was 100% (7726 of 7726 nonhomozygous test challenges, 95% CI: 99.95-100%), while the analytic sensitivity was 97% (130 of 134 homozygous test challenges, 95% CI: 92.5-99.2%)...We conclude that the test methods for C282Y are robust, highly sensitive and specific, and that a DNA-based HH-screening program can be performed at reasonable laboratory costs" (Stuhrmann et al., 2005).

The College of American Pathologists provided blinded proficiency testing (PT) for any interested laboratories completing common *HFE* genetic testing methods; researchers used ten years of data provided from these PT studies to determine overall *HFE* testing laboratory performance. A total of 257 different labs participated and several different genotyping methods were used including "differential restriction enzyme fragment lengths (51%), melting curve-based methods (15%), probe-specific real-time PCR (TaqMan) methods (eight percent), direct sequencing (seven percent), and allele-specific PCR (seven percent)" (Press et al., 2016). A very low error rate was found (0.73% in 7,663 results), with more errors found in specific variants (C282Y heterozygous, H63D homozygous, and C282Y homozygous); very high sensitivity and specificity values were identified at >98.5% and >99.5% respectively (Press et al., 2016).

Clinical Utility and Validity

A study by Bulaj et al. (1996) published in the New England Journal of Medicine found that of the ten percent of Caucasians heterozygous for classical HH, 20% of males and eight percent of females had higher than normal mean serum ferritin concentrations than the control group and that four percent of males and eight percent of females had elevated TSAT levels as compared to the control, wildtype group. "The clinical and biochemical expression of hemochromatosis was more marked in heterozygotes with paternally transmitted mutations than in those with maternally transmitted mutations. Liver-biopsy abnormalities were generally associated with alcohol abuse, hepatitis, or porphyria cutanea tarda. The phenotype of persons heterozygous for hemochromatosis differs from that of normal subjects, but complications due to iron overload alone in these heterozygotes are extremely rare" (Bulaj et al., 1996).

Another systematic review in 2008 of eleven different studies for classical HH testing in at-risk populations show that the "clinical sensitivity of C282Y homozygosity for hereditary haemochromatosis ranged from 28.4% to 100%; when considering studies that used strict criteria to classify hereditary haemochromatosis, the clinical sensitivity ranged from 91.3% to 92.4%" (Bryant et al., 2008). Another study investigating the accuracy of self-reporting family history of hemochromatosis showed that 81.4% of patients reporting a family history for hemochromatosis correlated positively. The

authors then concluded: "Self-reported family history of hemochromatosis or iron overload can be used to identify individuals whose risk of hemochromatosis or iron overload and associated conditions is increased. These individuals could benefit from further evaluation with iron phenotyping and *HFE* mutation analysis" (Acton et al., 2008).

Lanktree et al. (2017) utilized next-generation sequencing (NGS) of an iron metabolism gene panel to provide patients with a non-*HFE* hemochromatosis diagnosis; the panel was constructed of 15 genes related to iron metabolism. A total of 190 patients with a potential iron overload were screened, and six were diagnosed with non-*HFE* iron overload based on homozygous hemojuvelin (*HFE2*) mutations (Lanktree et al., 2017). Additional pathogenic mutations were found from molecular sequencing results.

Rabideau et al. (2014) also used NGS in a panel with *HFE, HAMP, HFE2, SLC40A1,* and *TFR2* genes to detect rare, other HH-causing mutations not typically assayed. They found that these particular genes "resulted in an additional diagnostic yield compared to *HFE* C282Y and H63D testing alone," and that in patients with such a genetic attribution, management of care "can be personalized based on genotype-phenotype correlation (e.g. N144Y *SLC40A1* mutations may lead to reduced phlebotomy tolerance) and at-risk family members can be screened" (Rabideau et al., 2014).

A 2018 study by Sandhu et al. (2018) conducted a phenotypic analysis across both *HFE* and non-*HFE* variants of hemochromatosis to identify differences in severity of iron overload and disease presentation. Data from 156 patients with genetically confirmed autosomal recessive non-*HFE* HH were compared against 984 patients with *HFE*-p.C282Y homozygous HH, and were found to have both "an earlier age of onset and a more severe clinical course than *HFE* HH, with the most severe presentations found among those with *HJV* and *HAMP* HH (Sandhu et al., 2018). These two juvenile forms had a greater association with all clinical outcomes as well, including cardiomyopathy and hypogonadism, but not arthritis and arthropathy, which was found more in the *HFE* HH population. Higher proportions of those with non-*HFE* HH were derived from Italy (30%) and Greece (ten percent), and most of those with non-*HFE* HH were homozygous for their respective mutations. This study conveys how the type of HH mutation would influence the level of urgency for treatment of a patient's presentation (Sandhu et al., 2018).

The *HFE* gene mutations, specifically C282Y and H63D, have also been tested in association with cancer. From a meta-analysis performed by Lv et al. (2016), "C282Y was found to increase the risk of cancer twofold in the recessive model and 1.1-fold in the allele mode…The results suggest that the C282Y/C282Y genotype is associated with a twofold elevated risk for breast cancer, a 1.7-fold elevated risk of colorectal, and a 3.6-fold increased risk of hepatocellular cancer." This study demonstrated the utility of *HFE* gene mutations beyond HH to cancer risk, and how "living environment,

genetic background and dietary habits are candidate factors that influence the risk of cancer because of HFE mutations" (Lv et al., 2016).

The finding with hepatocellular cancer was conferred by Atkins et al. (2020), who, in a cohort of 451,186 UK Biobank participants who had the HFE p.282Y and p.H63D phenotypes, found that among 1294 male p.282Y homozygotes, there were 21 incident hepatic malignancies. A significant finding was not found to be statistically significant in women. For projections of the male p.282Y homozygote lifetime risk of primary hepatic malignancy up to age 75, the risk was "7.2% (95% CI, 3.9%-13.1%), compared with 0.6% (95% CI, 0.4%-0.7%) for men with neither variant, and the risk of death was 19.5% (95% CI, 15.8%-24.0%), compared with 15.1% (95% CI, 14.7%-15.5%) among men with neither variant" (Atkins et al., 2020).

Moreover, Lim et al. (2020) performed a retrospective analysis on individuals in Newfoundland and Labrador, Canada, homozygous for the C282Y mutation between 1999 and 2009. Of the 306 individuals with C282Y/C282Y and with adequate follow-up, 56 (18.3%) were observed to have end-organ damage, with 5.8% developing liver disease and that such end organ damage was observed more frequently in men (24.3%) than in women (10.5%); however, when separated across pre- vs post-menopausal groups for women, iron overload-related disease was met by 4.1% and 18.3%, respectively. As such, the authors concluded that given the relatively low clinical penetrance of HH mutations, C282Y homozygosity uncommonly causes end-organ damage and liver disease (Lim et al., 2020).

Hereditary hemochromatosis, with mutations in the *HFE* gene, has been associated with osteoarthritis (Milman et al., 2019). A recent prospective cross-sectional study analyzed data from 940 patients younger than 70 years old previously diagnosed with end-stage osteoarthritis of the hip; all participants were compared to a healthy control of similar age and sex (Oppl et al., 2018). Results did not show a relationship between *HFE* mutations and osteoarthritis; the authors stated that "No greater prevalence of C282Y homozygosity mutation or elevated serum ferritin or transferrin saturation levels was found in the study cohort with severe osteoarthritis of the hip than in controls from the general population" (Oppl et al., 2018).

Tamosauskaite et al. (2019) also conducted a study on musculoskeletal effects of HH C282 homozygosity among 200,975 UK Biobank participants aged 60-70 years. They tested the association with Fried frailty, sarcopenia, and chronic pain, and found that "C282Y homozygote men had increased likelihood of reporting chronic pain (odds ratio [OR] 1.23: 95% confidence interval [CI] 1.05-1.45, p = .01) and diagnoses of polymyalgia rheumatica… They were also more likely to have sarcopenia (OR 2.38: 1.80-3.13, p = 9.70 × 10-10) and frailty (OR 2.01: 1.45-2.80, p = 3.41 × 10-05). C282Y homozygote women (n = 312, 0.7%) aged 65-70 were more likely to be frail (OR 1.73: 1.05-2.84, p = .032) and have chronic knee, hip, and back pain" (Tamosauskaite et al.,

2019). This continues to solidify the association between musculoskeletal comorbidities and HH and could ultimately contribute to precision medicine approaches to improving quality of life among the elderly.

Hereditary hemochromatosis patients with *HFE* mutations typically present with elevated erythrocyte levels; until recently, this data has not been used in clinical practice. Adris et al. (2019) analyzed data from a total of 2,688 participants (144 with HH, 1844 healthy controls, and 700 with chronic diseases). Results showed that the "mean cell volume (MCV) and mean cell haemoglobin (MCH) were always significantly higher" in HH subjects when compared to other participants; thus, the use of erythrocyte parameters "demonstrated excellent diagnostic utility for detection of HH in men and women (AUROC 0.83-0.9; maximal sensitivity and specificity 82% and 78%)" (Adris et al., 2019).

VI. Guidelines and Recommendations

United States Preventive Services Task Force (USPSTF)

The USPSTF recommends against genetic screening for HH in the general, asymptomatic population, due to the low penetrance of the disease among those with causative mutations (USPSTF, 2014; Whitlock et al., 2006). This 2006 guideline is now listed as an "Inactive Topic" as of 09/17/2018. USPSTF (2006) guidelines state the following:

The U.S. Preventive Services Task Force (USPSTF) has decided not to review the evidence and update its recommendations for this topic. The previous evidence review, and recommendation may contain information that is outdated.

The USPSTF bases its recommendations on current evidence about preventive services. The USPSTF decides not to update some topics (or "inactivate" them) for several reasons. Topics may be inactivated because they are no longer relevant to clinical practice. This may be the result of changes in technology, a new understanding of the etiology or natural history of the disease, or the evolving natural history of the disease. Topics may also be inactivated because they involve services that cannot be implemented in a primary care setting or are not referable by a primary care clinician. In addition, topics that have a low public health burden or that otherwise fall outside the scope of the USPSTF may be inactivated.

The USPSTF encourages primary care clinicians to consult other sources for current evidence regarding this topic. If new evidence becomes available, the USPSTF may elect to update this topic" (USPSTF, 2006).

Canadian Association for the Study of the Liver (CASL) and Choosing Wisely Canada (CWC) Choosing Wisely Canada-Top Five List in Hepatology

The CASL developed a list of the top five recommendations in hepatology based on data provided by the CWC. One of these recommendations mention *HFE* genotyping:

- "Don't order *HFE* genotyping based on serum ferritin values alone to diagnose hereditary hemochromatosis" (Brahmania et al., 2019).

American Association for the Study of Liver Diseases (AASLD)

The AASLD has published the following recommendations in Bacon et al. (2011):

1. "We recommend that patients with abnormal iron studies should be evaluated as patients with hemochromatosis, even in the absence of symptoms. (A)
2. All patients with evidence of liver disease should be evaluated for hemochromatosis. (1B)
3. In a patient with suggestive symptoms, physical findings, or family history, a combination of TS and ferritin should be obtained rather than relying on a single test. (1B) If either is abnormal (TS ≥45% or ferritin above the upper limit of normal), then *HFE* mutation analysis should be performed. (1B)
4. Diagnostic strategies using serum iron markers should target high-risk groups such as those with a family history of HH or those with suspected organ involvement. (1B)
5. We recommend screening (iron studies and HFE mutation analysis) of first-degree relatives of patients with *HFE*-related HH to detect early disease and prevent complications. (1A)"

European Association for the Study of the Liver (EASL)

The EASL published clinical practice guidelines for *HFE* hemochromatosis. In general and patient populations, EASL (2010) states:

- "General population:
  - Genetic screening for HFE-HC is not recommended, because disease penetrance is low and only in few C282Y homozygotes will iron overload progress (1B).
- Patient populations:
  - HFE testing should be considered in patients with unexplained chronic liver disease pre-selected for increased transferrin saturation (1C).
  - HFE testing could be considered in patients with:
    - Porphyria cutanea tarda (1B).

- Well-defined chondrocalcinosis (2C).
- Hepatocellular carcinoma (2C).
- Type 1 diabetes (2C).

- HFE testing is not recommended in patients with
  - Unexplained arthritis or arthralgia (1C)
  - Type 2 diabetes (1B)."

Guidelines from 2022 recommend that "Individuals with clinical and biochemical signs of haemochromatosis, elevated transferrin saturation and high serum ferritin concentrations, or otherwise unexplained persistently elevated transferrin saturation should be genetically tested for haemochromatosis after informed consent for genetic testing has been obtained (LoE 2, strong recommendation, strong consensus). Patients with increased liver iron evident on liver biopsy or MRI should be clinically assessed and biochemically tested for haemochromatosis (serum ferritin and transferrin saturation) (LoE 2, strong recommendation, strong consensus)" (EASL, 2023).

"Genotyping for p.C282Y in HFE should be carried out in individuals of European origin with biochemical evidence of iron overload (females with transferrin saturation >45% and serum ferritin >200 lg/L and males with transferrin saturation >50% and ferritin >300 lg/L, or otherwise unexplained persistently elevated transferrin saturation) with or without clinical signs or symptoms suggestive of haemochromatosis (LoE 2, strong recommendation, strong consensus). Adult (>18 years of age) first-degree relatives of patients with p.C282Y homozygous haemochromatosis should be tested for the p.C282Y variant in HFE (LoE 4, strong recommendation, strong consensus)" (EASL, 2023).

Regarding family screening, the EASL states "Siblings of patients with HFE-related HC must undergo screening, since they have a 25% chance of being susceptible. Serum ferritin, and transferrin saturation should be assessed. Ideally HFE mutation analysis should be encouraged after appropriate counseling with regard to the pros and cons of testing (mortgage, insurance issues)" (EASL, 2010).

In the 2022 guidelines EASL (2023) recommends "Adult individuals with a positive family history of first-degree relatives with haemochromatosis should be genetically tested for haemochromatosis after informed consent for genetic testing has been obtained (LoE 4, strong recommendation, strong consensus)."

In using genetic testing to diagnose HH, the EASL adds:

- "Patients from liver clinics should be screened for fasting transferrin saturation and serum ferritin (1C) and offered genetic HFE testing if transferrin saturation is increased (1B)

- Diagnosis of HFE hemochromatosis should not be based on C282Y homozygosity alone but requires evidence of increased iron stores (1B).
- Genetic testing of 'other hemochromatosis genes' (*TFR2, SLC40A1, HAMP, HJV*) could be considered in patients with increased iron stores after exclusion of C282Y homozygosity if (i) iron excess has been proven by direct assessment, i.e. by MRI or liver biopsy, and (ii) other hepatic and haematological disorders have been ruled out (2C)."

European Molecular Quality Network (EMQN)

The EMQN has published the following recommendations for diagnostic and predictive testing:

1. "Population screening for the p.C282Y variant is not currently recommended (1B).
2. It is considered to be good practice to confirm elevated TS before *HFE* genetic diagnosis testing (1B).
3. Testing adult siblings (brothers and sisters) of p.C282Y homozygotes is recommended owing to the increased risk of p.C282Y homozygosity and related increased morbidity (1B).
4. Testing adult offspring of p.C282Y homozygotes is recommended owing to increased risk of p.C282Y homozygosity and related increased morbidity (1C).
5. Testing asymptomatic parents of p.C282Y homozygotes is not recommended systematically but rather as a clinical decision depending on their age, sex and ferritin, all three influencing the probability to develop severe iron overload (1C).
6. Systematic testing of adult first-degree relatives of p.C282Y heterozygotes is not currently recommended, in the absence of evidence of benefit (2C).
7. *HFE* testing of minors is not recommended (1B).
8. Prenatal diagnosis is not appropriate in *HFE*-related HH because it is a treatable, adult-onset condition (1C)" (Porto et al., 2016).

American College of Gastroenterology (ACG)

Hereditary hemochromatosis is one of the most common causes of inherited liver disorders which causes abnormal liver chemistries. In the cases where patients have abnormal liver chemistries without acute hepatitis, ACG recommends ("strong recommendation, very low level of evidence") that those patients should undergo testing for hereditary hemochromatosis with an iron level, transferrin saturation, and serum ferritin; further, "*HFE* gene mutation analysis should be performed in patients with transferrin saturation ≥45% and/or elevated serum ferritin" (Kwo et al., 2017).

In regards to family members, the ACG has stated that "We recommend that family members, particularly first-degree relatives, of patients diagnosed with HH should be

screened for HH (strong recommendation, moderate quality of evidence)" (Kowdley et al., 2019).

The ACG also recommends that "individuals with the H63D or S65C mutation in the absence of C282Y mutation should be counseled that they are not at increased risk of iron overload (conditional recommendation, very low quality of evidence) … We suggest against further genetic testing among patients with iron overload testing negative for the C282Y and H63D alleles (conditional recommendation, very low quality of evidence)" (Kowdley et al., 2019).

Regarding non-*HFE* HH, the ACG writes that "Before pursuing testing for non-*HFE* hemochromatosis, alternative explanations for elevated serum iron tests should be excluded, because abnormal iron studies due to conditions such as AUD or NAFLD are far more common than non-*HFE* hemochromatosis. Contrarily, sequencing of non-*HFE* genes may be considered in atypical cases of iron overload, such as a younger patient presenting with endocrine or cardiac involvement" (Kowdley et al., 2019).

American College of Medical Genetics and Genomics (ACMG)

The ACMG has listed *HFE* genetic testing on its Choosing Wisely list. The ACMG recommends that physicians "Don't order HFE genetic testing for a patient without iron overload or a family history of HFE-associated hereditary hemochromatosis." They expound upon this with the following: "*HFE* genotyping should only be performed among individuals with iron overload (e.g., elevated fasting transferrin saturation >45%) or a known family history of *HFE*-associated hereditary hemochromatosis. In the setting of genome or exome sequencing, it is now recommended that patients who are homozygous for the pathogenic variant C282Y in HFE should receive this result and consider evaluation" (ACMG, 2023).

British Society for Haematology (BSH)

The BSH recommendations include the following as published by Fitzsimons et al. (2018):

1. "Unselected population screening for *HFE* gene mutation is not recommended. (1B)
2. Genetic haemochromatosis (GH) patients who present with serum ferritin (SF) >1000 µg/l and any with raised transaminases should be referred to a hepatologist for fibrosis assessment and exclusion of cirrhosis. (1B)
3. Patients of north European ancestry with clinical features suggestive of GH should have the following laboratory investigations; full blood count (FBC), liver function tests (LFTs), SF and transferrin saturation (Tsat). Molecular testing for

HFE GH should follow if results fulfil the criteria of recommendation 5 (see below). (1B)

4. All adult patients of north European ancestry with unexplained raised SF and random Tsat (>300 µg/l and >50% males; >200 µg/l and >40% females) and normal FBC should have molecular testing for *HFE* GH. (1B)
5. Laboratory screening to include FBC, LFTs, SF, Tsat and *HFE* should be offered to family members after the diagnosis of *HFE* GH. Family screening should include parents (if available), siblings, partner and children (over the age of consent). Extended family screening is not recommended if an individual is identified as a C282Y/H63D compound heterozygote. (1B)
6. Investigation of all confirmed C282Y homozygotes should include FBC, LFTs, SF and Tsat. Thereafter further investigation may be required as follows:
   i. SF <1000 µg/l, normal LFTs, normal clinical examination; no further investigation required. Follow recommendation [7]. (1C)
   ii. SF >1000 µg/l and or abnormal LFTs. All such patients require referral to Hepatology for fibrosis assessment to exclude the presence of cirrhosis. A minimum would be elastography. For patients with confirmed cirrhosis monitor with ▪ -fetoprotein (AFP) and hepatic ultrasound every six months. (2C)
7. Non C282Y homozygotes with significant iron loading as confirmed by magnetic resonance imaging and or liver biopsy should be investigated for rare iron loading genotypes or digenic inheritance. (1C)
8. At diagnosis, all fit GH patients with biochemical iron loading should undergo weekly venesection until SF ~20–30 µg/l and Tsat <50%. During this phase of venesection FBC should be monitored weekly and SF Tsat monitored monthly. Homozygotes with normal iron indices and compound heterozygotes with minimal elevation of iron indices may be suitable for blood donation and annual monitoring of SF and Tsat. (1B)
9. During maintenance, venesect as required, preferably at a blood donation centre to maintain normal FBC, SF <50 µg/l and Tsat <50%. (1C)"

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Recently, the U.S. Food and Drug Administration (FDA) has authorized a direct-to-consumer Genetic Health Risk Hereditary Hemochromatosis test developed by 23andMe. This test provides information on an individual's genetic predisposition from European descent for Hereditary Hemochromatosis by testing two variants (C282Y; H63D) in the *HFE* gene in genomic DNA obtained from a human saliva. However, this test cannot determine an individual's overall risk of developing a disease (FDA, 2017).

LabCorp (2024) has developed a hereditary hemochromatosis test which utilizes PCR for DNA analysis; this testing method utilizes a whole blood or swab kit and analyzes the C282Y, H63D, and S65C mutations of the *HFE* gene. This test has not been approved by the FDA.

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81256	*HFE* (hemochromatosis) (e.g., hereditary hemochromatosis) gene analysis, common variants (e.g., C282Y, H63D)
81479	Unlisted molecular pathology procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Hereditary Pancreatitis

Policy Number: AHS – M2079 – Genetic Testing for Hereditary Pancreatitis	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Pancreatitis is defined as inflammation of the pancreas that progresses from acute (AP) (sudden onset; duration <6 months) to recurrent acute (RAP) (>1 episode of acute pancreatitis) to chronic (CP) (duration >6 months) (LaRusch et al., 2014). This recurrent inflammation can lead to total destruction of the pancreas with subsequent pancreatic insufficiency, secondary diabetes, increased risk for pancreatic cancer, and severe unrelenting pain (Ravi Kanth & Nageshwar Reddy, 2014). Hereditary pancreatitis is the early onset form of chronic pancreatitis that is carried in an autosomal dominant pattern with variable penetrance (LaRusch et al., 2012).

II. Related Policies

Policy Number	Policy Title
AHS-G2153	Pancreatic Enzyme Testing for Acute Pancreatitis
AHS-M2114	Pancreatic Cancer Risk Testing Using Pancreatic Cyst Fluid

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals under 20 years of age, genetic testing for hereditary pancreatitis (see Note 1) **MEETS COVERAGE CRITERIA** when at least **one** of the following conditions is met:

a) For individuals with recurrent (two separate, documented episodes with hyperlipasemia) attacks of acute pancreatitis for which there is no identifiable cause.

b) For individuals with unexplained chronic pancreatitis.

c) For individuals with a first- or second-degree relative (see Note 2) with a history of recurrent acute pancreatitis, idiopathic chronic pancreatitis, **or** childhood pancreatitis without a known cause.

d) For individuals with an unexplained episode of pancreatitis that required hospitalization.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For all other situations not described above, genetic testing for hereditary pancreatitis **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162-Reimbursement Policy.

Note 2: First-degree relatives include parents, full siblings, and children of the individual. Second-degree relatives include grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings of the individual.

IV. Table of Terminology

Term	Definition
ACG	American College of Gastroenterology
AP	Acute pancreatitis
ARP	Acute recurrent pancreatitis
ARUP	Associated Regional and University Pathologists, Inc.
ASCO	American Society of Clinical Oncology
CASR	*Calcium sensing receptor*
CEL	Carboxyl ester lipase
CF	Cystic fibrosis
CFTR	*Cystic fibrosis transmembrane conductance regulator*
CLDN2	*Claudin-2*

CP	Chronic pancreatitis
CPA1	Carboxypeptidase A1
CTRC	*Chymotrypsin C*
DNA	Deoxyribonucleic acid
DNA2	*Deoxyribonucleic acid replication helicase/nuclease 2*
DNAJC21	*Deoxyribonucleic acid J heat shock protein family (Hsp40) member C21*
EFL1	*Elongation factor like-1*
EPC	European Pancreatic Club
HP	Hereditary pancreatitis
HPSG	Hungarian Pancreatic Study Group
IAP	Idiopathic acute pancreatitis
INSPPIRE	International Study Group of Pediatric Pancreatitis
KSS	Kearns-Sayre syndrome
MAGI2	*Membrane-associated Guanylate Kinase Inverted-2*
MODY	Maturity-onset diabetes of the young
MT	Mitochondrial
MYO9B	Myosin IXB
NAPS2	North American Pancreatitis Study 2
NCCN	National Comprehensive Cancer Network
NGS	Next generation sequencing
OPA1	*Mitochondrial dynamin*
OR	Odds ratio
PARD3	Partitioning defective 3
PEO	Progressive external ophthalmoplegia
POLG	*DNA polymerase subunit gamma*
PRSS1	*Cationic* trypsinogen
RAP	Recurrent acute pancreatitis
RRM2B	*Ribonucleotide-diphosphate reductase subunit M2*
SBDS	Shwachman-Bodian-Diamond syndrome
SCP	Smoking-associated chronic pancreatitis
SLC25A4	*Solute carrier family 25 member 4*
SPINK1	Serine protease inhibitor
SRP54	*Pancreatic secretory trypsin inhibitor Kazal type 1*
TIGAR-O	Toxic-Metabolic; Idiopathic; Genetic; Autoimmune; Recurrent and Severe Acute Pancreatitis; Obstructive
TWNK	Twinkle mitochondrial deoxyribonucleic acid helicase
TYMP	Thymidine phosphorylase

UEG	United European Gastroenterology
WES	Whole exome sequencing

V. Scientific Background

Pancreatitis is caused by unregulated trypsin activity within the pancreatic acinar cell or pancreatic duct that leads to pancreatic autodigestion and pancreatic inflammation (Lerch & Gorelick, 2000; Whitcomb, 1999). Under acinar cell stress (e.g., hyperstimulation, intracellular hypercalcemia), intracellular trypsinogen is likely converted to trypsin, which activates other digestive enzymes causing injury. Injury releases immune system-activating molecules that cause an initial acute inflammatory response, followed by recruitment of tissue macrophages and activated pancreatic stellate cells. Recurrent injury leads to chronic pancreatitis and fibrosis, mediated by pancreatic stellate cells (Werlin et al., 2015).

Chronic pancreatitis (CP) is a progressive inflammatory disease in which the pancreatic tissue is destroyed over time and replaced by fibrous tissue. The process of fibrosis usually leads to progressive worsening in the structural integrity of the pancreas, changes in arrangement, and composition of the islets, and deformation of the large ducts, eventually resulting in the impairment of both exocrine and endocrine functions (Brock et al., 2013). The annual incidence of the disease has been estimated to be 5-10 per 100,000 persons (Molven et al., 2015). The main symptom of CP is pain; however, it is highly variable in character, frequency, and severity (Mullady et al., 2011; Whitcomb et al., 2008). Therapeutic efforts are mostly aimed at extracting stones and decompressing pancreatic ducts to achieve ideal drainage of the pancreatic duct (Li et al., 2010; Tandan & Nageshwar Reddy, 2013). Genetic risk factors play a larger role in early-onset CP as opposed to late-onset CP. Older adults have a host of environmental and genetic factors that contribute to CP development while hereditary pancreatitis is postulated to make up less than 4% of CP in late-onset groups (Wertheim-Tysarowska et al., 2021).

The etiologies of chronic pancreatitis are classified by the TIGAR-O system into alcoholism, hyperlipidemia, obstructive damage caused by trauma or congenital anomalies, hereditary pancreatitis, autoimmune pancreatitis, and idiopathic (Etemad & Whitcomb, 2001; Sun et al., 2015). The genetic factors listed in TIGAR-O are *PRSS1* (listed as "cationic trypsinogen"), *CFTR*, *SPINK1*, and alpha-1-antitrypsin (listed as "possible") (Etemad & Whitcomb, 2001). TIGAR-O Version 2 was published in 2019, and lists *PRSS1, CFTR, SPINK1, CTRC, CASR*, and *CEL* as genetic factors, as well as some modifier genes such as *CLDN2* (Whitcomb, 2019).

Hereditary pancreatitis (HP) presents as an autosomal dominant chronic pancreatitis with variable penetrance. It mainly develops in childhood (Wertheim-Tysarowska et al., 2021). This variability has been attributed to a genetic predisposition to chronic pancreatitis with the additive effects of environmental and inherited factors. Most genes associated with HP either directly encode components of the trypsin system of the exocrine pancreas or are likely to perturb this system indirectly. HP is recognized when pathogenic gene variants of the *PRSS1* gene are found or when acute or chronic pancreatitis develops with a distinct family history (Wertheim-Tysarowska et al., 2021). The phenotype of HP is increased susceptibility to acute pancreatitis, resulting in chronic pancreatitis (including pancreatic fibrosis, chronic pain, maldigestion, and diabetes mellitus) occurring in at least 50%. The risk of pancreatic cancer is also increased (Schwarzenberg, 2023).

Genes Linked to Hereditary Pancreatitis

PRSS1 encodes trypsin-1 (cationic trypsinogen), a major pancreatic digestive enzyme. Mutations in *PRSS1* typically result in a trypsin protein that is either prematurely activated or resistant to degradation (LaRusch et al., 2012; Masson et al., 2008), causing autosomal dominant pancreatitis in 60%-100% of families with hereditary pancreatitis (LaRusch & Whitcomb, 2011). "The age of onset for *PRSS-1* related HP ranges from 10 to 12 years" (Hasan et al., 2018).

SPINK1 encodes serine protease inhibitor, Kazel-type 1, a trypsin inhibitor that is upregulated by inflammation (Grendell, 2003). It is not a typical susceptibility gene for acute pancreatitis, but rather a susceptibility gene for the chronic pancreatitis that follows acute pancreatitis.

CTRC encodes chymotrypsin C. Prematurely activated trypsin is destroyed by *CTRC* by acting on the molecule within the calcium-binding loop in the absence of calcium and, therefore, is a crucial candidate gene in the pathogenesis of pancreatitis (Szmola & Sahin-Toth, 2007).

CASR encodes calcium sensing receptor, mutations of which can cause increased calcium ion levels increasing trypsin activation and failed trypsin degradation (Whitcomb, 2004).

CFTR encodes the cystic fibrosis transmembrane conductance protein. Mutations are associated with recurrent acute and chronic pancreatitis since dysfunctional *CFTR* can result in retention of zymogens that can become active and result in pancreatitis (LaRusch & Whitcomb, 2011).

CLDN2 encodes claudin-2, a tight-junction protein that seals the space between epithelial cells. Normally expressed in the proximal pancreatic duct, CLDN2 is thought to facilitate the transport of water and sodium into the duct to match the chloride and bicarbonate that are actively secreted by pancreatic duct cells through *CFTR*. It is strongly associated with alcohol-related chronic pancreatitis rather than recurrent acute pancreatitis (Ravi Kanth & Nageshwar Reddy, 2014).

CPA1 encodes carboxypeptidase A1; mutated CPA1 is associated with nonalcoholic chronic pancreatitis, especially with an early age of onset (Witt et al., 2013). Risk for chronic pancreatitis unrelated to trypsin activation appears to be related to endoplasmic reticulum stress from pathogenic CPA1 variants that alter protein folding, triggering the unfolded protein response.

MYO9B gene and the two tight-junction adaptor genes, **PARD3** and **MAGI2**, have been linked to gastrointestinal permeability. Impairment of the mucosal barrier plays an important role in the pathophysiology of acute pancreatitis (Nijmeijer et al., 2013).

CEL encodes carboxyl-ester lipase, and CEL mutations can cause an autosomal dominant syndrome of maturity-onset diabetes of the young (MODY) and exocrine pancreatic dysfunction (Molven et al., 2015).

TRPV6 is a potential novel susceptibility gene for CP that plays a role in epithelial calcium absorption and reabsorption. Variants of this gene also co-occur with pathogenic variants of genes such as *SPINK1* and *CFTR* (Wertheim-Tysarowska et al., 2021).

Disorder(s)	Genetic Cause(s)	Consequence(s)	Source Citation
Shwachman-Diamond syndrome	*SBDS, DNAJC21, EFL1,* and *SRP54*	affect RNA function	(Nelson & Myers, 2008)

Johanson-Blizzard syndrome	*UBD1*	protein synthesis	(Kniffin & McKusick, 2012)

Syndromes that Include Pancreatitis or Pancreatic Insufficiency

Several genes are associated with rare disorders in which pancreatitis or pancreatic insufficiency is part of their phenotype (Durie, 1996; Lerch et al., 2006).

As the number of genes and mutations involved in the onset and progression of pancreatitis becomes higher (Ooi et al., 2010; Walker et al., 2013), the time and cost of screening and sequencing specific genes continues to increase. However, massive parallel sequencing or next generation sequencing (NGS) is becoming standardized (Ballard et al., 2015), and the cost per patient is rapidly dropping (Palermo et al., 2016). NGS includes whole genome sequencing, whole exome sequencing (WES) and other methods. Because the cost of WES is now less than the cost of sequencing *CFTR*, use of this technology is becoming an attractive alternative to classic targeted gene sequencing or mutation specific genotyping for a genetic counseling workup (LaRusch et al., 2012). In response to this accelerating development of sequencing techniques, several firms have created genetic panels focusing on hereditary pancreatitis. For example, Invitae offers a six-gene panel (*CASR, CFTR, CPA1, CTRC, PRSS1, SPINK1*) for chronic pancreatitis (Invitae, 2023). Other firms offering proprietary panels include ARUP Laboratories (4 genes), LabCorp (3 genes), and Ambry (6 genes) (Ambry, 2023; ARUP, 2023; LabCorp, 2023). Still other firms evaluate as many as 12 genes and more (Schwarzenberg, 2023).

Clinical Utility and Validity

Testing for mutations in the *PRSS1*, *SPINK*, and *CFTR* genes is usually done by either direct sequence analysis or next generation sequencing, both of which have high analytic validity. Several studies have evaluated the clinical validity of genetic testing (Applebaum-Shapiro et al., 2001; Ceppa et al., 2013; Poddar et al., 2015; Sultan et al., 2012). One limitation with some studies was lack of inclusion of patients with clinically defined hereditary pancreatitis. Hence, the true clinical sensitivity and specificity of genetic testing in hereditary pancreatitis cannot be accurately determined and needs to be further researched. Similarly, there is a lack of published literature on the clinical utility of testing. Further research is required to evaluate how genetic testing will impact patient management decision and clinical outcomes.

Kumar et al. (2016) sought to characterize and identify risk factors associated with acute recurrent pancreatitis (ARP) and CP in childhood in a multinational cross-sectional study (INSPPIRE). The authors analyzed 301 children with ARP or CP. They found that "At least 1 gene mutation in pancreatitis-related genes was found in 48% of patients with ARP vs 73% of patients with CP. Children with *PRSS1* or *SPINK1* mutations were more likely to present with CP compared with ARP (*PRSS1*: OR = 4.20 and *SPINK1*: OR = 2.30). Obstructive risk factors presented in 33% in both groups, but toxic/metabolic risk factors were more common in children with ARP (21% overall; 26% ARP, 15% CP). They concluded that "The high disease burden in pediatric CP underscores the importance of identifying predisposing factors for progression of ARP to CP in children" (Kumar et al., 2016).

Grabarczyk et al. (2017) also found that *CTRC* variants are strong CP risk factors in pediatric patients. The authors investigated 136 pediatric patients with CP and compared them to 401 controls. They showed that p.Arg254Trp (4.6%) and p.Lys247_Arg254del (5.3%) heterozygous mutations are frequent and significantly associated with CP risk in pediatric patients (odds ratio [OR] = 19.1; 95% CI 2.8-160; P = 0.001 and OR = 5.5; 95% CI 1.6-19.4; P = 0.001, respectively). The c.180TT genotype of common p.Gly60Gly variant was found to be a strong and independent CP risk factor (OR = 23; 95% CI 7.7-70; P < 0.001) with effect size comparable to p.Arg254Trp mutation (Grabarczyk et al., 2017).

Schwarzenberg et al. (2015) evaluated the genetic spectrum of CP. 76 CP patients were examined, and 51 were found to have a genetic risk factor for CP. Of these 51 mutations, 33 were a *PRSS1* mutation, 14 were a *SPINK1* mutation, 11 were a *CFTR* mutation, and 2 were a *CTRC* mutation. The final 25 patients were found to have an obstructive risk factor (Schwarzenberg et al., 2015).

Zou et al. (2018) evaluated the prevalence of four CP-related genes (*SPINK1, PRSS1, CTRC, CFTR*) in Han Chinese patients. The authors performed next-generation sequencing on 1061 patients and 1196 controls. The 1061 patients were further divided into three categories, idiopathic CP (ICP, 715 patients), alcoholic CP (ACP, 206), and smoking-associated CP (SCP, 140). The impact of rare pathogenic variants on age of onset and clinical outcomes was evaluated. Rare pathogenic variants were found in 535 CP patients compared to 71 controls. Mutation positive patients were found to have earlier age of onset as well additional clinical features such as pancreatic stones and diabetes mellitus compared to mutation negative ICP patients. Overall, pathogenic variants were found in 57.1% of ICP patients, compared to 39.8% of ACP patients and 32.1% of SCP patients. The authors concluded that rare pathogenic variants "significantly" influenced age of onset and clinical outcomes of CP (Zou et al., 2018).

Nabi et al. (2020) evaluated 239 children in a prospective study from January 2015 to May 2018 to examine genetic risk factors in children with idiopathic acute recurrent pancreatitis (IARP). Among the enrollees, 85.35% children had IARP, and found that family history of pancreatitis was found among 4.6% of participants. For specific genes, "mutations/polymorphisms in at least 1 gene were identified in 89.5% (129/144) children including *SPINK1* in 41.9%, *PRSS1* (rs10273639) in 58.2%, *CTRC* in 25.6%, *CTSB* in 54.9%, *CLDN2* in 72.9%, and *CFTR* in 2.3%." This conveys the overlapping genetic nature of IARP with related genes in HP, making genetic testing important for managing potential disease progression.

Suzuki et al. (2020) investigated the currently understood genetic abnormalities in pancreatitis, and found that "patients with these genetic predispositions [*PRSS1* and *SPINK1* genes], both children and adults, have often been initially diagnosed with idiopathic acute pancreatitis, in approximately 20-50% pediatric cases and 28-0% of adult cases… Patients with chronic pancreatitis (CP) due to *SPINK1* gene mutation and HP patients have a potentially high risk of pancreatic exocrine insufficiency, diabetes mellitus, and of particular importance, pancreatic cancer." This conveys the continuously emphasized clinical utility of genetic testing to pursue opportunities for counselling and symptom management with disease progression, despite not having gene therapy options for directly targeting HP causing and associated genes (Suzuki et al., 2020).

Weiss et al. (2020) discussed the potential pitfalls from using next generation sequencing (NGS) to diagnose *PRSS1* mutations in chronic pancreatitis. Due to the "high degree of DNA sequence homology (>91%) between *PRSS1* and other members of the trypsinogen multigene family," there may be erroneous diagnoses of pathologic chronic pancreatitis among patients with benign variants of other *PRSS1*- related genes, like *PRSS2* or *PRSS3P2*. The researchers concluded that sequence homology "can confound the mapping of short NGS reads to a reference genome and lead to technical artefacts." They recommend "careful clinical evaluation, pretest and post-test genetic counselling and confirmation of NGS test results by Sanger sequencing" to confirm a diagnosis of genetically mutated chronic pancreatitis. This presented the precautions that must be accounted for when utilizing genetic testing for hereditary pancreatitis (Weiss et al., 2020).

Zou et al. (2020) performed whole genome sequencing on a population of 464 Chinese CP patients and on a group of 504 control participants. The *Transient receptor potential cation channel, Subfamily V, Member 6 (TRPV6)* gene was identified as a gene significantly associated with chronic pancreatitis through a "burden test of aggregated rare nonsynonymous variants with a combined annotation dependent depletion score > 20 ($p = .020$)." In another phase of the study, Sanger sequencing was used to analyze

the entire coding sequence and exon/intron boundaries of the *TPRV6* gene. Combining the two phases of the study, the authors identified 25 distinct variants of *TPRV6* and noted that loss-of-function variants were over-represented in the chronic pancreatitis group. The authors concluded that *TPRV6* is likely a novel susceptibility gene for chronic pancreatitis.

VI. Guidelines and Recommendations

Consensus Committees of the European Registry of Hereditary Pancreatic Diseases, the Midwest Multi-Center Pancreatic Study Group and the International Association of Pancreatology

A Consensus Committees of the European Registry of Hereditary Pancreatic Diseases, the Midwest Multi-Center Pancreatic Study Group and the International Association of Pancreatology developed guidelines for genetic testing of the *PRSS1* gene and genetic counseling for HP (Ellis et al., 2001). The recommended indications for symptomatic patients included:

- Recurrent (two separate, documented episodes with hyperlipasemia) attacks of acute pancreatitis for which there is no explanation (anatomical anomalies, ampullary or main pancreatic strictures, trauma, viral infection, gallstones, alcohol, drugs, hyperlipidaemia, etc.)
- Unexplained chronic pancreatitis
- A family history of pancreatitis in a first- or second-degree relative
- Unexplained episode of pancreatitis in a child that required hospitalization

Predictive (presymptomatic) genetic testing of unaffected relatives is considered more complex. Predictive testing is recommended only for individuals with a first-degree relative with a defined HP gene mutation, and who are over 16 years of age and capable of making an independent and fully informed decision (Ellis et al., 2001).

American Society of Clinical Oncology (ASCO)

The ASCO states that "genetic testing is sometimes considered for patients who develop recurrent pancreatitis at young ages. Genetic testing is available for mutations in the *PRSS1, SPINK1*, and *CFTR* genes." However, the authors note that "it is unknown if mutations in these genes cause an increased risk of pancreatic cancer. The authors believe that other genes may be associated with HP, and studies are ongoing to learn more about this condition" (ASCO, 2021). It is also noted that "Screening for pancreatic cancer is suggested for people known to have HP beginning at age 40, 20 years after the onset of pancreatitis, or 10 years before the youngest pancreatic cancer diagnosis in the family, whichever is earliest. However, the effectiveness of current screening

techniques for the early diagnosis of pancreatic cancer is not proven." Nevertheless, the most commonly used screening tests include magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) (ASCO, 2021).

American College of Gastroenterology (ACG)

In 2013, the ACG issued guidelines for the management of acute pancreatitis. They include the following recommendation: "genetic testing may be considered in young patients (< 30 years old) if no cause is evident and a family history of pancreatic disease is present (conditional recommendation, low quality of evidence)." ACG also states that "the role of genetic testing in AP has yet to be determined, but may be useful in patients with more than one family member with pancreatic disease. Individuals with IAP and a family history of pancreatic diseases should be referred for formal genetic counseling" (Tenner et al., 2013).

In 2020, the ACG published clinical guidelines on chronic pancreatitis. There, they state that "In patients with clinical features of CP, a comprehensive review of all risk factors should be performed. This provides information on the underlying mechanisms, identifies both fixed and modifiable risk factors, identifies potential targets for therapies, and provides clinically relevant prognostic information." As part of that initial approach, they recommend genetic testing in patients "with clinical evidence of a pancreatitis-associated disorder or possible CP [chronic pancreatitis] in which the etiology is unclear, especially in younger patients (strong recommendation, low quality of evidence)." The guideline goes on to state that "at minimum, patients with idiopathic CP should be evaluated for *PRSS1*, *SPINK1*, *CFTR*, and *CTRC* gene mutation analysis…" The guideline mentions that assessment of germline mutations is primarily for prognostic and therapeutic purposes, rather than diagnostic (Gardner et al., 2020).

United European Gastroenterology (UEG)

The United European Gastroenterology published evidence-based guidelines for the diagnosis and therapy of chronic pancreatitis which recommend (Lohr et al., 2017):

"All patients with a family history or early onset disease (<20 years) should be offered genetic testing for associated variants."

"Genetic screening for every CP patient cannot be recommended since alcohol abuse is the predominant cause of the disease in up to 60% of adult cases."

"In patients with early onset CP, genetic screening can be offered after informed consent."

"In patients with alcoholic CP, routine genetic testing cannot be recommended."

The working group also noted that "variants in *SPINK1* and *CTRC*, and to a lesser extent, common single-nucleotide polymorphisms (SNPs) in the *PRSS1* and CLDN2-MORC4 loci, are associated with alcoholic CP" (Lohr et al., 2017).

European Pancreatic Club (EPC) and Hungarian Pancreatic Study Group (HPSG)

The European Pancreatic Club, in collaboration with the Hungarian Pancreatic Study Group, organized a consensus guideline meeting on the diagnosis and management of pancreatitis in the pediatric population which state the following:

"Pediatric AP and RAP often develop in the background of genetic susceptibility and genetic testing is warranted in patients with a second episode of idiopathic AP or first episode of idiopathic AP and a family history of AP or CP. Full sequence analysis of *PRSS1*, *SPINK1*, *CTRC*, *CPA1* and *CFTR* gene exons and exon-intron boundaries and testing for the pathogenic CEL hybrid allele are recommended". The authors go further to mention that "Variants in the *PRSS1* and *CPA1* genes may be associated with a family history of pancreatitis or even autosomal dominant hereditary pancreatitis. Children with a single episode of AP are at risk for developing a second episode. However, genetic testing is cumbersome and expensive. There is usually no therapeutic consequence, but it may assist in long term prognosis" (Parniczky et al., 2018).

"The presence of mutations in the above mentioned genes increases the risk of ARP and CP. Hereditary pancreatitis associated with mutations in *PRSS1*, especially p.R122H, that could considerably increase the risk of pancreatic adenocarcinoma. Knowing the genetic risk factors may not alter the therapy, but it helps to understand the disease's etiological background for the disease and may lead to future targeted investigation" (Parniczky et al., 2018).

Regarding the etiological factors in childhood onset CP, the authors assert that "Genetic variations are the most common risk factors for development of pediatric CP. *(GRADE 1/A, full agreement)* However, other risk factors such as obstruction, autoimmune and toxic and metabolic factors also need to be examined. *(GRADE 2/B, full agreement)*". Moreover, as "There is an association between CP and cystic fibrosis (CF), therefore a sweat test should be performed to screen for CF as a possible etiological factor in children. *(GRADE 1/A, strong agreement)*" (Parniczky et al., 2018).

International Study Group of Pediatric Pancreatitis: In search for a cuRE (INSPPIRE) Consortium

This group was formed "to collect detailed information on a cohort of children with ARP and CP with the aim to fill gaps in knowledge and improve clinical care." Their genetic testing-related guidelines are listed below:

- "The search for a genetic cause of ARP or CP should include a sweat chloride test (even if newborn screening for cystic fibrosis (CF) is negative) and *PRSS1* gene mutation testing. Genetic testing for CF should be considered if a sweat test is unable to be performed."
- "Mutation analysis of the genes *SPINK1*, *CFTR* and *CTRC* may identify risk factors for ARP or CP."
- "Patients with ARP or CP and a sweat test <=60 mmol/L should have expanded *CFTR* mutation testing done if there is no other identified cause of their pancreatic disease (such as a *PRSS1* mutation or a clear obstructive etiology)" (Gariepy et al., 2017).

National Comprehensive Cancer Network (NCCN)

The NCCN notes familial pancreatitis and non-hereditary forms of pancreatitis are both linked with an increased risk of pancreatic cancer. Additionally, chronic pancreatitis is another risk factor for pancreatic cancer. The NCCN specifically lists *PRSS1*, *SPINK1*, and *CFTR* as contributing genes to familial pancreatitis. The approximate increase in risk of pancreatic cancer is somewhere between 26-fold and 87-fold in those with the *PRSS1*, *SPINK1*, and *CFTR* gene mutations (NCCN, 2023).

International Association of Pancreatology, American Pancreatic Association, Japan Pancreas Society, and European Pancreatic Club

In 2020, the International Association of Pancreatology, the American Pancreatic Association, the Japan Pancreas Society, and European Pancreatic Club released a set of international consensus guidelines on surveillance for pancreatic cancer in the setting of chronic pancreatitis. Though the working group did not explicitly endorse or oppose genetic testing, it was clear that due to the recommendations separated by genetic variants within chronic pancreatitis, genetic testing would become critical for surveillance. With regards to the conditions by which hereditary pancreatitis would warrant surveillance for cancer, the working group stated:

- "The risk of pancreatic cancer in affected individuals with an autosomal dominant history of hereditary pancreatitis due to inherited *PRSS1* mutations is high enough to justify surveillance. *Quality assessment: high; recommendation: strong*"
- "The risk of pancreatic cancer in affected individuals with an autosomal dominant history of hereditary pancreatitis but without *PRSS1* mutations is high enough to justify surveillance. *Quality assessment: moderate; recommendation: weak*"
- "The risk of pancreatic cancer in patients with chronic pancreatitis associated with *SPINK1* p. N34S is not high enough to justify screening or surveillance. *Quality assessment: moderate; recommendation: strong*"

- "The risk of pancreatic cancer in patients with chronic pancreatitis associated with other germline mutations including those of *CFTR, CTRC, CPA1, and CEL*, is not high enough to justify screening or surveillance. *Quality assessment: moderate; recommendation: conditional*" (Greenhalf et al., 2020).

National Institute for Health and Care Excellence (NICE)

NICE updated their guidelines on pancreatitis in December 2020. With regards to genetic testing for hereditary pancreatitis (acute) and patient information, NICE stated the following:

"Give people with pancreatitis, and their family members or carers (as appropriate), written and verbal information on the following, where relevant, as soon as possible after diagnosis:

- pancreatitis and any proposed investigations and procedures, using diagrams
- hereditary pancreatitis, and pancreatitis in children, including specific information on genetic counselling, genetic testing, risk to other family members, and advice on the impact of their pancreatitis on life insurance and travel
- the long-term effects of pancreatitis, including effects on the person's quality of life
- the harm caused to the pancreas by smoking or alcohol."

For an individual with chronic pancreatitis, NICE recognizes that the cause may not be alcohol-related, but can include "genetic factors; autoimmune disease, in particular IgG4 disease; metabolic causes; [and] structural or anatomical factors" (NICE, 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory

Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81222	CFTR (cystic fibrosis transmembrane conductance regulator) (eg, cystic fibrosis) gene analysis; duplication/deletion variants
81223	CFTR (cystic fibrosis transmembrane conductance regulator) (eg, cystic fibrosis) gene analysis; full gene sequence
81224	CFTR (cystic fibrosis transmembrane conductance regulator) (eg, cystic fibrosis) gene analysis; intron 8 poly-T analysis (eg, male infertility)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81479	Unlisted molecular pathology procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Inherited Cardiomyopathies and Channelopathies

Policy Number: AHS – M2025 – Genetic Testing for Inherited Cardiomyopathies and Channelopathies	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Cardiomyopathies are diseases of the heart muscle. These conditions are frequently genetic and do not include muscle abnormalities caused by coronary artery disease, hypertension, valvular disease, and congenital heart disease. Symptoms include arrhythmia, cardiac dysfunction, and heart failure (Cooper Jr, 2022).

Channelopathies, also known as primary electrical disease, are a group of cardiac diseases caused by genetic defects in ion channels of the heart leading to arrhythmias, syncope, and the risk of sudden cardiac death (SCD) (Campuzano et al., 2015).

II. Related Policies

Policy Number	Policy Title
AHS-M2180	Genetic Markers for Assessing Risk of Cardiovascular Disease

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic counseling **IS REQUIRED** for individuals prior to and after undergoing genetic testing for diagnostic, carrier, and/or risk assessment purposes.

2) Sequencing of long QT syndrome (LQTS)-associated genes **MEETS COVERAGE CRITERIA** for the following:
   a) For individuals who have had a syncopal event and who have a Schwartz score greater than 1.
   b) For individuals for whom a cardiologist has a strong clinical suspicion of LQTS based on the individual's clinical history, family history, and electrocardiogram (ECG) findings (e.g., Schwartz score greater than or equal to 3.5).
   c) For individuals with QT prolongation (QTc greater than 480 ms for prepubescent individuals, QTc greater than 500 ms for postpubescent individuals) in the absence of other clinical conditions that might prolong the QT interval (e.g., electrolyte abnormalities, hypertrophy, bundle branch block).
   d) For individuals with a close relative (see Note 1) with confirmed LQTS and for whom the familial mutation is not known.
3) For close relatives (see Note 1) of an individual with a documented LQTS-causing mutation, testing for the known familial likely pathogenic or pathogenic variant **MEETS COVERAGE CRITERIA**.
4) For individuals with a negative sequence analysis where the clinical suspicion of congenital LQTS remains high based on a Schwartz score greater than 1, genetic testing for LQTS with duplication/deletion analysis **MEETS COVERAGE CRITERIA**.
5) Genetic testing for catecholaminergic polymorphic ventricular tachycardia (CPVT) **MEETS COVERAGE CRITERIA** in the following situations:
   a) For individuals who have a close relative (see Note 1) with a known CPVT likely pathogenic or pathogenic variant.
   b) For individuals who have a close relative (see Note 1) diagnosed with CPVT by clinical means but whose genetic status is unavailable.
   c) For individuals with signs and/or symptoms indicating a moderate-to-high pretest probability of CPVT, but for whom a definitive diagnosis cannot be made without genetic testing.
   d) For individuals who display exercise-, catecholamine-, or emotion-induced PVT or ventricular fibrillation in a structurally normal heart.
6) Genetic testing for Brugada syndrome **MEETS COVERAGE CRITERIA** in the following situations:
   a) For individuals with signs and/or symptoms consistent with Brugada Syndrome but for whom a definitive diagnosis cannot be made without genetic testing.

b) For individuals who have a close relative (see Note 1) with a known Brugada Syndrome likely pathogenic or pathogenic variant.

7) Sequencing of short QT syndrome (SQTS)-associated genes **MEETS COVERAGE CRITERIA** for the following:

   a) For individuals for whom a cardiologist has a strong clinical suspicion of SQTS based on the individual's clinical history, family history, and ECG findings (e.g., abnormally short QT intervals [less than or equal to 360 ms in males; less than or equal to 370 ms in females], an increased propensity to develop atrial and ventricular tachyarrhythmia in the absence of structural heart disease).

   b) Testing for the known familial likely pathogenic or pathogenic variant in asymptomatic individuals with a close relative (see Note 1) with a known SQTS likely pathogenic or pathogenic variant.

8) For individuals with dilated cardiomyopathy and significant cardiac conduction disease (i.e., first-, second-, or third-degree heart block) and/or who have one or more family members who experienced sudden cardiac death or developed unexplained heart failure before 60 years of age, genetic testing for dilated cardiomyopathy **MEETS COVERAGE CRITERIA**.

9) In asymptomatic close relatives (see Note 1) of an affected individual, genetic testing for a known familial likely pathogenic or pathogenic variant associated with dilated cardiomyopathy **MEETS COVERAGE CRITERIA**.

10) Genetic testing for arrhythmogenic right ventricular cardiomyopathy (ARVC) **MEETS COVERAGE CRITERIA** in the following situations:

   a) For individuals with signs and/or symptoms consistent with ARVC but for whom a definitive diagnosis cannot be made without genetic testing.

   b) For individuals who have a close relative (see Note 1) with a known ARVC likely pathogenic or pathogenic variant.

11) In asymptomatic close relatives (see Note 1) of an affected individual, genetic testing for a known familial likely pathogenic or pathogenic variant associated with progressive cardiac conduction disease (CCD or Lev-Lenegre disease) **MEETS COVERAGE CRITERIA**.

12) In asymptomatic close relatives (see Note 1) of an affected individual, genetic testing for a known familial likely pathogenic or pathogenic variant associated with restrictive cardiomyopathy (RCM) **MEETS COVERAGE CRITERIA**.

13) Genetic testing for left ventricular noncompaction (LVNC) **MEETS COVERAGE CRITERIA** in the following situations:

   a) For individuals with signs and/or symptoms consistent with LVNC but for whom a definitive diagnosis cannot be made without genetic testing.

   b) For individuals who have a close relative (see Note 1) with a known LVNC likely pathogenic or pathogenic variant.

14) For individuals who meet the diagnostic criteria for hypertrophic cardiomyopathy (HCM), genetic testing for predisposition to HCM **MEETS COVERAGE CRITERIA**.

15) For individuals who have a first-degree relative with established HCM, genetic testing for the known familial likely pathogenic or pathogenic variant **MEETS COVERAGE CRITERIA**.

16) For individuals with a family history of HCM in which a first-degree relative with HCM has tested negative for likely pathogenic or pathogenic variants, genetic testing for a predisposition to HCM **DOES NOT MEET COVERAGE CRITERIA**.

17) For symptomatic individuals with a Schwartz score less than or equal to 1, genetic testing for LQTS **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

18) For individuals with known LQTS, genetic testing for LQTS to determine prognosis and/or direct therapy **DOES NOT MEET COVERAGE CRITERIA**.

19) For all other situations when the above criteria are not met, genetic testing for LQTS or CPVT **DOES NOT MEET COVERAGE CRITERIA**.

20) For all other situations not meeting the criteria outlined above, genetic testing for Brugada Syndrome **DOES NOT MEET COVERAGE CRITERIA**.

21) For all other situations not meeting the criteria outlined above, genetic testing for SQTS **DOES NOT MEET COVERAGE CRITERIA**.

22) Genetic testing for Early Repolarization "J-wave" Syndrome, Sinus Node Dysfunction (SND), and/or other rhythm disorders **DOES NOT MEET COVERAGE CRITERIA**.

23) For all other individuals, genetic testing for a predisposition to HCM **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Close blood relatives include first-degree relatives (e.g., parents, siblings, and children), second-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings), and third-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins).

IV. Table of Terminology

Term	Definition
ACC	American College of Cardiology
ACM	Arrhythmic cardiomyopathy
ACCF	American College of Cardiology Foundation
ACMG	American College of Medical Genetics and Genomics
ACTA2	*Actin alpha 2, smooth muscle gene*
ACTC1	*Actin alpha cardiac muscle 1 gene*
AF	Atrial fibrillation
APHRS	Asia Pacific Heart Rhythm Society
APOB	*Apolipoprotein B gene*
ARVC	Arrhythmogenic right ventricular cardiomyopathy
ARVC/D	Arrhythmogenic right ventricular cardiomyopathy/dysplasia
BrS	Brugada syndrome
CASQ2	*Calsequestrin 2 gene*
CCD	Cardiac conduction disease
CLQTS	Congenital long QT syndrome
COL3A1	*Collagen type III alpha 1 chain gene*
CPVT	Catecholaminergic polymorphic ventricular tachycardia
DCM	Dilated cardiomyopathy
DSC2	*Desmocoilin 2 gene*
DSG2	*Desmoglein 2 gene*
DSP	*Desmoplakin gene*
ECG	Electrocardiogram
ECS	European Society of Cardiology
EHRA	European Heart Rhythm Association
ER	Early repolarization
FBN1	*Fibrillin-1 gene*
FLNC	*Filamin C gene*
HCM	Hypertrophic cardiomyopathy

HF	Heart failure
HFSA	Heart Failure Society of America
HRS	Heart Rhythm Society
IVF	Idiopathic ventricular fibrillation
KCNE1	*Potassium voltage-gated channel subfamily E regulatory subunit 1 gene*
KCNE2	*Potassium voltage-gated channel subfamily E regulatory subunit 2 gene*
KCNH2	*Potassium voltage-gated channel subfamily H member 2 gene*
KCNQ1	*Potassium voltage-gated channel subfamily Q member 1 gene*
LDLR	*Low density lipoprotein receptor gene*
LMNA	*Lamin A/C gene*
LQTS	Long QT syndrome
LV	Left ventricle
LVH	Left ventricular hypertrophy
LVNC	Left ventricular noncompaction
MYBPC3	*Myosin binding protein C3 gene*
MYH7	*Myosin heavy chain 7 gene*
MYH11	*Myosin heavy chain 11 gene*
MYL2	*Myosin light chain 2 gene*
MYL3	*Myosin light chain 3 gene*
PCCD	Progressive cardiac conduction disease
PCSK9	*Proprotein convertase subtilisin/kexin type 9 gene*
PKP2	*Plakophilin 2 gene*
PRKAG2	*Protein kinase AMP-activated non-catalytic subunit gamma 2 gene*
RCM	Restrictive cardiomyopathy
RYR2	*Ryanodine receptor 2 gene*
SCA	Sudden cardiac arrest
SCD	Sudden cardiac death
SCN5A	*Sodium voltage-gated channel alpha subunit 5 gene*
SMAD3	*SMAD family member 3 gene*
SND	Sinus node dysfunction
SUDS	Sudden unexplained death syndrome
SQTS	Short QT syndrome
TGFBR1	*Transforming growth factor beta receptor 1 gene*
TGFBR2	*Transforming growth factor beta receptor 2 gene*
TMEM43	*Transmembrane protein 43 gene*
TNNI3	*Troponin I3, cardiac type gene*

TNNT2	*Troponin T2, cardiac type gene*
TPM1	*Tropomyosin 1 gene*
TRDN	*Triadin gene*
TTN	*Titin gene*
WGS	Whole genome sequencing

V. Scientific Background

Cardiomyopathies

In 1995, the World Health Organization (WHO) divided cardiomyopathies into five categories: dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D), and unclassified cardiomyopathies. Cardiomyopathies have a variety of genotypes and phenotypes that typically require echocardiographic evaluation. Either phase of the heartbeat (systole or diastole) may be affected by cardiomyopathies (Cooper Jr, 2022).

Systolic dysfunction is usually characterized by a decrease in myocardial contractility. This decrease causes a reduction in the ejection fraction of the left ventricle (LV), thereby forcing one of two compensatory mechanisms; either the LV itself increases in size (leading to larger stroke volume) or the contractility of the heart increases in response to increased stretch. However, these compensatory mechanisms will eventually fail, leading to physiological manifestations of heart failure. This dysfunction is often seen in DCM, as well as some HCM patients (Cooper Jr, 2022).

Diastolic dysfunction refers to abnormal LV relaxation and filling, as well as elevated filling pressures. As with systolic dysfunction, the primary issue with diastole is caused by abnormal contractility of the heart muscle. The contractility of the myocardium influences both the LV relaxation phase (the isovolumetric period between the aortic valve's close and mitral valve's opening) and passive compliance phase (variable pressure, starting at mitral valve's opening) of diastole. Due to the impaired contractility of the myocardium, the pressure in each phase is abnormal. Dysfunction in this phase is often seen in HCM, RCM, and DCM (Cooper Jr, 2022).

Hypertrophic cardiomyopathy (HCM)

Hypertrophic cardiomyopathy (HCM) is a commonly inherited cardiovascular disease defined as thickening of the ventricular wall resulting from more than 1500 mutations in 11 or more genes encoding proteins of the cardiac sarcomere (Maron, 2022).

Hypertrophic cardiomyopathy (HCM) is characterized by left ventricular hypertrophy (LVH, thickness of ≥15 mm), observed by echocardiography or magnetic resonance imaging and not otherwise explainable by other cardiovascular issues, such as coronary artery disease, hypertension, valvular disease, and congenital heart disease. Development of LVH usually starts in adolescence and is complete by early adulthood. Symptoms include chest pain, dyspnea and syncope, and severe disease can lead to disabling complications, including heart failure and malignant ventricular arrhythmias. However, many patients with HCM are asymptomatic or have minimal symptoms and are only discovered through means such as family screenings or an abnormal ECG (Maron, 2022). HCM is the most frequent cause of sudden death in young people and can lead to functional disability from heart failure and stroke (Maron, 2003). HCM has a prevalence of approximately 1 in 500 people (Maron et al., 1995). However, estimates of clinically expressed HCM plus gene carriers are as high as 1 in 200 (Semsarian et al., 2015).

More than 90% of HCM is inherited as an autosomal-dominant disease with variable expressivity and age-related penetrance (Frustaci et al., 2018). Currently, relevant genetic abnormalities can be detected in approximately 60 percent of patients with clinically documented HCM (Cirino et al., 2017; Maron et al., 2012). Most of the genetic mutations associated with HCM are found in the genes encoding various proteins that make up the cardiac sarcomere, the basic contractile unit of cardiac myocytes. More than 1500 pathogenic variants have been identified in at least 11 different genes (Cirino, 2014; Maron et al., 2012). Mutations in myosin heavy chain (*MYH7*) and myosin-binding protein C (*MYBPC3*) are the most common and account for roughly 70 percent of HCM. Other genes implicated in HCM are regulatory myosin light chain (*MYL2*) and cardiac troponin T (*TNNT2*). Non-sarcomeric genes encoding plasma membrane or mitochondrial proteins, or Z-disc encoding genes, have also been documented (Frustaci et al., 2018).

Wide phenotypic variability exists, ranging from asymptomatic to severe life-threatening heart failure even within the same mutation. This variability in clinical expression may be related to environmental factors and modifier genes (Alcalai et al., 2008). Moreover, no strong correlation between left ventricular problems and symptoms exists; patients with major obstructions or hypertrophy may be asymptomatic and vice versa. The primary characteristic of LVH is present in multiple conditions, such as systemic hypertension, Fabry disease, aortic stenosis, and more. Such conditions should be excluded before a diagnosis of HCM is made (Maron, 2022).

Diagnostic screening of first-degree relatives is important to identify at-risk patients. Guidelines have been established for clinically unaffected relatives of affected individuals. Clinical screening with physical examination, electrocardiography, and

echocardiography is recommended every 12 to 18 months for individuals between the ages of 12 to 18 years and every three to five years for adults with additional screening recommended for any change in symptoms (Gersh et al., 2011).

Dilated cardiomyopathy (DCM)

Dilated cardiomyopathy (DCM) is characterized by dilation and impaired contraction of one or both ventricles. The dilation often becomes severe and is invariably accompanied by an increase in total cardiac mass. Affected patients have impaired systolic function and clinical presentation is usually with features of heart failure (Cooper Jr, 2022).

Dilated cardiomyopathy is caused by a variety of disorders. The cause is unknown for over 50% of patients with the disease. Familial dilated cardiomyopathy is caused by a genetic mutation in 20-35% with the disease. DCM is transmitted primarily in an autosomal dominant inheritance pattern. Mutations in over 30 genes have been determined to cause familial dilated cardiomyopathy (Hershberger, 2023).

Other common causes for DCM include (AHA, 2024) coronary heart disease, heart attack, high blood pressure, diabetes, thyroid disease, viral hepatitis and HIV, infections, especially viral infections that inflame the heart muscle, alcohol, complications during the last month of pregnancy or within five months of birth, certain toxins such as cobalt, certain drugs (such as cocaine and amphetamines) and two medicines used to treat cancer (doxorubicin and daunorubicin).

Genetic forms of dilated cardiomyopathy are diagnosed by family history and molecular testing. Genes associated with familial dilated cardiomyopathy include *MYH7, MYBPC3, TNNT2, TNNC1, TNNI3, TPM1, MYL2, MYL3, ACTC1, ACTN2, CSRP3, PLN, TTR, PRKG2, LAMP2, GLA, LMNA, BAG3, RBM20, SCN5A, DES, DSC2, DSG2, DSP, JUP, PKP2, RYR2, TMEM43*, and *TTN* (Hershberger et al., 2018).

The frequencies of DCM mutations in any one gene are low (<1% to 6-8%), and a genetic cause is identified in only 30-35% of familial DCM cases. Therefore, routine genetic testing for DCM was only recommended in familial disease (≥2 affected family members) (Yancy et al., 2013). However, as molecular genetic testing laboratories offer DCM genetic testing panels of 12-30 genes utilizing next-generation sequencing methods, testing sensitivity now ranges from 15-25%, has become standard of care (M. J. Ackerman et al., 2011; Hershberger, 2023; Hershberger et al., 2009; Hershberger et al., 2010; Hershberger & Siegfried, 2011).

Guidelines now recommend testing for all patients with cardiomyopathy even if no other disease is evident in the family. Genetic testing is clinically useful in the management of affected individuals, as well as to assess risk in relatives (Hershberger et al., 2018). *LMNA* mutations are associated with high rates of conduction system

disease, ventricular arrhythmias, and sudden cardiac death (SCD), and may consequently lower the threshold for prophylactic ICD implantation. DCM patients with a variant of the *SCN5A* gene exhibit a phenotype associated with significant arrhythmias and frequent premature ventricular complexes. Although such patients responded poorly to conventional HF therapy, treatment with sodium channel blocking drugs produced a dramatic reduction in ectopy and normalization of left ventricular (LV) function (Japp et al., 2016).

Restrictive cardiomyopathy (RCM)

Restrictive cardiomyopathy (RCM) differs from other cardiomyopathies in that there may not be many physical abnormalities (i.e., no dilation or hypertrophy). However, the ventricular filling process is still significantly impaired. RCM may be difficult to see on two-dimensional imaging, and assessment of flow velocity across the mitral valve is more accurate in detecting these filling abnormalities (Cooper Jr, 2022). Some cases of RCM are secondary to a more apparent cardiac condition. However, idiopathic cases of RCM are generally genetic conditions. Pathogenic mutations in sarcomeric or cytoskeletal genes such as *TNNI3, TNNT2,* and *TPN1* have been linked to familial RCM (Ammash, 2024).

Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D)

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is characterized by changes in myocardium of the right (and often left as well) ventricular free wall. This myocardium is replaced by fibrous or fibro-fatty tissue, causing dysfunction of the affected ventricles (Cooper Jr, 2022). At the molecular level, the desmosomes are typically impaired due to genetic mutations. This causes the mechanical stress of the heart to detach myocytes, which eventually leads to their death. The initial repair mechanisms of this detachment are what produces the fibrous tissue. Up to 30% of ARVC cases are familial, and mutations in gene products such as plakoglobin and desmoplakin have been associated with ARVC (McKenna, 2024).

Unclassified Cardiomyopathies

Other types of cardiomyopathies that do not fall into one of the other four categories are considered "unclassified." For example, left ventricular noncompaction (LVNC) falls in this category due to its characteristic myocardial wall; the myocardial wall consists of "prominent trabeculae and deep intertrabecular recesses", thereby resulting in two layers of myocardium of different thickness. This condition may be sporadic or familial; up to 50% of LVNC cases are familial. Genes such as alpha-dystrobrevin or other sarcomeric genes may contribute to LVNC (Attenhofer-Jost & Connolly, 2022).

This category also includes cardiomyopathies such as stress-induced cardiomyopathy and cirrhotic cardiomyopathy (Cooper Jr, 2022).

Clinical Utility and Validity (Cardiomyopathies)

A study by Cirino et al. (2017) compared the results from panel genetic testing to whole genome sequencing (WGS). Forty-one patients with HCM who had undergone targeted genetic testing (either multigene panel or familial variant test) were recruited into a clinical trial of WGS. Panel size ranged from 4-62 genes, and all but two subjects were tested for the main eight sarcomeric genes (*MYH7, MYBPC3, TNNT2, TPM1, MYL2, MYL3, TNNI3, ACTC*). The authors stated that WGS detected nearly all variants identified on panel testing and allowed further analysis of posited disease genes. Several variants of uncertain clinical use and other genetic findings were also identified. Panel testing and WGS provided similar results, but WGS provides reanalysis over time; however, WGS also requires genomic expertise to correctly interpret results (Cirino et al., 2017).

A study focusing on the non-sarcomeric genes contributing to HCM was performed by Walsh et al. (2017). A reference sample of 60,706 exomes were analyzed and compared to 6,179 HCM cases. This comparison revealed many gene variants in the main eight sarcomeric genes (*MYH7, MYBPC3, TNNT2, TPM1, MYL2, MYL3, TNNI3, ACTC1*) but very few variants of the non-sarcomeric genes in HCM cases. The authors concluded the variation in most of the non-sarcomeric genes does not affect HCM significantly as 99% of HCM pathogenic variants were found to be in the main eight sarcomeric genes. Four non-sarcomeric genes were found to have an excess of variants, but even these amounted to only 2% of the HCM cases overall; the other 26 non-sarcomeric genes examined were found to have very little or no excess variation over the reference sample of exomes. Furthermore, the authors state that only the well-known variants are symptomatic whereas the other variants are of unknown significance or benign, making clinical sequencing of limited use. The authors recommended that the only genes tested should be the eight sarcomeric genes, the metabolic cardiomyopathy genes, and possibly *ACTN2* and *MYOZ2* (Walsh et al., 2017).

Bhonsale et al. (2015) assessed the impact of genotype on clinical outcomes of ARVC patients. Pathogenic mutations were evaluated in 577 patients. The investigators found that patients with a *desmoplakin*-associated mutation had an over four-fold occurrence of left ventricular (LV) dysfunction and heart failure than *PKP2* carriers. No significant difference was found between clinical outcomes of patients with missense mutations and patients with truncating or splice site mutations. Patients with multiple mutations had more severe symptoms, such as lower survival rate without ventricular fibrillation or tachycardia, more frequent LV dysfunction, heart failure, cardiac transplant, and earlier occurrence of sustained ventricular fibrillation and tachycardia, as compared to those with only one mutation (Bhonsale et al., 2015).

Kostareva et al. (2016) evaluated the "genetic spectrum" of idiopathic RCM. The authors screened for 108 cardiomyopathy and arrhythmia-associated genes in 24 patients with idiopathic RCM. They found pathogenic and "likely-pathogenic" variants in 13 of the 24 patients (54%), and half of these genotype-positive patients carried a combination of pathogenic variants, likely-pathogenic variants, and variants of unknown significance. The most frequent combination included mutations in sarcomeric and cytoskeletal genes (Kostareva et al., 2016).

Kayvanpour et al. (2017) evaluated the genetic-phenotype associations for DCM. The study included 48 studies encompassing 8097 patients, and the authors investigated mutations in *LMNA, PLN, RBM20, MYBPC3*, *MYH7, TNNT2* and *TNNI3*. The authors results were as follows: "The average frequency of mutations in the investigated genes was between 1 and 5 %. The mean age of DCM onset was the beginning of the fifth decade for all genes. Heart transplantation (HTx) rate was highest in *LMNA* mutation carriers (27 %), while *RBM20* mutation carriers were transplanted at a markedly younger age (mean 28.5 years). While 73 % of DCM patients with *LMNA* mutations showed cardiac conduction diseases, low voltage was the reported ECG hallmark in *PLN* mutation carriers. The frequency of ventricular arrhythmia in DCM patients with *LMNA* (50 %) and *PLN* (43 %) mutations was significantly higher. The penetrance of DCM phenotype in subjects with *TTN* truncating variants increased with age and reached 100 % by age of 70" (Kayvanpour et al., 2017).

Genetic testing has been recognized as a valuable part of diagnosis and classification in pediatric cardiomyopathy. Lipshultz et al. (2019) identified a single-center study of 63 children with cardiomyopathy that reported that 42% of the illness could be attributed to a genetic cause, as defined by the presence of an affected first-degree family member having tested positive for an HCM or DCM gene panel mutation. However, it was noted that though the morphofunctional phenotype in children may be similar to those of adults, the causes and proportion resulting from them differ. These differences are believed to be neuromuscular, metabolic, mitochondrial, and syndromic causes also playing important roles in children. Lipshultz et al. (2019) identified another study to corroborate this finding: in 916 children with an identified case of cardiomyopathy, an underlying metabolic or syndromic cause was present in more than a third, and a metabolic or syndromic cause was present in 40% to 50% of 61 children with HCM and 8% of 1731 children with DCM in the Pediatric Cardiomyopathy Registry (Lipshultz Steven et al., 2019).

Parker and Landstrom (2021) reviewed current literature on what role genetic testing play in diagnosing and managing patients and families with a history of pediatric CM. With relation to HCM, the researchers identified multiple studies demonstrating that patients with "sarcomere variants tend to be more severely affected than patients with

non-sarcomeric variants" and "within the sarcomere genes, some argue that specific sarcomere variants are inherently more pathogenic than others." On top of that, there appear to be some other genetic and environmental factors that influence the HCM phenotype in each patient, thus indicating that the genotype-phenotype correlation could greatly affect the clinical course and prognosis. Especially for metabolic forms of HCM and patients with a clear genetic etiology, treatment may be adopted based on these genetic findings; for instance, "in *GAA*- positive Pompe disease, alpha-glucosidase enzyme replacement therapy is associated with HCM reversal in affected children" (Parker & Landstrom, 2021).

Similar concepts were mentioned for DCM, as some genotypes yielded worse phenotypes. For example, "*TNNC1* variants are associated with early onset DCM, and increased rates of heart transplant and SCD compared to other genes." Gene therapy could also be explored as an option, such as for Duchenne muscular dystrophy, to "target and rescue functional expression of pathogenic variants." For arrhythmic cardiomyopathy (ACM), Parker and Landstrom (2021) specifically mention how confirming an ACM diagnosis via genetic testing "versus an arrhythmic syndrome secondary to a cardiac channelopathy" could aid clinical management. Variants in the *PKP2* and *TMEM43* genes have been found to be associated with exercise-induced disease progression and risk of sudden cardiac arrest (SCA), so this could impact chosen involvement in sports (Parker & Landstrom, 2021).

Grondin et al. (2022) studied the clinical utility of genetic testing in unexplained cardiac arrest. The study included 228 unexplained cardiac arrest survivors. Whole exome sequencing was performed on each participant to identify pathogenic or likely-pathogenic variants. In total, 23 of the 228 participants (10%) had a pathogenic or likely-pathogenic variant. Genetic testing increased the proportion of "explained" cases from 9%, with only phenotyping, to 18%, with phenotyping and WES. "The majority of disease-causing variants was located in cardiomyopathy-associated genes, highlighting the arrhythmogenic potential of such variants in the absence of an overt cardiomyopathy diagnosis" (Grondin et al., 2022).

Cardiac Ion Channelopathies

The electromechanical pumping action of the heart maintains circulation and ensures the delivery of blood and nutrients to all organs to support their normal function. Synchronized contraction of the myocardium is necessary to generate sufficient pressure to drive blood flow (Voorhees & Han, 2015). Mechanical contraction of cardiac myocytes is coordinated by the generation and propagation of an action potential (Fernandez-Falgueras et al., 2017) through the synergistic activation and inactivation of several voltage-dependent ion channels. Membrane depolarization

during the action potential leads to the opening of the voltage-gated calcium channels resulting in an inward current, followed by the efflux of potassium ions, generation of an outward current, and cell repolarization (Garcia-Elias & Benito, 2018). Action potential duration is determined by the magnitude and timing of inward and outward currents (Kirk & Kass, 2015). Differential expression, selectivity, and gating properties of cardiac ion channels in distinct regions of the heart promote unidirectional propagation of electrical activity (Fernandez-Falgueras et al., 2017).

Mutations in genes encoding these specific channels or associated proteins may impair ionic conduction resulting in changes in action potential, synchronization, and/or propagation of electrical impulse and predispose to potentially malignant arrhythmias (Nerbonne & Kass, 2005; Roden et al., 2002). Dyssynchronous contraction of the ventricle, arising from electrical activation delays, also significantly worsens morbidity and mortality in heart failure (HF) patients (Kirk & Kass, 2015). Ion channelopathies have been identified as a significant cause of sudden cardiac death (SCD) in patients with structurally normal hearts (Campuzano et al., 2015; Magi et al., 2017), and some cases of otherwise unexplained stillbirth (Munroe et al., 2018).

Patients can show early symptoms of palpitations or hemodynamic compromise, including dizziness, seizure, or syncope, particularly following exertion; however, in many cases SCD is the only sign of cardiac trouble (Martin et al., 2013). Electrical disturbances in the heart rhythm that can be detected on electrocardiogram (ECG) of some patients with channelopathies result in diagnosis of:

- Long QT Syndrome (LQTS) is characterized by prolonged ventricular repolarization and electrocardiographic prolongation of the QT interval (QTc ≥ 480 ms in repeated 12-lead ECG, although a QTc ≥ 460 ms is sufficient in the presence of unexplained syncope). The variable clinical manifestations of LQTS range from asymptomatic patients diagnosed through family screening, to SCD, syncope, convulsions, malignant ventricular arrhythmias, VF, and *torsade de pointes* (Fernandez-Falgueras et al., 2017). The prevalence of LQTS in infants is approximately 1 in 2000 (Schwartz et al., 2009).
    - Diagnosis of LQTS is made using the Schwartz Score, which indicates high probability of LQTS with a score ≥3.5. The table of diagnostic criteria is shown below (Schwartz & Crotti, 2011):

Electrocardiographic findings #	
A QTc^	
≥480 ms	3
460–479 ms	2
450–459 ms (in males)	1
B QTc^ 4th minute of recovery from exercise stress test ≥480 ms	1
C Torsade de pointes*	2
D T wave alternans	1
E Notched T wave in 3 leads	1
F Low heart rate for age@	0.5
Clinical history	
A Syncope*	
With stress	2
Without stress	1
B Congenital deafness	0.5
Family history	
A Family members with definite LQTS$	1
B Unexplained sudden cardiac death below age 30 among immediate family members$	0.5

In the absence of medications or disorders known to affect these electrocardiographic features.
^ QTc calculated by Bazett's formula where QTc = QT/√RR.
* Mutually exclusive.
Resting heart rate below the 2nd percentile for age.
The same family member cannot be counted in A and B.
SCORE: ≤1 point: low probability of LQTS.
1.5 to 3 points: intermediate probability of LQTS.
≥3.5 points high probability.

- Brugada Syndrome (BrS) is clinically characterized by right ventricular conduction delay and ST-segment elevation in the anterior right precordial leads. Syncope is one of the main clinical manifestations; individuals with BrS develop a monomorphic ventricular tachycardia that may precipitate during sleep, rest, or fever (Magi et al., 2017). Recent reports suggest that BrS could be responsible for 4%–12% of all sudden death (SD) and up to 20% of SD in patients with structurally normal hearts (Fernandez-Falgueras et al., 2017).
- Short QT Syndrome (SQTS) is characterized by abnormally short QT intervals and an increased propensity to develop atrial and ventricular tachyarrhythmia in the absence of structural heart disease. Cardiac arrest seems to be the most frequent symptom (up to 40%). Palpitations are a common symptom (30%), followed by syncope (25%) and atrial fibrillation (AF), which are the first symptoms of the disease in up to 20% of patients. The episodes may occur in a wide range of situations, such as in reaction to loud noise, at rest, during exercise, and during daily activity (Fernandez-Falgueras et al., 2017)

- Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT) is characterized by a normal ECG and ventricular arrhythmia in genetically predisposed individuals during intense physical exercise or acute emotional stress. Typical clinical manifestations of CPVT include dizziness and syncope. Ventricular arrhythmia, however, may degenerate into rapid polymorphic ventricular tachycardia and ventricular fibrillation, leading to SCD (Magi et al., 2017).
- Progressive Cardiac Conduction Disease (PCCD) is characterized by problems with the cardiac impulse of the heart. These conduction abnormalities may be accompanied by structural problems such as fibrous or fatty calcification, and an ECG may display unusual patterns such as a prolonged P-wave or prolonged QRS interval. These arrhythmias may lead to sudden cardiac death. Mutations in ion channel proteins such as *TRPM4* or *SCN5A* have been associated with CCDs (M. J. Ackerman et al., 2011; Wilde et al., 2005).

Not all cases are accompanied by changes in ECG, which makes them more difficult to diagnose. Genetic testing can contribute substantially both to the diagnosis of affected patients and with the identification of asymptomatic individuals at risk (Bastiaenen & Behr, 2011; Priori et al., 2013).

Currently, mutations associated with SCD have been identified in sodium, potassium and calcium channels and associated proteins (Fernandez-Falgueras et al., 2017). A general overview of the main genetic variants that have been linked to the major cardiac channelopathies is displayed in the table below [adapted from (Garcia-Elias & Benito, 2018; Magi et al., 2017; Munroe et al., 2018; Tester & Ackerman, 2011)].

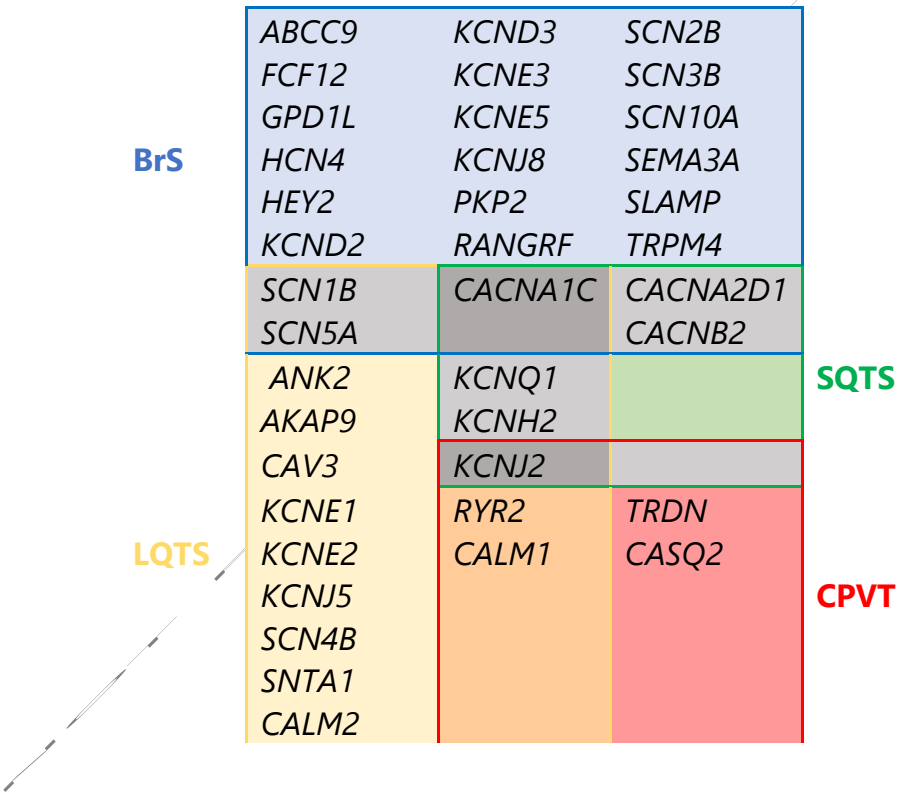
Gene	Protein	Prevalence	Other Associations
Brugada Syndrome (BrS)			
	Ion Channel Subunits		
*SCN5A**	NaV1.5 (α-subunit of the voltage-dependent Na^+channel)	≃25% (BrS1)	DCM, ARVC, Heart block, LQTS, SSS, SIDS
*SCN1B**	β1-subunit of the voltage-dependent Na^+ channel	<1%	CCD, Epilepsy
*SCN2B**	β2-subunit of the voltage-dependent Na^+ channel	<1%	AF
*SCN3B**	β3-subunit of the voltage-dependent Na^+ channel	<1%	AF, VF, SIDS
*SCN10A**	NaV1.8 (α-subunit of the neuronal voltage-dependent Na^+ channel)	≃10%	LQTS, AF, painful small-fiber peripheral neuropathy

Gene	Protein	Prevalence	Other Associations
*CACNA1C**	CaV1.2 (α1C-subunit of the voltage-dependent L-type Ca^{2+} channel)	<1%	Timothy syndrome, LQTS
*CACNB2b**	β2-subunit of the voltage-dependent L-type Ca^{2+}channel	<1%	SQTS
*KCND3**	KV4.3 (α-subunit of the voltage-dependent K^+ channel)	<1%	SIDS, Spinocerebellar ataxia
*KCNE3**	minK-related peptide 2 (β-subunit of the voltage-dependent K^+ channel)	<1%	
KCNAB2	β2-subunit of the voltage-dependent K^+ channel	<1%	
KCND2	KV4.2 (voltage-dependent K^+ channel)	<1%	Epilepsy
*KCNE5**	minK-related peptide 4 (β-subunit of the voltage-dependent K^+ channel)	<1%	AF, VF
*KCNJ8**	Kir6.1 (inward-rectifier K^+ channel, subunit of the ATP-sensitive K^+ channel)	<1%	VF, SIDS, Cantu syndrome
*ABCC9**	SUR2 (sulfonylurea receptor, subunit of the ATP-sensitive K^+ channel)	<1%	DCM, ERS, Cantu syndrome and related disorders
*KCNH2**	KV11.1/hERG (α-subunit of the voltage-dependent K^+ channel)	<1%	LQTS, SQTS
*CACNA2D1**	α2/δ subunit of the volatge-dependent L-type Ca^{2+}channel	<1%	Epilepsy
*HCN4**	hyperpolarization-activated, cyclic nucleotide-gated ion channel 4	<1%	SSS, AF, AV block, Bradycardia, Tachycardia, NCC
*TRPM4**	Transient receptor potential melastatin 4	<1%	Herat Block, LQTS
	Auxiliary Proteins		
FGF12	fibroblast growth factor 12	<1%	Epilepsy
*GPD1L**	glycerol-3-phosphate dehydrogenase 1-like	<1%	
SLMAP	sarcolemma associated protein (striatin-interacting phosphatase and kinase complex)	<1%	
*PKP2**	plakophillin-2	<1%	ARVC

Gene	Protein	Prevalence	Other Associations
SEMA3A	semaphorin-3A	<1%	
*RANGRF**	MOG1 (multicopy suppressor of *Gsp1*)	<1%	histiocytoid cardiomyopathy
HEY2	CHF1 (cardiovascular helix-loop-helix factor 1)	<1%	
Long QT Syndrome (LQTS)			
	Ion Channel Subunits		
*KCNQ1**	KV7.1 (α-subunit of the voltage-dependent K^+ channel)	≃40% (LQT1)	JLNS, SQTS
*KCNH2**	KV11.1/hERG (α-subunit of the voltage-dependent K^+ channel)	≃30% (LQT2)	SQTS
*SCN5A**	NaV1.5 (α-subunit of the voltage-dependent Na^+ channel)	≃10% (LQT3)	BrS, DCM, ARVC, Heart block, SSS, SIDS
*KCNE1**	minK (β1-subunit of the voltage-dependent K^+ channel)	<1%	JLNS
*KCNE2**	MiRP1 (β2-subunit of the voltage-dependent K^+ channel)	<1%	
*KCNJ2**	Kir2.1 (inward rectifying K^+ channel)	<1% (LQT7)	Andersen-Tawil syndrome, SQTS, AF
*KCNJ5**	Kir3.4 (G protein-activated inward rectifying K^+ channel 4)	<1%	LQTS, Hyperaldosteronism
*SCN1B**	β1-subunit of the voltage-dependent Na^+ channel	<1%	BrS, CCD, Epilepsy
*SCN4B**	β4-subunit of the voltage-dependent Na^+ channel	<1%	AF
*CACNA1C**	CaV1.2 (α1C-subunit of the voltage-dependent L-type Ca^{2+} channel)	<1% (LQT8)	BrS, Timothy syndrome
	Auxiliary Proteins		
*AKAP9**	A-kinase anchor protein-9	<1%	
*ANK2**	ankyrin B	<1%	Arrhythmia
*CALM1**	calmodulin (CaM)	<1%	CVPT
*CALM2**	calmodulin (CaM)	<1%	CVPT
*CALM3**	calmodulin (CaM)	<1%	CVPT
*SNTA1**	α1-syntrophin	<1%	
*TRDN**	triadin	<1%	CVPT

Gene	Protein	Prevalence	Other Associations
*CAV3**	caveolin-3	<1%	HCM, LGMD, Rippling muscle disease, Tateyama-type distal myopathy, SIDS
*TRPM4**	Transient receptor potential melastatin 4	<1%	Herat Block, BrS
*RYR2**	ryanodine receptor 2 (RyR2)	<1%	ARVC, CPVT
Short QT Syndrome (SQTS)			
	Ion Channel Subunits		
*KCNH2**	KV11.1/hERG (α-subunit of the voltage-dependent K^+ channel)	≃15% (SQT1)	LQTS
*KCNQ1**	KV7.1 (α-subunit of the voltage-dependent K^+ channel)	<1%	JLNS, LQTS
*KCNJ2**	Kir2.1 (inward rectifying K^+ channel)	<1%	Andersen-Tawil syndrome, AF
*CACNA1C**	CaV1.2 (α1C-subunit of the voltage-dependent L-type Ca^{2+} channel)	<1%	BrS, Timothy syndrome
*CACNB2b**	β2-subunit of the voltage-dependent L-type Ca^{2+}channel	<1%	BrS
*CACNA2D1**	α2/δ-subunit of the voltage-dependent L-type Ca^{2+} channel	<1%	BrS, Epilepsy
Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT)			
*RYR2**	ryanodine receptor 2 (RyR2)	≃50–60% (CPVT1)	ARVC
KCNJ2	Kir2.1	10%	
*CASQ2**	calsequestrin 2	≃5%	
*TRDN**	triadin	<1%	LQTS
*CALM1**	calmodulin (CaM)	<1%	LQTS
*CALM2**	calmodulin (CaM)	<1%	LQTS
*CALM3**	calmodulin (CaM)	<1%	LQTS
TECLR	trans-2,3-enoyl-CoA reductase- like	<1%	

* - *commercially available test*



Abbreviations: AF – Atrial fibrillation; ARVC- Arrhythmogenic right ventricular cardiomyopathy; AV – Atrioventricular; BrS – Brugada syndrome; CCD – Cardiac conduction defect; CHD – Congenital heart defects; CPVT –Catecholaminergic polymorphic ventricular tachycardia; DCM – Dilated cardiomyopathy; EMD – Emery Dreifuss muscular dystrophy; ERS –Early repolarization syndrome; HCM – Hypertrophic cardiomyopathy; HCC -

Gene	Protein	Prevalence	Other Associations

histiocytoid cardiomyopathy; JLNS – Jervell and Lange-Nielsen syndrome; LGMD – Limb girdle muscular dystrophy; LQTS – Long QT syndrome; SIDS – Sudden infant death syndrome; SQTS – Short QT syndrome; SSS – Sick sinus syndrome; SUDS – Sudden unexpected death syndrome; VF – Ventricular fibrillation

The clinical presentations of these conditions overlap as shown below (adapted from Campuzano, 2015), and genetic testing may clarify diagnoses, etiologies, and treatments in symptomatic individuals (Spoonamore & Johnson, 2016). However, predicting clinical presentation based on genetic mutation is also challenging (Bezzina et al., 2015) due to the incomplete penetrance of most of these genes (Giudicessi & Ackerman, 2013).

Gene Mutations and their Associated Conditions

Proprietary Testing (Channelopathies)

Proprietary gene panels exist for the assessment of cardiac ion channelopathies. For example, GeneDX offers several customizable panels for various channelopathies and cardiomyopathies. Conditions such as ARVC, Brugada Syndrome, and CPVT are available as separate panels, and GeneDX offers combined panels such as a "Custom Arrhythmia Panel", a "Custom Cardiomyopathy Panel", and a "Combined Cardiac

Panel" (GeneDX, 2024). Other commercially available panels include offerings from Invitae (Invitae, 2024), Fulgent, (Fulgent, 2024) and BluePrint Genetics (BluePrint, 2024).

Analytical Validity (Channelopathies)

Ware et al. (2013) compared two NGS approaches for diagnostic sequencing inherited arrhythmia syndromes. PCR-based target enrichment and long-read sequencing (PCR-LR) was compared to in-solution hybridization-based enrichment and short-read sequencing (Hyb-SR). The PCR-LR assay comprehensively assessed five long QT genes (*KCNQ1, KCNH2, SCN5A, KCNE1* and *KCNE2*) and "hot spots" in *RYR2*. The Hyb-SR assay targeted 49 genes, including those in the PCR-LR assay. The sensitivity for detection of control variants was identical. In both assays, the major limitation was upstream target capture, particularly in regions of extreme GC content. These initial experiences with NGS cardiovascular diagnostics achieved up to 89% sensitivity at a fraction of current costs (Ware et al., 2013).

Proost et al. (2017) validated a targeted gene panel for next-generation sequencing of 51 genes associated with primary electrical disease with 20 Human Polymorphism Study Center samples and 19 positive control samples with a total of 1479 variants. "An analytical sensitivity and specificity of 100% and 99.9% were obtained." After validation, the assay was applied to "114 PED patients which identified 107 variants in 36 different genes, 18 of which were classified as pathogenic or likely pathogenic, 54 variants were of unknown significance, and 35 were classified as likely benign." They concluded "that the PED Multiplex Amplification of Specific Targets for Resequencing Plus assay is a proficient and highly reliable test to routinely screen patients experiencing primary arrhythmias" (Proost et al., 2017).

Clinical Utility and Validity (Channelopathies)

Garcia et al. (2016) proposed a framework for establishing clinical validity for assessing polymorphisms of inherited cardiac conditions, as well as evaluating the strength of association between genotype and phenotype, from a logical argument. Clinical validity of a gene is established when a gene is known to cause disease; since a specific variant must be responsible for causing the disease, a gene variant must be known to cause that disease. Conversely, if no variants can be established to cause disease, the clinical validity association has not been established. Variants of unknown significance (VUS) would, therefore, not have established clinical validity. Garcia et al. (2016) proposed three categories of strength of association: strong, suggested, and emerging.

- "Strong" refers to "cases where there exists at least one clinically observed variant supported by sufficient evidence to classify that variant as pathogenic. "Strong" indicates that the relationship has been proven."

- "Suggested" is used in cases where some preliminary evidence exists suggesting a causal relationship, but the relationship has not yet been formally proven."
- "Emerging" is used to describe a growing suspicion that a specific condition is caused by a gene that has already been proven to cause disease.

The authors go on to state that if one "strong" relationship exists, then clinical validity has been established. If not, the gene should be considered of "uncertain significance" (Garcia et al., 2016).

The authors also provide recommendations for gene panels to test for certain conditions. They "propose that a comprehensive panel test designed for the molecular diagnosis of a particular condition should include the following classes of genes:

- Genes that have been conclusively proven to cause the condition in question.
- Genes suspected but not yet proven to cause the condition in question.
- Genes that have been conclusively proven to cause a condition within the clinical differential. This category should include genes that cause a condition that can progress into the condition in question, genes that cause a condition that can be confused with the condition in question, and genes that cause a syndrome that include the condition in question as a primary feature.

They suggest that the clinical validity of a panel is established when that panel includes a set of genes that account for a substantial proportion of the genetic causes of the disease in question. Conversely, a panel is NOT valid if it omits certain genes that account for a substantial proportion of the known genetic risk. A clinically valid panel may also include genes for which some preliminary evidence of clinical validity exists ("preliminary evidence genes") (Garcia et al., 2016).

Hofman et al. (2013) analyzed the yield of DNA testing over 15 years. They analyzed results from 7021 individuals who were counseled, 6944 from 2298 different families (aged 41±19 years; 49% male). In 702 families (31%), a possible disease-causing mutation was detected. The yield of DNA testing of probands with primary electric diseases was 47% in LQTS, 26% in BrS, and 37% in CPVT. Cascade screening revealed 1539 mutation-positive subjects, and in 372 families counseled after sudden unexplained death an inherited arrhythmia syndrome was diagnosed in 29% (n=108) (Hofman et al., 2013).

Le Scouarnec et al. (2015) et al. examined 167 index cases presenting with a Brugada pattern on the electrocardiogram as well as 167 individuals aged over 65-years old and showing no history of cardiac arrhythmia. They found that "a significant enrichment in rare coding variation (with a minor allele frequency below 0.1%) was observed only for *SCN5A*, with rare coding variants carried by 20.4% of cases with BrS versus 2.4% of

control individuals. No significant enrichment was observed for any other arrhythmia-susceptibility gene, including *SCN10A* and *CACNA1C*. These results indicate that, except for *SCN5A*, rare coding variation in previously reported arrhythmia-susceptibility genes do not contribute significantly to the occurrence of BrS in a population with European ancestry. Extreme caution should thus be taken when interpreting genetic variation in molecular diagnostic setting, since rare coding variants were observed in a similar extent among cases versus controls, for most previously reported BrS-susceptibility genes" (Le Scouarnec et al., 2015).

Tester et al. (2012) examined 173 cases of sudden unexplained death that were referred for cardiac channel molecular autopsy. The mutational analysis included the long QT syndrome genes (*KCNQ1*, *KCNH2, SCN5A, KCNE1*, and *KCNE2*) and a catecholaminergic polymorphic ventricular tachycardia (CPVT) type 1–associated gene (*RYR2*). Overall, 45 putative pathogenic mutations absent in 400 to 700 controls were identified in 45 autopsy-negative SUD cases (26.0%) (Tester et al., 2012).

Seidelmann et al. (2017) evaluated the use of whole exome sequencing for clinical diagnosis, risk stratification, and management of inherited CVD. They found that genetic diagnosis was reached with a success rate of 26.5% (53/200 patients). This compares to 18% (36/200) that would have been diagnosed using commercially available genetic panels; although, this finding was not statistically significant. The authors concluded, "Whole exome sequencing was particularly useful for clinical diagnosis in patients with aborted sudden cardiac death, in whom the primary insult for the presence of both depressed cardiac function and prolonged QT had remained unknown. The analysis of the remaining cases using genome annotation and disease segregation led to the discovery of novel candidate genes in another 14% of the cases" (Seidelmann et al., 2017).

Munroe et al. (2018) examined tissue from 242 stillbirths (≥22 weeks), including those where no definite cause of death could be confirmed after a full autopsy. Seventy cases were examined, which were then sequenced for a custom panel of 35 genes. One putative pathogenic variant was found, and several novel variants of uncertain significance resulting in cardiac channelopathies was identified in some cases of otherwise unexplained stillbirth. The authors concluded "these variants may have a role in fetal demise" (Munroe et al., 2018).

Wang et al. (2017) examined the "genetic spectrum" of LVNC. The authors sequenced 73 cardiomyopathy-related genes in 102 patients, and 43 pathogenic variants were identified in 16 genes in 39 patients. Sarcomeric variants accounted for 63% of these variants whereas variants associated with channelopathies accounted for 12%. *MYH7* and *TAZ* pathogenic variants were the most common, and patients with pathogenic

variants showed more severe symptoms such as earlier age of onset (Wang et al., 2017).

van Lint et al. (2019) evaluated the detection rates for variants of unknown (class 3), likely (class 4), and certain (class 5) pathogenicity in cardiogenetic gene panels. The study included 936 patients that were evaluated with the arrhythmia panels (four versions), and 1970 patients were evaluated with the cardiomyopathy panels (six versions). The arrhythmia panels detected class 3 variants in 34.8% of patients, class 4 variants in 4.2% of patients, and class 5 variants in 4.6% of patients. The cardiomyopathy panels detected class 3 variants in 40.8% of patients, class 4 variants in 7.9% of patients, and class 5 variants in 12% of patients. Overall, the arrhythmia panels detected variants of interest in 44% of patients, and the cardiomyopathy panels detected variants of interest in 61% of patients. The authors concluded that "larger gene panels can increase the detection rate of likely pathogenic and pathogenic variants, but mainly increase the frequency of variants of unknown pathogenicity" (van Lint et al., 2019).

VI. Guidelines and Recommendations

American Heart Association, American College of Cardiology, and the Heart Rhythm Society

In 2017 (Al-Khatib Sana et al., 2018) the American Heart Association (AHA), the American College of Cardiology (ACC), and the Heart Rhythm Society (HRS) published the *Guideline for Management of Patients With Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death* that recommends the following:

Genetic Considerations in Arrhythmia Syndromes

- In patients and family members in whom genetic testing for risk stratification for SCA or SCD is recommended, genetic counseling is beneficial. (I)
- The diagnosis of most inherited arrhythmia syndromes is based on clinical features and family history. The availability of genetic testing for inherited arrhythmia syndromes can: 1) provide opportunity to confirm a suspected clinical diagnosis and sometimes provide prognostic information for the proband and 2) offer cascade screening of potentially affected family members when a disease-causing mutation is identified in the proband. The yield of genetic testing varies by disease.
- Genotyping is frequently most useful when a pathogenic mutation is identified in the proband, such that screening can be applied to relatives who are in a preclinical phase, allowing institution of lifestyle changes, therapy, or ongoing monitoring for those who are gene mutation-positive.

- In young patients (<40 years of age) without structural heart disease who have unexplained cardiac arrest, unexplained near drowning, or recurrent exertional syncope, genetic testing may be important to identify an inherited arrhythmia syndrome as a likely cause.

Arrhythmogenic Right Ventricular Cardiomyopathy

- "Selected first-degree relatives refers to relatives who are willing to undergo further testing and who could benefit from further screening and testing (and not the terminally ill patients or those who do not want to be screened and tested)."
- "Arrhythmogenic right ventricular cardiomyopathy is detected clinically in approximately 35% to 40% of first-degree relatives, most commonly in siblings or symptomatic first-degree relatives"
- "The proband with arrhythmogenic right ventricular cardiomyopathy is usually diagnosed by the presence of clinical symptoms along with the presence of arrhythmogenic right ventricular cardiomyopathy Task Force criteria"
- "A pathogenic genetic mutation was added to the major Task Force criteria in 2010. The yield of genetic testing in probands with suspected arrhythmogenic right ventricular cardiomyopathy is generally 30% to 54% and is up to 58% among patients with a strong family history of SCD in multiple members. A negative genetic test for arrhythmogenic right ventricular cardiomyopathy does not exclude the disease, and a positive genetic test currently does not guide therapy."

Hypertrophic Cardiomyopathy

- "In first-degree relatives of patients with HCM due to a known causative mutation, genetic counseling and mutation-specific genetic testing are recommended."
- "In patients with clinically suspected or diagnosed HCM, genetic counseling and genetic testing are reasonable."
- "When genetic testing reveals a mutation in the index patient, ascertainment of genetic status in first- and second-degree relatives can be predictive of risk for developing HCM. Relatives with overt HCM will have the same pathogenic HCM mutation as the index patient."

Cardiac Channelopathies

- In first-degree relatives of patients who have a causative mutation for long QT syndrome, catecholaminergic polymorphic ventricular tachycardia, short QT syndrome, or Brugada syndrome, genetic counseling and mutation-specific genetic testing are recommended (I)

- Clinical screening of first-degree relatives of patients with inherited arrhythmia syndromes is crucial to identifying affected family members. Due to the increased risk of adverse cardiac events in genotype-positive patients with long QT syndrome, catecholaminergic polymorphic ventricular tachycardia, and Brugada syndrome, targeted screening for the identified family-specific mutation can identify individuals who are at risk for these adverse outcomes

Congenital Long QT Syndrome

- In patients with clinically diagnosed long QT syndrome, genetic counseling and genetic testing are recommended (I)
- Genetic testing for disease-causing mutations in long QT syndrome offers important diagnostic, prognostic, and therapeutic information in addition to the clinical evaluation, and a positive test can facilitate establishing risk for family members. The yield of genetic testing in long QT syndrome phenotype-positive patients is 50% to 86%, with the higher range present in patients with marked QT prolongation or positive family history of SCD. A negative genetic test does not exclude the diagnosis of long QT syndrome, which relies on the clinical evaluation.

Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT)

- In patients with catecholaminergic polymorphic ventricular tachycardia and with clinical VT or exertional syncope, genetic counseling and genetic testing are reasonable (IIa)
- Genetic testing may be useful to confirm the diagnosis of catecholaminergic polymorphic ventricular tachycardia, which is suggested by the development of bidirectional VT with exertion or stress. Recognition of catecholaminergic polymorphic ventricular tachycardia as the cause for exertional symptoms should prompt aggressive therapy to prevent the significant risk of SCD. Therapy for catecholaminergic polymorphic ventricular tachycardia is not guided by genotype status, but screening of first-degree relatives may be facilitated with genetic testing.

Brugada Syndrome

- In patients with suspected or established Brugada syndrome, genetic counseling and genetic testing may be useful to facilitate cascade screening of relatives (IIb)
- The yield of genetic testing in phenotype-positive patients is approximately 20% to 30% in Brugada syndrome. *SCN5A* variants account for most of this subset of genotype-positive Brugada syndrome. However, 2% to 10% of otherwise healthy individuals host a rare variant of *SCN5A*. A negative genetic test does not exclude

the diagnosis of Brugada syndrome, which is usually based on electrocardiographic and clinical characteristics. Risk stratification is based on symptoms and clinical findings; genotype status is not correlated with the risk of adverse events. Identification of a pathogenetic mutation may help facilitate recognition of carrier status in family members, allowing for lifestyle modification and potential treatment.

Short QT syndrome

- In patients with short QT syndrome, genetic testing may be considered to facilitate screening of first-degree relatives (IIb)
- Pathogenic mutations in potassium channels have been identified in approximately 10% to 20% of patients with short QT syndrome, including in *KCNH2* (SQT1), *KCNQ1* (SQT2), and *KCNJ2* (SQT3).

Early Repolarization "J-wave" Syndrome

- In patients with early repolarization pattern on ECG, genetic testing is not recommended (III-no benefit)

Postmortem Evaluation of SCD

- In first-degree relatives of SCD victims who were 40 years of age or younger, cardiac evaluation is recommended, with genetic counseling and genetic testing performed as indicated by clinical findings (I)
- For family risk profiling, it is important to use the disease-specific genetic test panel that corresponds to the autopsy findings. Risk profiling of family members of an SCD victim suspected of having an inherited cardiomyopathy at autopsy is important. Although phenotyping of surviving family members is crucial, genotyping of the SCD proband provides a mechanism for efficient follow-up evaluation of those relatives with the disease-causing mutation found in the proband (Al-Khatib Sana et al., 2018).

American Heart Association/American College of Cardiology/Heart Failure Society of America (AHA/ACC/HFSA) Guideline for the Management of Heart Failure

These 2022 guidelines provide guidelines on genetic evaluation and testing for the management of heart failure. The relevant recommendations are captured below:

- "In first-degree relatives of selected patients with genetic or inherited cardiomyopathies, genetic screening and counseling are recommended to

detect cardiac disease and prompt consideration of treatments to decrease HF progression and sudden death."

- "In select patients with nonischemic cardiomyopathy, referral for genetic counseling and testing is reasonable to identify conditions that could guide treatment for patients and family members."

These joint recommendations also urge that "In patients in whom a genetic or inherited cardiomyopathy is suspected, a family history should be performed, including at least 3 generations and ideally diagrammed as a family tree pedigree" (Heidenreich et al., 2022).

American College of Cardiology Foundation (ACCF)/American College of Cardiology (ACC) and American Heart Association (AHA)

In 2020, the AHA released a joint guideline with the ACC for the diagnosis and treatment of patients with hypertrophic cardiomyopathy (Ommen et al., 2020). This guideline replaced the 2011 guideline released jointly by the ACCF and the AHA. The updated 2020 guideline has also been endorsed by the Heart Rhythm Society (HRS). With relation to genetic testing, they released the following with a level B-NR quality of evidence, signifying "moderate-quality evidence from 1 or more well-designed, well-executed nonrandomized studies, observational studies, or registry studies; meta-analyses of such studies":

Class 1 (Benefit >>> Risk)

- "In patients with HCM, evaluation of familial inheritance, including a 3-generation family history, is recommended as part of the initial assessment
- In patients with HCM, genetic testing is beneficial to elucidate the genetic basis to facilitate the identification of family members at risk for developing HCM (cascade testing)
- In patients with an atypical clinical presentation of HCM or when another genetic condition is suspected to be the cause, a work-up including genetic testing for HCM and other genetic causes of unexplained cardiac hypertrophy ("HCM phenocopies") is recommended
- In patients with HCM who choose to undergo genetic testing, pre- and post-test genetic counseling by an expert in the genetics of cardiovascular disease is recommended so that risks, benefits, results, and their clinical significance can be reviewed and discussed with the patient in a shared decision-making process
- When performing genetic testing in an HCM proband, the initial tier of genes tested should include genes with strong evidence to be disease-causing in HCM*

- In first-degree relatives of patients with HCM, both clinical screening (ECG and 2D echocardiogram) and cascade genetic testing (when a pathogenic/likely pathogenic variant has been identified in the proband) should be offered
- In families where a sudden unexplained death has occurred with a postmortem diagnosis of HCM, postmortem genetic testing is beneficial to facilitate cascade genetic testing and clinical screening in first-degree relatives
- In patients with HCM who have undergone genetic testing, serial reevaluation of the variant(s) identified is recommended to assess for variant reclassification, which may impact diagnosis and cascade genetic testing in family members
- In affected families with HCM, preconception and pre-natal reproductive and genetic counseling should be offered"
- NOTE: "Strong evidence HCM genes include, at the time of this publication, *MYH7, MYBPC3, TNNI3, TNNT2, TPM1, MYL2, MYL3,* and *ACTC1*"

Class 2b (Benefit ≥ Risk)

- "In patients with HCM, the usefulness of genetic testing in the assessment of risk of SCD [sudden cardiac death] is uncertain
- In patients with HCM who harbor a variant of uncertain significance, the usefulness of clinical genetic testing of phenotype-negative relatives for the purpose of variant reclassification is uncertain"

No benefit

- "For patients with HCM who have undergone genetic testing and were found to have no pathogenic variants (i.e., harbor only benign/likely benign variants), cascade genetic testing of the family is not useful
- Ongoing clinical screening is not indicated in genotype-negative relatives in families with genotype-positive HCM, unless the disease-causing variant is downgraded to variant of uncertain significance, likely benign, or benign variant during follow-up" (Ommen et al., 2020).

The ACCF and AHA also published a joint guideline, regarding the "Management of Heart Failure", which states that "Increasingly, it is recognized that many (20% to 35%) patients with an idiopathic DCM have a familial cardiomyopathy (defined as 2 closely related family members who meet the criteria for idiopathic DCM)." "Advances in technology permitting high-throughput sequencing and genotyping at reduced costs have brought genetic screening to the clinical arena" and refers to the 2009 and 2011 published guidelines. The guidelines further note that genetic testing may be considered in conjunction with counseling in familial DCM (Yancy et al., 2013).

American Heart Association (AHA)

The AHA published a guideline regarding cardiomyopathy in children. In it, they state that "genetic testing should first be performed in the individual known to have a specific cardiomyopathy phenotype and should be informed by the child's overall presentation, with a detailed examination looking for dysmorphic features, muscle weakness, scoliosis, or specific laboratory findings." They also state that indications for genetic testing include "determining the cause of HCM, predicting the clinical course and severity, screening first-degree relatives, and determining recurrence risk."

This guideline addresses HCM, DCM, RCM, LVNC, Arrhythmogenic Ventricular Cardiomyopathy (both right and left ventricles), as well as cardiomyopathy caused by channelopathies such as Long-QT syndrome (Lipshultz et al., 2019). However, though it addresses the many manifestations of cardiomyopathy, few suggestions for clinical practice are made due to "the lack of evidence and consensus in the classification and diagnosis of children with cardiomyopathy," such that the document takes the form of a scientific statement instead of clinical guidelines.

In a 2023 scientific statement regarding cardiomyopathy in children, the AHA goes on to state that when "cardiomyopathy is identified in a child without a known preexisting risk, panel genetic testing or whole exome sequencing is recommended. A pathogenic or likely pathogenic variant in the proband should prompt cascade genetic testing of first-degree relatives who are at risk for cardiomyopathy" (Bogle et al., 2023).

The AHA also published a guideline discussing early repolarization. In it, they remark that the biological basis for early repolarization pattern "remains incompletely understood." Therefore, the AHA proposes "large-scale, unbiased (e.g., genome-wide association studies), family-guided genetic discovery approaches, as well as efforts aimed at understanding both the mechanisms underlying ER and the associated arrhythmogenesis" (Patton et al., 2016).

In a 2020 statement from the AHA titled "Genetic Testing for Inherited Cardiovascular Diseases: A Scientific Statement from the American Heart Association", the AHA pointed towards a 2018 conjoint guideline by the HFSA with the ACMG for guidance for genetic testing of cardiomyopathies. The pertinent recommendations were extracted and are presented below:

"A family history of at least 3 generations should be obtained for all patients with a primary cardiomyopathy. Second, clinical screening for cardiomyopathy is recommended for at-risk first-degree relatives. Third, patients with genetic, familial, or other unexplained forms of cardiomyopathy should be referred to expert centers. Genetic counseling is recommended for all patients with cardiomyopathy and their family members.

In a family, testing should be directed to the most clearly affected family member. If that individual is found to have a gene variant that is judged to be pathogenic or likely pathogenic, then cascade genetic testing for that variant should be offered to at-risk family members. For infants with cardiomyopathy, in addition to any routine newborn screening tests that might have been performed, the specialized evaluation is likely to include genetic testing and should also include an evaluation for syndromic or metabolic conditions for which a specific intervention or therapy might be warranted" (Musunuru et al., 2020).

Finally, the guideline notes that the management of certain conditions may benefit or otherwise be influenced by the results of genetic testing. Long-QT syndrome, HCM, DCM, and RCM are listed as having variants that may be specifically targeted with certain treatments (Musunuru et al., 2020).

Heart Failure Society of American and American College of Medical Genetics and Genomics (ACMG)

In 2018, the Heart Failure Society of America and the American College of Medical Genetics and Genomics published a clinical practice resource for the genetic evaluation of cardiomyopathy. There,

"Recommendation 1. Genetic testing is recommended for patients with cardiomyopathy

(a) Genetic testing is recommended for the most clearly affected family member.
(b) Cascade genetic testing of at-risk family members is recommended for pathogenic and likely pathogenic variants.
(c) In addition to routine newborn screening tests, specialized evaluation of infants with cardiomyopathy is recommended, and genetic testing should be considered."

On the point of whom to test, the societies have the following to say:

"To yield the most conclusive, informative results, diagnostic genetic testing is optimally initiated on a confirmed affected individual. Furthermore, as there are sometimes multiple genetic variants contributing to disease in a single family, the testing should ideally be initiated on the person who is most likely to harbor the disease-causing variant or variants. This is frequently the individual in the family with the most severe disease and/or the earliest disease onset. This is a well established principle in clinical genetics, as selecting the individual with the most evident disease increases the likelihood of finding a genetic cause. If the ideal person for initiation of genetic testing in a family is unavailable or unwilling to proceed, then comprehensive

genetic testing should be considered for another unequivocally affected family member."

As for when to test, ACMG "recommend[s] genetic testing at the time a new cardiomyopathy diagnosis is made, but it can be conducted at any time following diagnosis. Education and counseling regarding genetic testing options are a key component of the process. For those who have had genetic testing in the past, retesting may be appropriate if the previous testing produced negative or inconclusive results and the test's detection rate has improved. This latter point is particularly relevant for DCM as the gene panels have rapidly expanded (e.g., *TTN* and others) and are anticipated to continue" (Hershberger et al., 2018). A chart of selected genes implicated in various cardiomyopathies is included below.

Table 1 Selected genes in association with cardiomyopathy

	Core genes[a]	Estimates of genetic testing diagnostic yield	ACMG secondary findings gene list	Metabolic causes of cardiomyopathty	Examples of genetic syndromes
HCM	*MYH7, MYBPC3, TNNT2, TNNC1, TNNI3, TPM1, MYL2, MYL3, ACTC1, ACTN2, CSRP3, PLN, TTR, PRKAG2, LAMP2, GLA*	30–60%	*MYBPC3, MYH7, TNNT2, TNNI3, TPM1, MYL3, ACTC1, PRKAG2, GLA, MYL2, LMNA*	*GAA* (Pompe); Mitochondrial disease genes	RASopathies (e.g., Noonan syndrome, others); Friedreich ataxia
DCM	*TTN*[b], *LMNA, MYH7, TNNT2, BAG3, RBM20, TNNC1, TNNI3, TPM1, SCN5A, PLN*. For testing, all HCM, ARVC genes are recommended to be included	10–40%		Mitochondrial disease genes	Muscular dystrophies; Alström syndrome
ARVC	*DES, DSC2, DSG2, DSP, JUP, LMNA, PKP2, PLN, RYR2, SCN5A, TMEM43, TTN*[b]; consider full DCM panel	10–50%	*PKP2, DSP, DSC2, TMEM43, DSG2, RYR2 SCN5A*		Naxos syndrome; Carvajal syndrome
RCM	Consider HCM or DCM gene panel	10–60%			
LVNC	Use the gene panel for the cardiomyopathy identified in association with the LVNC phenotype	Unknown		Mitochondrial disease genes including *TAZ* in Barth syndrome	1p36 deletion syndrome; RASopathies

[a]Core gene lists represent genes with the highest diagnostic yield and/or strongest evidence of the gene in association with the listed phenotype; the genes listed are not exhaustive and should be considered illustrative for the type of cardiomyopathy. Considerable overlap of genes between cardiomyopathy phenotypes is well established. Genes known to cause metabolic disease or genetic syndromes are often included in testing panels, but vary depending on the clinical laboratory. Gene lists therefore need to be reviewed carefully before ordering testing. Metabolic and genetic syndrome columns provide examples only and are not intended to be comprehensive

[b]Only *TTN* truncating variants are thought relevant for cardiomyopathy

HCM hypertrophic cardiomyopathy, *DCM* dilated cardiomyopathy, *ARVC* arrhythmogenic right ventricular cardiomyopathy, *RCM* restrictive cardiomyopathy, *LVNC* left ventricular noncompaction, *ACMG* American College of Medical Genetics and Genomics

(Table 1 above appropriated from *(Hershberger et al., 2018)*)

The specific cardiomyopathy comments are as follows:

HCM

- "Beyond sarcomeric genes, core genes to screen in patients with HCM include *GLA, PRKAG2*, and *LAMP2*."
- "Consultation with a geneticist is indicated."

DCM

- "Core genes to be tested in individuals with DCM include genes encoding sarcomeric and cytoskeletal proteins."
- "Genetic testing is important in mothers of individuals with Duchenne or Becker to determine carrier status because carrier females may develop DCM in the third to fifth decade of life."

LVNC

- "Genetic testing is not recommended when the LVNC phenotype is identified serendipitously in asymptomatic individuals with otherwise normal cardiovascular structure and function."

As such, these genes may form an important backdrop upon which the following is performed:

"Recommendation 2. Focused cardiovascular phenotyping is recommended when pathogenic or likely pathogenic variants in cardiomyopathy genes, designated for reporting of secondary findings by the ACMG, are identified in an individual.

(a) If a cardiovascular phenotype is identified as would be predicted by currently available knowledge of the gene/ variant pair, all usual approaches described in this document for a genetic evaluation, including family-based approaches, are recommended.
(b) If no cardiovascular disease phenotype is identified in the individual, recommendations for surveillance screening at intervals should be considered.
(c) If no cardiovascular phenotype is identified in the individual, cascade evaluation of at-risk relatives may be considered, tempered by the strength of evidence supporting the pathogenicity of the variant, the usual age of onset of the gene/variant pair, and pedigree information (e.g., the ages of at-risk family members, other previously known cardiovascular clinical data in the pedigree, and related information)" (Hershberger et al., 2018).

American College of Medical Genetics and Genomics (ACMG)

In 2023 version 3.2, ACMG referenced several myopathies and channelopathies in their "minimum" list of genes for which mutations should be reported when whole genome sequencing is performed for other primary purposes (incidental findings). Those genes are listed below:

- *FBN1, TGFBR1, TGFBR2, SMAD3, ACTA2, MYH11* for aortopathies
- *PKP2, DSP, DSC2, TMEM43*, and *DSG2* for ARVC
- *RYR2, CASQ2,* and *TRDN* for Catecholaminergic polymorphic ventricular tachycardia (CPVT)
- *TNNT2, LMNA, FLNC, TTN, BAG3, DES, RBM20, and TNNC1* for DCM
- *COL3A1* for Ehlers-Danlos syndrome, vascular type
- *LDLR, APOB,* and *PCSK9* for Familial hypercholesterolemia
- *MYH7, MYBP3, TNNI3, TPM1, MYL3, ACTC1, PRKAG2,* and *MYL2* for HCM
- *KCNQ1* and *KCNH2* for Long QT syndrome types 1 and 2

- *SCN5A* for Long QT syndrome 3; Brugada syndrome
- *CALM1, CALM2, CALM3* for Long QT syndrome types 14-16 (Miller et al., 2023).

In an erratum published in 2021, the authors appended a series of new gene-phenotype pairings, each associated with the cardiovascular phenotype "Risk of sudden death with preventive interventions available": *CASQ2*/catecholaminergic polymorphic ventricular tachycardia (CPVT), *TRDN*/catecholaminergic polymorphic ventricular tachycardia (CPVT) & long QT syndrome, *FLNC*/cardiomyopathy, and *TTN*/cardiomyopathy (Miller et al., 2021).

The Heart Rhythm Society (HRS)/The European Heart Rhythm Association (EHRA) Expert Consensus Statement

Hypertrophic Cardiomyopathy (HCM)

Class I recommendations (is recommended):

- "Comprehensive or targeted (*MYBPC3, MYH7, TNNI3, TNNT2, TPM1*) HCM genetic testing is recommended for any patient in whom a cardiologist has established a clinical diagnosis of HCM based on examination of the patient's clinical history, family history, and electrocardiographic/echocardiographic phenotype."
- "Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of the HCM-causative mutation in an index case."

Dilated Cardiomyopathy (DCM)

Class I recommendations:

- "Comprehensive or targeted (*LMNA* and *SCN5A*) DCM genetic testing is recommended for patients with DCM and significant cardiac conduction disease (i.e., first-, second-, or third- degree heart block) and/or with a family history of premature unexpected sudden death."
- "Mutation-specific testing is recommended for family members and appropriate relatives following the identification of a DCM-causative mutation in the index case."

Class IIa (can be useful) recommendations:

- Genetic testing can be useful for patients with familial DCM to confirm the diagnosis, to recognize those who are highest risk of arrhythmia and syndromic

features, to facilitate cascade screening within the family, and to help with family planning.

Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC)

Class I recommendations:

- "Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of the ACM/ARVC- causative mutation in an index case."

Class II recommendations:

- "Comprehensive or targeted (*DSC2*, *DSG2*, *DSP*, *JUP*, *PKP2*, and *TMEM43*) ACM/ARVC genetic testing can be useful for patients satisfying task force diagnostic criteria for ACM/ARVC." (II-A, can be useful)
- "Genetic testing may be considered for patients with possible ACM/ARVC (1 major or 2 minor criteria) according to the 2010 task force criteria (European Heart Journal)." (II-B, may be considered)

Left Ventricular Noncompaction (LVNC)

Class I recommendations:

- "Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of a LVNC-causative mutation in the index case."

Class IIa recommendations:

- LVNC genetic testing can be useful for patients in whom a cardiologist has established a clinical diagnosis of LVNC based on examination of the patient's clinical history, family history, and electrocardiographic/echocardiographic phenotype. (II-A)

Restrictive Cardiomyopathy (RCM)

Class I recommendations:

- "Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of a RCM-causative mutation in the index case."

Class IIb (may be considered) recommendations:

- "RCM genetic testing may be considered for patients in whom a cardiologist has established a clinical index of suspicion for RCM based on examination of the patient's clinical history, family history, and electrocardiographic/echocardiographic phenotype."

Long-QT Syndrome

Class I recommendations:

- "Comprehensive or LQT1-3 (*KCNQ1, KCNH2*, and *SCN5A*) targeted LQTS genetic testing is recommended for any patient in whom a cardiologist has established a strong clinical index of suspicion for LQTS based on examination of the patient's clinical history, family history, and expressed electrocardiographic (resting 12-lead ECGs and/or provocative stress testing with exercise or catecholamine infusion) phenotype.
- Comprehensive or LQT1-3 (*KCNQ1, KCNH2*, and *SCN5A*) targeted LQTS genetic testing is recommended for any asymptomatic patient with QT prolongation in the absence of other clinical conditions that might prolong the QT interval (such as electrolyte abnormalities, hypertrophy, bundle branch block, etc., i.e., otherwise idiopathic) on serial 12-lead ECGs defined as QTc >480 ms (prepuberty) or >500 ms (adults).
- Mutation-specific genetic testing is recommended for family members and other appropriate relatives subsequently following the identification of the LQTS-causative mutation in an index case."

Class IIb recommendations:

- "Comprehensive or LQT1-3 (*KCNQ1, KCNH2,* and *SCN5A*) targeted LQTS genetic testing may be considered for any asymptomatic patient with otherwise idiopathic QTc values >460 ms (prepuberty) or >480 ms (adults) on serial 12-lead ECGs."

Catecholaminergic polymorphic ventricular tachycardia (CPVT)

Class I recommendations:

- Comprehensive or CPVT1 and CVPT2 (*RYR2* and *CASQ2*) targeted CPVT genetic testing is recommended for any patient in whom a cardiologist has established a clinical index of suspicion for CPVT based on examination of the patient's clinical history, family history, and expressed electrocardiographic phenotype during provocative stress testing with cycle, treadmill, or catecholamine infusion.

- Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of the CPVT-causative mutation in an index case.

Brugada Syndrome

Class I recommendations:

- Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of the BrS-causative mutation in an index case.

Class IIa recommendations:

- Comprehensive or BrS1 (*SCN5A*) targeted BrS genetic testing can be useful for any patient in whom a cardiologist has established a clinical index of suspicion for BrS based on examination of the patient's clinical history, family history, and expressed electrocardiographic (resting 12-lead ECGs and/or provocative drug challenge testing) phenotype

Genetic testing is not indicated in the setting of an isolated type 2 or type 3 Brugada ECG pattern.

Short QT syndrome

Class I recommendations:

- Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of the SQTS-causative mutation in an index case.

Class IIb recommendations:

- Comprehensive or SQT1-3 (*KCNH2, KCNQ1*, and *KCNJ2*) targeted SQTS genetic testing may be considered for any patient in whom a cardiologist has established a strong clinical index of suspicion for SQTS based on examination of the patient's clinical history, family history, and electrocardiographic phenotype.

Sinus Node Dysfunction (SND)

- "In idiopathic sinus node dysfunction (SND), mutations in the cardiac pacemaker channel gene *HCN4* and in sodium channel genes can be identified in an unknown portion. However, because non-genetic causes appear more frequently

in idiopathic SND, genetic testing for idiopathic SND should be considered on an individual basis".

Progressive Cardiac Conduction Disease (CCD)

- "Genetic testing may be considered as part of the diagnostic evaluation for patients with either isolated CCD or CCD with concomitant congenital heart disease, especially when there is documentation of a positive family history of CCD."
- "Mutation-specific genetic testing is recommended for family members and appropriate relatives following the identification of the CCD-causative mutation in an index case."
- "Taken together, tiered genetic testing for patients with CCD and congenital heart disease or cardiomyopathies is useful because other cardiac and non-cardiac disease features may be present or may develop; individual genes should be considered after discussion of clinical features with an experienced cardiogenetic center".

Post-Mortem Genetic Testing in Sudden Unexpected Death Cases

- "In the setting of autopsy-negative SUDS, comprehensive or targeted (*RYR2, KCNQ1, KCNH2*, and *SCN5A*) ion channel genetic testing **may be considered** in an attempt to establish probable cause and manner of death and to facilitate the identification of potentially at-risk relatives and **is recommended** if circumstantial evidence points toward a clinical diagnosis of LQTS or CPVT specifically (such as emotional stress, acoustic trigger, drowning as the trigger of death)."
- "Mutation-specific genetic testing is recommended for family members and other appropriate relatives following the identification of a SUDS-causative mutation in the decedent" (Ackerman et al., 2011; M. J. Ackerman et al., 2011).

Heart Rhythm Society (HRS), European Heart Rhythm Association (EHRA), and Asia Pacific Heart Rhythm Society (APHRS)

In an international consensus statement released by the HRS, EHRA, and APHRS, the three medical societies provide expert recommendations for diagnosing "inherited primary arrhythmia syndromes." The pertinent guidelines are listed below:

- "Expert Consensus Recommendations on LQTS Diagnosis
  1. LQTS is diagnosed:
     a. In the presence of an LQTS risk score ≥3.5 in the absence of a secondary cause for QT prolongation *and/or*

b. In the presence of an unequivocally pathogenic mutation in one of the LQTS genes *or*
c. In the presence of a QT interval corrected for heart rate using Bazett's formula (QTc) ≥500 ms in repeated 12-lead electrocardiogram (ECG) and in the absence of a secondary cause for QT prolongation.

2. LQTS can be diagnosed in the presence of a QTc between 480-499 ms in repeated 12-lead ECGs in a patient with unexplained syncope in the absence of a secondary cause for QT prolongation and in the absence of a pathogenic mutation."

- "Expert Consensus Recommendations on Brugada Syndrome Diagnosis
  1. BrS *is diagnosed* in patients with ST-segment elevation with type 1 morphology ≥2 mm in ≥1 lead among the right precordial leads V1, V2, positioned in the 2nd, 3rd or 4th intercostal space occurring either spontaneously or after provocative drug test with intravenous administration of Class I antiarrhythmic drugs.
  2. BRS ***is diagnosed*** in patients with type 2 or type 3 ST-segment elevation in ≥1 lead among the right precordial leads V1, V2 positioned in the 2nd, 3rd or 4th intercostal space when a provocative test with intravenous administration of Class I antiarrhythmic drugs induces a **type I** ECG morphology."
- "Expert Consensus Recommendations on [Catecholaminergic Polymorphic Ventricular Tachycardia] Diagnosis
  1. CPVT ***is diagnosed*** in the presence of a structurally normal heart, normal ECG, and unexplained exercise or catecholamine-induced bidirectional VT or polymorphic ventricular premature beats or VT in an individual < 40 years of age.
  2. CPVT ***is diagnosed*** in patients (index case or family member) who have a pathogenic mutation.
  3. CPVT ***is diagnosed*** in family members of a CPVT index case with a normal heart who manifest exercise-induced premature ventricular contractions (PVCs) or bidirectional/ polymorphic VT.
  4. CPVT ***can be diagnosed*** in the presence of a structurally normal heart and coronary arteries, normal ECG, and unexplained exercise or catecholamine-induced bidirectional VT or polymorphic ventricular premature beats or VT in an individual >40 years of age."
- "Expert Consensus Recommendations on Short QT Syndrome Diagnosis
  1. SQTS ***is diagnosed*** in the presence of a QTc ≤330 ms.
  2. SQTS ***can be diagnosed*** in the presence of a QTc <360 ms and one or more of the following: a pathogenic mutation, family history of SQTS, family history of sudden death at age ≤40, survival of a VT/VF episode in the absence of heart disease."

- "Expert Consensus Recommendations on Early Repolarization Diagnosis
  1. ER ***syndrome is diagnosed*** in the presence of J-point elevation ≥1mm in ≥2 contiguous inferior and/or lateral leads of a standard 12-lead ECG in a patient resuscitated from otherwise unexplained VF/polymorphic VT.
  2. ER syndrome ***can be diagnosed*** in an SCD victim with a negative autopsy and medical chart review with a previous ECG demonstrating J-point elevation ≥1mm in ≥2 contiguous inferior and/or lateral leads of a standard 12-lead ECG
  3. ER syndrome ***can be diagnosed*** in the presence of J-point elevation ≥1mm in ≥2 contiguous inferior and/or lateral leads of a standard 12-lead ECG."
- "Expert Consensus Recommendations on Progressive Cardiac Conduction Disease Diagnosis
  1. Progressive cardiac conduction disease (PCCD) is diagnosed in the presence of unexplained progressive conduction abnormalities in young (<50 years) individuals with structurally normal hearts in the absence of skeletal myopathies, especially if there is a family history of PCCD."
- "Unexplained Cardiac Arrest:
  1. Expert Consensus Recommendations on Idiopathic Ventricular Fibrillation (IVF) Diagnosis
     a. IVF ***is defined*** as a resuscitated cardiac arrest victim, preferably with documentation of VF, in whom known cardiac, respiratory, metabolic and toxicological etiologies have been excluded through clinical evaluation.
  2. Expert Consensus Recommendations on Idiopathic Ventricular Fibrillation Evaluation
     a. **Class IIa** - Genetic testing in IVF ***can be useful*** when there is a suspicion of a specific genetic disease following clinical evaluation of the IVF patient and/or family members.
     b. **Class III** - Genetic screening of a large panel of genes in IVF patients in whom there is no suspicion of an inherited arrhythmogenic disease after clinical evaluation ***should not be performed***.
- "Unexplained Sudden Cardiac Death: Expert Consensus Recommendations on Sudden Unexplained Death Syndrome Evaluation
  1. Class I – Collection of blood and/or suitable tissue for molecular autopsy/postmortem genetic testing **is recommended** in all SUDS victims.
  2. Class IIa – An arrhythmia syndrome focused molecular autopsy/postmortem genetic testing **can be useful** for all SUDS victims" (Priori et al., 2013).

Heart Rhythm Society (HRS)

Arrhythmogenic Cardiomyopathies

The HRS published an "Expert Consensus Statement" on "Evaluation, Risk Stratification, and Management of Arrhythmogenic Cardiomyopathy." In it, they include recommendations on genetic testing for this set of cardiac disorders.

"For individuals and decedents with either a clinical or necropsy diagnosis of ACM, genetic testing of the established ACM-susceptibility genes is recommended."

"For genetic testing of the established ACM-susceptibility genes, comprehensive analysis of all established genes with full coverage is recommended."

"When a likely pathogenic or pathogenic genetic variant has been identified in the proband, cascade genetic testing can be offered to first-degree at-risk relatives… Cascade genetic testing is therefore only offered to family members where a likely pathogenic or pathogenic variant in a known disease-associated gene is identified in the proband…" (Towbin et al., 2019).

Canadian Cardiovascular Society/Canadian Heart Rhythm Society

Long QT Syndrome

Genetic testing is recommended in the cardiac arrest survivor with LQTS for the primary purpose of screening first-degree relatives, in the patient with syncope and QTc prolongation that is attributed to LQTS, and in the asymptomatic patient with consistent QTc prolongation that is clinically suspected to represent LQTS.

Brugada Syndrome

Genetic testing in the cardiac arrest survivor, patient with syncope, or asymptomatic patient with a persistent or provocable type 1 Brugada ECG pattern is recommended for the primary purpose of screening of family members. However, patients with types 2 or 3 Brugada ECG patterns are not recommended for genetic testing.

CPVT

Genetic testing is recommended for the primary purpose of screening family members (Gollob et al., 2011).

-

European Society of Cardiology (ECS)

Genetic counselling is recommended for all HCM patients when the HCM is not explained solely by a non-genetic cause.

Genetic testing is recommended for patients fulfilling the diagnostic criteria for HCM, both as a confirmatory test and to enable genetic testing for relatives. Both cascade genetic screening and a clinical evaluation are recommended for first-degree relatives that carry the same mutation as the HCM patient ("proband"). Even if a mutation is absent, relatives should consider reassessment should symptoms appear, or other clinical data emerges. A genetic analysis, such as pedigree analysis and high-throughput sequencing, should include the most implicated sarcomere protein genes. If a rarer condition is suspected, the analysis should include the gene responsible for that condition.

Pre-natal genetic testing is not recommended due to phenotypic variability (Elliott et al., 2014).

In 2023, the ESC released clinical practice guidelines delineating the management of cardiomyopathies. The pertinent recommendations from this update are listed below:

- "Recommendations for diagnostic work-up in cardiomyopathies:
  - It is recommended that all patients with suspected or established cardiomyopathy undergo systematic evaluation using a multiparametric approach that includes clinical evaluation, pedigree analysis, ECG, Holter monitoring, laboratory tests, and multimodality imaging (Class I recommendation, evidence level C)
  - It is recommended that all patients with suspected cardiomyopathy undergo evaluation of family history and that a three- to four-generation family tree is created to aid in diagnosis, provide clues to underlying aetiology, determine inheritance pattern, and identify at-risk relatives (Class I recommendation, evidence level C)"
- "Recommendations for genetic counselling and testing in cardiomyopathies
  - Genetic counselling, provided by an appropriately trained healthcare professional and including genetic education to inform decision-making and psychosocial support, is recommended for families with an inherited or suspected inherited cardiomyopathy, regardless of whether genetic testing is being considered (Class I recommendation, evidence level B)
  - It is recommended that genetic testing for cardiomyopathy is performed with access to a multidisciplinary team, including those with expertise in genetic testing methodology, sequence variant interpretation, and clinical application of genetic testing, typically in a specialized cardiomyopathy service or in a

network model with access to equivalent expertise (Class I recommendation, evidence level B)

- Pre- and post-test genetic counselling is recommended in all individuals undergoing genetic testing for cardiomyopathy (Class I recommendation, evidence level B)
- If pre-natal diagnostic testing is to be pursued by the family, it is recommended that this is performed early in pregnancy, to allow decisions regarding continuation or co-ordination of pregnancy to be made (Class I recommendation, evidence level C)
- For index patients:
  - Genetic testing is recommended in patients fulfilling diagnostic criteria for cardiomyopathy in cases where it enables diagnosis, prognostication, therapeutic stratification, or reproductive management of the patient, or where it enables cascade genetic evaluation of their relatives who would otherwise be enrolled into long-term surveillance (Class I recommendation, evidence level B)
  - Genetic testing is recommended for a deceased individual identified to have cardiomyopathy at post-mortem if a genetic diagnosis would facilitate management of surviving relatives (Class I recommendation, evidence level C)
  - Genetic testing may be considered in patients fulfilling diagnostic criteria for cardiomyopathy when it will have a net benefit to the patient, considering the psychological impact and preference, even if it does not enable diagnosis, prognostication, or therapeutic stratification, or cascade genetic screening of their relatives (Class IIb recommendation, evidence level C)
  - Genetic testing in patients with a borderline phenotype not fulfilling diagnostic criteria for a cardiomyopathy may be considered only after detailed assessment by specialist teams (Class IIb recommendation, evidence level C)
- For family members:
  - It is recommended that cascade genetic testing, with pre- and post-test counselling, is offered to adult at-risk relatives if a confident genetic diagnosis (i.e. a P/LP variant) has been established in an individual with cardiomyopathy in the family (starting with first-degree relatives if available, and cascading out sequentially) (Class I recommendation, evidence level B)
  - Cascade genetic testing with pre- and post-test counselling should be considered in paediatric at-risk relatives if a confident genetic diagnosis (i.e. a P/LP variant) has been established in an individual with

cardiomyopathy in the family (starting with first-degree relatives, if available, and cascading out sequentially), considering the underlying cardiomyopathy, expected age of onset, presentation in the family, and clinical/legal consequences (Class IIa recommendation, evidence level B)

- Testing for the presence of a familial variant of unknown significance, typically in parents and/or affected relatives, to determine if the variant segregates with the cardiomyopathy phenotype should be considered if this might allow the variant to be interpreted with confidence (Class IIa recommendation, evidence level C)
- Diagnostic genetic testing is not recommended in a phenotype-negative relative of a patient with cardiomyopathy in the absence of a confident genetic diagnosis (i.e. a P/LP variant) in the family (Class III recommendation, evidence level C)" (Arbelo et al., 2023).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81401	Molecular pathology procedure, Level 2 (e.g., 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81403	Molecular pathology procedure, Level 4 (e.g., analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more

	independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (e.g., analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (e.g., analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (e.g., analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)
81407	Molecular pathology procedure, Level 8 (e.g., analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)
81408	Molecular pathology procedure, Level 9 (e.g., analysis of >50 exons in a single gene by DNA sequence analysis)
81413	Cardiac ion channelopathies (e.g., Brugada syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia); genomic sequence analysis panel, must include sequencing of at least 10 genes, including ANK2, CASQ2, CAV3, KCNE1, KCNE2, KCNH2, KCNJ2, KCNQ1, RYR2, and SCN5A
81414	Cardiac ion channelopathies (e.g., Brugada syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia); duplication/deletion gene analysis panel, must include analysis of at least 2 genes, including KCNH2 and KCNQ1
81439	Hereditary cardiomyopathy (e.g., hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy), genomic sequence analysis panel, must include sequencing of at least 5 cardiomyopathy-related genes (e.g., DSG2, MYBPC3, MYH7, PKP2, TTN)
81479	Unlisted molecular pathology procedure
0237U	Cardiac ion channelopathies (e.g., Brugada syndrome, long QT syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia), genomic sequence analysis panel including ANK2, CASQ2, CAV3, KCNE1, KCNE2, KCNH2, KCNJ2, KCNQ1, RYR2, and SCN5A, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® Cardiac Ion Channelopathies Analysis Lab/Manufacturer: Variantyx Inc

S3861	Genetic testing, sodium channel, voltage-gated, type V, alpha subunit (SCN5A) and variants for suspected brugada syndrome
S3865	Comprehensive gene sequence analysis for hypertrophic cardiomyopathy
S3866	Genetic analysis for a specific gene mutation for hypertrophic cardiomyopathy (HCM) in an individual with a known HCM mutation in the family

Genetic Testing for Lactase Insufficiency

Policy Number: AHS – M2080 – Genetic Testing for Lactase Insufficiency	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Lactose intolerance (LI) is a common clinical syndrome defined by abdominal pain, flatulence, bloating, borborygmus and osmotic diarrhea; LI is caused by the breakdown of nondigested lactose by the gut microflora (Ponte et al., 2016a).

Lactose malabsorption (LM) is the non-digestion of lactose caused by low expression of the enzyme lactase and is a physiologic feature occurring in most mammals after infancy (Di Rienzo et al., 2013; Ponte et al., 2016b).

II. Related Policies

Policy Number	Policy Title
N/A	Not Applicable

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

1) For the prediction of lactase insufficiency, targeted mutation analysis of *LCT* -13910 C>T **DOES NOT MEET COVERAGE CRITERIA**.

2) For individuals with lactose intolerance and/or lactase insufficiency, genetic testing of *LCT* and/or *MCM6* **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

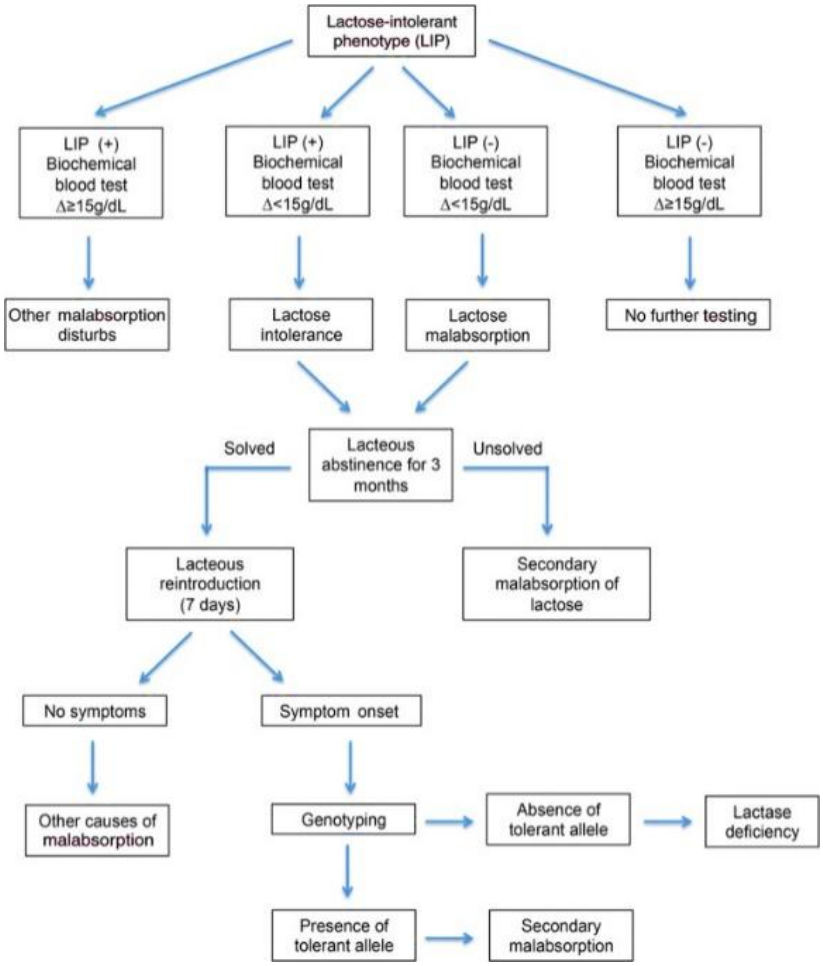
Term	Definition
AAP	American Academy of Pediatrics
ACG	American College of Gastroenterology
BSACI	British Society for Allergy & Clinical Immunology
C/T-13910	Eurasian lactase persistence variant
CLIA	Clinical Laboratory Improvement Amendments
CMS	Centers for Medicare and Medicaid Services
FODMAP	Fermentable oligo-, di- and monosaccharides and polyols
FGID	Functional gastrointestinal disorders
HBT	Hydrogen breath test
IBD	Inflammatory bowel disease
LBT	Lactose breath test
LCT	Lactase/lactase-phlorizin hydrolase
LD	Lactase deficiency
LDTs	Laboratory developed tests
LI	Lactose intolerance
LIP	Lactose-intolerant phenotype
LM	Lactose malabsorption
LNP	Lactase non-persistence
LTT	Lactose tolerance test
MCM6	*Minichromosome maintenance complex component 6*
NIH	National Institutes of Health
PCR	Polymerase chain reaction
RNA	Ribonucleic acid
RT-PCR	Real-time polymerase chain reaction
SNPs	Single nucleotide polymorphisms

V. Scientific Background

Lactose is a disaccharide, which is a class of sugars comprised of two monosaccharides or simple sugars. Lactose consists of galactose bound to glucose and is the main source of carbohydrates from mammalian milk. Intestinal absorption of lactose

requires initial hydrolysis by the enzyme lactase. Low lactase activity results in undigested lactose and colonic bacterial fermentation of that lactose. This leads to the characteristic symptoms of lactose intolerance, such as bloating and flatulence (Luyt et al., 2014).

Lactase expression decreases as consequence of the normal maturational down-regulation after weaning, ultimately to undetectable levels in most populations (Swallow, 2003). Lactase expression persists, however, in descendants of populations that traditionally practice cattle domestication who maintain the ability to digest milk and other dairy products into adulthood (Deng et al., 2015). Adult expression of the gene encoding lactase (LCT), located on chromosome two at 2q21 appears to be regulated by *cis*-acting elements (Wang et al., 1995) and is inherited as an autosomal recessive trait (Enattah et al., 2002). The LCT gene is regulated by the nearby *MCM6* gene (minichromosome maintenance complex component 6), which encodes a helicase complex. A few different *MCM6* variants have been identified in affecting LCT gene expression (NIH, 2024). Single nucleotide polymorphisms (SNPs) associated with the lactase persistence vary by region. In European populations it is associated with C/T-13910 and G/A-22018 mutations of the LCT gene (Enattah et al., 2002; Hogenauer et al., 2005; Poulter et al., 2003; Ridefelt & Hakansson, 2005). Additional mutations have been identified in Saudi Arabia populations with G-13915 (Imtiaz et al., 2007), and in African tribes with the G-14010, G-13915, and G-13907 polymorphisms (Ingram et al., 2007; Tishkoff et al., 2007). No SNP associated with lactase persistence has been identified in the lactase gene regulatory sequence in Chinese populations (Zheng et al., 2016). In adult patients with homozygous lactase persistence, enzyme levels are 10-times higher than for patients with homozygous non-persistence, and heterozygous individuals (Deng et al., 2015; Enattah et al., 2007).



Lactase deficiency Baffour-Awuah et al. (2015) is defined as markedly reduced brush-border lactase activity relative to the activity observed in infants (Deng et al., 2015). Continued dairy consumption despite low expression of lactase results in unabsorbed lactose being present in the intestinal tract (lactose malabsorption [LM]), which can lead to symptoms of lactose intolerance (LI) in susceptible individuals (Hammer & Hogenauer, 2024).

Lactose intolerance is defined by patient reports of abdominal pain, bloating, borborygmi, and diarrhea induced by dairy consumption. Unabsorbed lactose increases the osmotic load thus increasing the intestinal water content, resulting in osmotic diarrhea. Additionally, lactose and other poorly-absorbed oligosaccharides, disaccharides, monosaccharides, and polyols ubiquitous in the diet are readily fermented by the colonic microbiome, leading to production of short-chain fatty acids and gas (mainly hydrogen [H_2], carbon dioxide [CO_2], and methane [CH_4]) (Magge &

Lembo, 2012; Shepherd et al., 2013). LI may be associated with nonspecific symptoms, abdominal pain, bloating, flatulence, diarrhea, or vomiting (Hammer & Hogenauer, 2024); however, it is unclear whether these symptoms are directly due to lactose ingestion. Although LM is nearly always attributable to LD, it is not possible to make a definitive diagnosis on clinical presentation alone because double-blind trials have shown that the reliability of self-reported LI is very poor (Deng et al., 2015; Suarez et al., 1995; Zheng et al., 2016).

Determining if reported symptoms of LI are resultant from LD can be approached through several different methods. The gold standard is the measurement of lactase, sucrase, and maltase activity through intestinal biopsies. However, this method is not commonly used due to its invasive nature (Di Rienzo et al., 2013). Other tests, such as the lactose breath test or biochemical blood tests are more frequently used (Furnari et al., 2013; Mattar et al., 2013; Ponte et al., 2016b). In addition to biochemical blood tests, genetic markers may be useful for LI diagnosis; however, a positive genetic test indicates whether lactase activity decline may represent a clinical problem for the patient, but the test does not give information on actual patient symptoms, making it inappropriate as an initial screening as not all patients with LM will develop symptoms of LI (Ponte et al., 2016a).

On the contrary, this information is more readily accessible by combining the lactose breath test with intolerance symptom evaluation (Di Stefano et al., 2009). Usual LI management involves excluding milk and milk products from the diet, while ensuring adequate calcium intake (Misselwitz, 2014; Ponte et al., 2016b; Usai-Satta et al., 2012). The use of genetic tests has been proposed as an adjunct to LI diagnosis to differentiate primary LD from secondary causes (Bodlaj et al., 2006) as depicted below in the figure taken from Ponte et al. (2016b).

Clinical Utility and Validity

Marton et al. (2012) compared the common polymorphism C/T 13910 with the lactase breath test and lactose tolerance test to assess each test's ability to predict genotype/phenotype relationships. The agreement of the breath test and genotype was 0.88 sensitivity and 0.85 specificity whereas the agreement between genotype and tolerance test was 0.94 sensitivity and 0.90 specificity (Marton et al., 2012).

Baffour-Awuah et al. (2015) studied the association of genotypes at the -13910 and -22018 SNPs with clinical characteristics, RNA quantification, and enzymatic phenotypes among a range of European ethnicities within the U.S. population. The authors concluded that "13910T/T genotype will frequently, but not perfectly, predict lactase persistence in this mixed European-ancestry population; a -13910T/C genotype will not predict the phenotype" (Baffour-Awuah et al., 2015).

Misselwitz et al. (2013) stated that genetic testing for the −13910*T genotype in certain African, Arabic, or Asian subpopulations has limited value because lactase persistence may be linked to different polymorphisms. The authors also stated that genetic tests

will be negative in patients with secondary causes of lactase deficiency and that no information about clinical symptoms lactose intolerance will be obtained during testing (Misselwitz et al., 2013).

Brasen et al. (2017) genotyped 3395 routine samples using real-time polymerase chain reaction (PCR) for the -13910C > T-variant to determine the prevalence of the variants in a Danish cohort examined for lactose intolerance as well as to improve the real-time PCR analysis for detection of the different variants. The researchers found that "Using real-time PCR resulted in 100% successful genotyping of the -13910C > T variant. By using a quality value of 99% and sequencing the undetermined samples we improved the ability of the assay to identify variants other than -13910C > T. This resulted in a reduction of the diagnostic error rate by a factor of 2.4 while increasing the expenses only 3%" (Brasen et al., 2017).

Coluccia et al. (2019) compared results from a lactose breath test and a lactase-gene polymorphism test in a total of 158 symptomatic adults to identify lactose intolerance. Whole blood samples were used for genetic testing purposes. Lactose breath testing resulted in positive results in 75.9% of participants, while genetic testing identified lactase-gene polymorphisms in 82.3% of participants. In conclusion, the authors state, "We suggest considering the use of the genetic test after LBT [lactose breath test] administration, when secondary hypolactasia is suspected, for completion of diagnostic procedures" (Coluccia et al., 2019).

Muendlein et al. (2019) developed a real-time PCR protocol for the detection of the LCT-13910C>T variant from whole blood samples. Lactose tolerance in adults is known to be strongly associated with the genetic variant LCT-13910C>T, which lies near the lactose encoding gene. Results from real-time PCR were compared to those from Sanger sequencing. A total of 105 whole blood samples were analyzed. When compared to Sanger sequencing, the real-time PCR protocol was determined to be a reliable method for the detection of the LCT-13910C>T (Muendlein et al., 2019).

In a cross-sectional study by Couce et al. (2020), 493 children suspected of functional gastrointestinal disorders (FGID) were studied using the exhaled H2 test, gastrointestinal symptoms, and SNP C/T-13910 genetic testing to observe the correlation between the genotype and phenotype of the C/T-13910 lactase non-persistence (LNP) gene. "The C/T-13910 genotype distribution was as follows: CC, 46.0%; CT, 39.5%; TT 14.4%. The frequency of the LP allele was 34.1%." A significant increase in LNP genotype, H2 test, and gastrointestinal symptoms were observed with increasing age. According to phenotype, CC carriers were mainly lactose non-absorbers (75.4%), TT carriers were lactose-absorbers (91.6%), and CT heterozygotes were predominantly lactose absorbers (90.7%) and lactose tolerant (74.3%). According

to these results and its prevalence in older age, the authors state that the C/T-13910 polymorphism is significantly correlated with the phenotype and the authors suggest that the practical value of genetic testing is greater in older children (Couce et al., 2020).

Nardone et al. (2021) studied the prevalence of lactose intolerance assessed by hydrogen breath test (H-BT) and investigated the prevalence of three single genetic polymorphisms of the lactase gene. A total of 54 IBD patients were recruited, and H-BT was positive in 64.8% of IBD patients and 62.3% control patients. The genetic analysis revealed that 46 IBD patients (85.2%) had the wild-type genotype (LCT-13910 CC) while the other polymorphisms (CT-22018, AG-13910, and CT-22018/AG-13910) were less common in IBD patients. In the control group, the wild genotype was found in 87% of the patients. Therefore, the prevalence of polymorphisms did not differ between the IBD group and the control group. The correlation between positive H-BT and genetic analysis showed that the "wild-type genotype was associated with higher rate of lactose intolerance in the total population" (Nardone et al., 2021).

Usai-Satta et al. (2021) reviewed the usefulness of hydrogen breath testing in the nutritional management of carbohydrate digestive disorders, including lactose malabsorption and intolerance, using the online databases PubMed, Medline, and Cochrane. According to the authors, the literature search yielded that though lactose breath testing is an indirect test for lactose malabsorption, "Lactose BT showed good sensitivity and optimal specificity for lactose malabsorption", leading them to conclude that "Before starting a low FODMAP [fermentable oligo-, di- and monosaccharides and polyols] diet, lactose BT should be suggested in a population with low prevalence of hypolactasia," helped in part by its non-invasiveness and inexpensiveness (Usai-Satta et al., 2021).

Cavichio et al. (2024) studied the agreement between C/T-13910 polymorphism genotyping results and lactose tolerance test (LTT) results in Brazil. LTT is the most commonly used LI diagnostic test in Brazil. The C/T-13910 polymorphism has mostly been studied in Caucasian populations; therefore, the authors of this study aimed to investigate the accuracy of C/T-13910 polymorphism genotyping in Brazil's "highly mixed" population. The authors included 404 patients who had undergone both C/T-13910 polymorphism genotyping and an LTT. Overall, "there was agreement between the genotyping and LTT results in 325 (80.4%) patients and discordance in 79 (19.6%) patients." The authors classified these results as "moderate agreement" and recommend additional studies to further investigate (Cavichio et al., 2024).

VI. Guidelines and Recommendations

American Academy of Pediatrics (AAP)

The AAP published guidelines (Heyman, 2006) on the evaluation of Lactose Intolerance in Infants, Children and Adolescents which recommend:

"Children with suspected lactose intolerance can be assessed clinically by dietary lactose elimination or by tests including noninvasive hydrogen breath testing or invasive intestinal biopsy determination of lactase (and other disaccharidase) concentrations. Treatment consists of use of lactase-treated dairy products or oral lactase supplementation, limitation of lactose-containing foods, or dairy elimination… If dairy products are eliminated, other dietary sources of calcium or calcium supplements need to be provided."

The AAP also reported that "Recent studies suggest that in the future, genetic testing may be useful for identifying individuals at increased risk of lactase deficiency and consequent diminished bone mineral density, potentially allowing early intervention with dietary manipulation or nutrient supplementation" (Heyman, 2006).

This statement was reaffirmed in 2012.

American College of Gastroenterology (ACG)
The ACG has a webpage focused on lactose intolerance in children. Regarding diagnoses, the ACG states that "Lactose intolerance is diagnosed by a simple test called a hydrogen breath test" (ACG, 2024). Genetic testing was not mentioned.

The 1st Rome Consensus Conference

The 1st Rome Consensus Conference issued their opinion on H_2-breath testing for sugar malabsorption. They found that "The determination of lactase activity in jejunal biopsy is currently considered the gold standard for lactose malabsorption. However, its results can be influenced by the irregular dissemination of lactase activity throughout the small intestine mucosa. On the basis of literature review, the lactose breath test is a reliable, non-invasive technique, which is provided with good sensitivity and optimal specificity."

Though it is acknowledged that there is no unequivocal reference test available for lactose malabsorption testing, the Conference graded the quality of evidence for the above as Class I ("Conditions with evidence or general accord that a particular procedure or treatment is useful or effective") of Strength A ("Data derived from multiple large and intermediate RCT") (Gasbarrini et al., 2009).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations

(LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP] by techniques such as restriction enzyme digestion or melt curve analysis)
81479	Unlisted molecular pathology procedure

Genetic Testing for Li-Fraumeni Syndrome

Policy Number: AHS – M2081 – Genetic Testing for Li-Fraumeni Syndrome	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Li-Fraumeni syndrome (LFS) is an autosomal dominant cancer predisposition syndrome characterized by a wide range of malignancies that appear at an unusually early age and is generally associated with defects in the tumor protein p53 gene (*TP53*) (Evans, 2024; Mai et al., 2016; Malkin, 2011).

II. Related Policies

Policy Number	Policy Title
AHS-M2003	Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate Cancers

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have received genetic counseling and who have a close blood relative (see Note 1) with a *TP53* mutation (see Note 2), the following germline testing **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial mutation.
   b) Comprehensive *TP53* gene sequencing when the specific *TP53* mutation is unknown.

2) For individuals who have received genetic counseling, germline testing for *TP53* mutations (single gene or multi-gene panel testing) **MEETS COVERAGE CRITERIA** under **any** of the following conditions:

   a) For an individual who meets either the classic or the Chompret clinical diagnostic criteria for LFS:

      i) Classic LFS is defined by the presence of **all** of the following criteria:

         (a) An individual with a sarcoma before 45 years of age.

         (b) Having a first-degree relative (see Note 1) with any cancer before 45 years of age.

         (c) Having an additional first- or second-degree relative (see Note 1) with any cancer before 45 years of age, or a sarcoma at any age.

      ii) Chompret clinical diagnostic criteria is defined by the presence of any **one** of the following:

         (a) Individual with a tumor belonging to the LFS tumor spectrum (e.g., soft tissue sarcoma, osteosarcoma, central nervous system (CNS) tumor, breast cancer, adrenocortical carcinoma) before age 46 years **AND** at least one first- or second-degree relative (see Note 1) with a LFS tumor (except breast cancer if proband has breast cancer) before 56 years of age or with multiple tumors at any age.

         (b) Individual with multiple tumors (except multiple breast tumors), two of which belong to the LFS tumor spectrum described above, with the first tumor having occurred before 46 years of age.

         (c) Individual with adrenocortical carcinoma (ACC), or choroid plexus tumor or rhabdomyosarcoma of embryonal anaplastic subtype, at any age, irrespective of family history.

         (d) Individual was diagnosed with breast cancer before 31 years of age.

   b) For an individual with a personal or family history of pediatric hypodiploid acute lymphoblastic leukemia.

   c) For individuals who have been diagnosed with any cancer before 30 years of age and for whom a pathogenic or likely pathogenic *TP53* variant has been identified on tumor-only genomic testing.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For all other situations not addressed above, single gene testing for a germline *TP53* mutation **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Close blood relatives include 1st-degree relatives (e.g., parents, siblings, and children), 2nd-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings), and 3rd-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins).

Note 2: At the present time, there are no specific, evidence-based, standardized guidelines for recommendations of which "at risk" relatives should be tested. In relatives of an index case, the risk of having a pathologic mutation, and developing disease, is influenced by numerous factors that should be considered in evaluating risk:

1. Proximity of relation to index case (first-, second-, or third-degree)
2. Mode of inheritance of mutation (autosomal dominant versus autosomal recessive)
3. Degree of penetrance of mutation (high, intermediate or low)
4. Results of detailed pedigree analysis
5. De novo mutation rate

If a proband has a *TP53* mutation, the risk to the proband's offspring of inheriting the mutation is 50 percent. If a proband has a *TP53* mutation, the risk to other relatives may depend on the genetic status of the proband's parents (that is, it is not a de novo mutation in the proband). Most *TP53* mutations are inherited from 1 of a proband's parents. After a mutation has been identified in a proband, the proband's parent with any pertinent cancer history of family history should be tested first to establish the lineage of the mutation; otherwise, both parents should be tested. A family history could appear to be negative because of incomplete penetrance of the mutation, limited family members available for testing, early death of a parent, etc.

IV. Table of Terminology

Term	Definition
ACC	Adrenocortical carcinoma
ACMG	American College of Medical Genetics and Genomics
ASBRS	American Society of Breast Surgeons
BAX	*BCL2 associated x* gene

BC	Breast cancer
BCL10	*BCL10 immune signaling adaptor* gene
BRCA 1	*Breast cancer 1* gene
BRCA 2	*Breast cancer 2* gene
CDKN2A	*Cyclin dependent kinase inhibitor 2A* gene
CHEK2	*Checkpoint kinase 2 gene*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CNS	Central nervous system
DNA	Deoxyribonucleic acid
ERN	European Reference Network
FDA	Food and Drug Administration
GIST	Gastrointestinal stromal cell tumors
LDT	Laboratory-developed test
LFL	Li-Fraumeni-like syndrome
LFS	Li-Fraumeni syndrome
LFSA	Li-Fraumeni Syndrome Association
NCCN	National Comprehensive Cancer Network
NORD	National Organization of Rare Diseases
PALB2	*Partner and localizer of BRCA2* gene
PGV	Pathogenic germline variant
PTEN	*Phosphatase and tensin homolog* gene
PV	Pathogenic variant
STK11	*Serine/threonine kinase 11* gene
STS	Soft tissue sarcomas
TP53	*Tumor protein p53* gene
TP63	*Tumor protein p63* gene

V. Scientific Background

Li-Fraumeni syndrome (LFS) is a rare cancer predisposition syndrome associated with a germline mutation in the tumor suppressor gene TP53 (tumor protein p53) on chromosome 17p13.1 (Correa, 2016). This genetic mutation has an autosomal dominant pattern of inheritance with high penetrance. TP53 encodes for a ubiquitous transcription factor that is responsible for a complex set of critical regulatory functions that promote DNA repair and tumor suppression during episodes of cellular stress and DNA damage (Sorrell et al., 2013). Most TP53 mutations are clustered in the DNA-binding domain within specific codons, such as 175 and 248 (Villani et al., 2016). TP53 mutations are often missense alterations (Petitjean et al., 2007) that cause a change in one nucleotide and encode for a different amino acid than the one

typically found in that location within the protein. Missense mutations are usually transcriptionally inactive leading to downstream events permissive for development of various malignancies throughout life; however, some reports have shown gain of function oncogenic effects in TP53 (Brosh & Rotter, 2009; Sigal & Rotter, 2000).

Li-Fraumeni syndrome is characterized clinically by the development of cancers arising in multiple organ systems, often at a young age (Birch et al., 1998; Birch et al., 1994; Garber et al., 1991; Li et al., 1988; Mai et al., 2012; Malkin et al., 1990; Olivier et al., 2010; Ruijs et al., 2010). These patients have a very high lifetime cumulative risk of developing malignancies and early-onset malignancies; around 50% of the individuals carrying mutations in TP53 will develop cancer by the age of 30 years (Hwang et al., 2003; Lustbader et al., 1992; Schneider et al., 2013). While many tumor types can be seen in patients with LFS, four cancers (breast, sarcoma, brain, and adrenocortical carcinoma) comprise about 80% of LFS associated tumors (Gonzalez et al., 2009; Li et al., 1988; Lynch et al., 1978; Olivier et al., 2003).

Breast Cancer accounts for about 30% of all LFS-associated tumors (Gonzalez et al., 2009; Olivier et al., 2003). Individuals with LFS-associated breast cancer tend to present at an earlier age (in the 20s or early 30s) with more advanced stage disease at the time of initial diagnosis (NCCN, 2024). The ability to distinguish between a germline TP53 mutation (LFS) and a somatic TP53 pathogenic variant (TP53 mosaicism or clonal hematopoiesis) is very important for breast cancer patients and relatives and may help to determine the best method of treatment; "For PV [pathogenic variant] carriers in high-penetrance genes like BRCA1, BRCA2, and TP53, prophylactic mastectomy is often recommended and radiation therapy avoided when possible" (Batalini et al., 2019).

Sarcomas account for about 30% of all LFS-associated tumors (Gonzalez et al., 2009; Ognjanovic et al., 2012; Olivier et al., 2003; Palmero et al., 2010). Multiple types of soft tissue sarcomas and osteosarcoma are associated with LFS; but Ewing's sarcoma, gastrointestinal stromal cell tumors (GIST), desmoid tumors, and angiosarcomas have not been reported in LFS patients (Olivier et al., 2003).

Brain Tumors occur in approximately 14% of individuals with TP53 mutations (Gonzalez et al., 2009; Olivier et al., 2003; Palmero et al., 2010; Ruijs et al., 2010). Glioblastomas/astrocytomas are the most common, but medulloblastoma, ependymoma, supratentorial primitive neuroectodermal tumors, and choroid plexus tumors may also be seen (Farrell & Plotkin, 2007; Ruijs et al., 2010).

Adrenocortical Carcinoma (ACC) accounts for about seven percent of cancers in TP53 mutation carriers overall (Gonzalez et al., 2009; Palmero et al., 2010). While ACC has been diagnosed in individuals with LFS at a wide range of ages, it is

considered a hallmark of LFS when diagnosed in childhood (Gonzalez et al., 2009; Herrmann et al., 2012; Palmero et al., 2010).

Other LFS Cancers

Beyond the four core LFS cancers, the next most frequently associated cancers include leukemia, lung, colorectal, skin, gastric, and ovarian (Gonzalez et al., 2009; Masciari et al., 2011; Olivier et al., 2003; Palmero et al., 2010; Walsh et al., 2011; Wong et al., 2006). All cancer types are diagnosed at younger than average ages.

Over the years, several types of classifying systems have been developed for LFS diagnostic purposes (shown below in table 1). The classic LFS phenotype was clinically defined before the identification of germline mutations in TP53; these criteria are the most stringent and are the ones used to make a clinical diagnosis of LFS (with or without the identification of a deleterious germline TP53 mutation) (Li et al., 1988). Further studies revealed that, although highly specific for TP53 germline mutations, these criteria fail to include many mutation-positive families. Broader criteria were developed by Birch and Eeles to identify families which are Li-Fraumeni-like (LFL) (Birch et al., 1994; Eeles, 1995). The most robust analysis of TP53 mutation carriers to date was performed in France by Bougeard et al. (2008); these analyses helped to develop the most recent version of the Chompret criteria which can better identify families with milder phenotypes (Bougeard et al., 2001; Bougeard, Renaux-Petel, Flaman, Charbonnier, Fermey, Belotti, Gauthier-Villars, Stoppa-Lyonnet, Consolino, Brugières, et al., 2015; Chompret et al., 2001; Gonzalez et al., 2009). The Chompret criteria for clinical diagnoses of LFS was shown to provide the highest positive predictive value and, when combined with the classic LFS criteria, provided the highest sensitivity for identifying individuals with LFS (Bougeard, Renaux-Petel, Flaman, Charbonnier, Fermey, Belotti, Gauthier-Villars, Stoppa-Lyonnet, Consolino, Brugieres, et al., 2015; Bougeard et al., 2008; Tinat et al., 2009).

Table 1: Types of LFS classifying systems

Clinical criteria	Description
Classical LFS (Li et al., 1988)	**I-**sarcoma diagnosed in childhood/young adulthood (≤ 45 years) **and**
	II-first-degree relative with any cancer in young adulthood (≤ 45 years) **and**
	III-first- or second-degree relative with any cancer diagnosed in young adulthood (≤ 45 years) **or** sarcoma diagnosed at any age.
LFL – Birch (Birch et al., 1994)	**I-**childhood cancer (at any age) or sarcoma, CNS tumor, or ACC in young adulthood (≤ 45 years) **and**

Clinical criteria	Description
	II-first- or second-degree relative with LFS-spectrum cancer (sarcoma, BC, CNS tumor, ACC, leukemia) at any age **and**
	III-first- or second-degree relative with any cancer diagnosed at age < 60 years.
LFL – Eeles 1 and 2 (Eeles, 1995)	**I-**at least two first- or second-degree relatives with LFS-spectrum cancer (sarcoma, BC, CNS tumor, ACC, leukemia, melanoma, prostate cancer, pancreatic cancer) diagnosed at any age **I-** sarcoma diagnosed at any age **and II-**at least two other tumors diagnosed in one or more first- or second-degree relatives: BC at age < 50 years; CNS tumor, leukemia, ACC, melanoma, prostate cancer, pancreatic cancer at age < 60 years; **or** sarcoma at any age.
LFL – Chompret (Chompret et al., 2001)	**I-**diagnosis of sarcoma, CNS tumor, BC, ACC at age < 36 years **and II-**first- or second-degree relative with any of the above cancers (except BC if proband had BC) **or** relative with multiple primary tumors at any age **or III-**multiple primary tumors, including two of the following: sarcoma, CNS tumor, BC, or ACC, with the first tumor diagnosed at age < 36 years regardless of family history; **or IV-**ACC at any age, regardless of family history.
LFL – Modified Chompret (Bougeard et al., 2008; Tinat et al., 2009)	**I-**index case with LFS-spectrum cancer (sarcoma, BC, CNS tumor, ACC, leukemia, bronchioloalveolar carcinoma) occurring at age < 46 years **and II-**a first- or second-degree relative with LFS-spectrum cancer occurring at age < 56 years (except BC if the index case has BC as well), **or** multiple tumors; **or III-**index patient with multiple tumors, at least two of which are in the LFS spectrum, the first occurring at age < 46 years; **or IV-**ACC or choroid plexus carcinoma occurring at any age or BC occurring at age < 36 years without *BRCA1* or *BRCA2* mutations.
LFL – Revisiting Li-Fraumeni Syndrome from TP53 Mutation Carriers (Bougeard, Renaux-Petel, Flaman, Charbonnier, Fermey, Belotti, Gauthier-Villars,	**Familial presentation:** proband with tumor belonging to LFS tumor spectrum (eg, premenopausal breast cancer, soft tissue sarcoma, osteosarcoma, CNS tumor, adrenocortical carcinoma) before age 46 yr, AND at least on first or second-degree relative with LFS tumor (except breast cancer if proband has breast cancer) before age 56 yr or with multiple tumors; **Multiple primitive tumors:** Proband with multiple tumors (except multiple breast tumors), two of which belong to LFS tumor spectrum and first of which occurred before age 46 yr. **Rare tumors:** patient with adrenocortical carcinoma, choroid plexus tumor or

Clinical criteria	Description
Stoppa-Lyonnet, Consolino, Brugières, et al., 2015)	rhabdomyosarcoma of embryonal anaplastic subtype, irrespective of family history; **Early-onset breast cancer:** Breast cancer before age 31 yr

ACC: adrenocortical carcinoma; BC: breast cancer; CNS: central nervous system; LFS: Li-Fraumeni syndrome; LFL: Li-Fraumeni-like syndrome.

As noted above, the TP53 gene has an autosomal dominant pattern of inheritance (Evans, 2024). Mutations such as this can be studied with a pedigree, which is a genetic based family tree. Pedigrees begin with the "proband," which is the subject being studied or tested. If one of the proband's parents carries the TP53 mutation, each sibling has a 50% risk of having the mutation. If neither parent is found to carry the mutation, the risk to siblings is low, but they should be tested due to the possibility of germline mosaicism. Offspring of a proband have a 50% risk of carrying the mutation. Phenotypes of families carrying TP53 mutations can be highly variable (Malkin, 2011; McBride et al., 2014).

Additionally, mutations in TP53 can lead to different consequences on gene function. A locus is a fixed position on a chromosome where a gene is located. The possibility of a second locus involved in LFS is an additional issue in the etiology of the syndrome since approximately 20% of LFS and up to 80% of LFL families do not exhibit TP53 mutations (Malkin, 2011; McBride et al., 2014). However, no association was found with p53 partners in tumor suppressor pathways, including BAX (BCL2 Associated X) (Barlow et al., 2004), CDKN2A (Cyclin Dependent Kinase Inhibitor 2A) (Portwine et al., 2000), TP63 (tumor protein p63) (Bougeard et al., 2001), CHEK2 (Checkpoint kinase 2) (Bougeard et al., 2001), BCL10 (BCL10 Immune Signaling Adaptor) (Stone et al., 1999), or PTEN (Phosphatase and tensin homolog) (Brown et al., 2000) in TP53-negative families. Although a few studies have linked other loci to LFS (Aury-Landas et al., 2013; Bachinski et al., 2005), TP53 remains the only gene conclusively associated to the syndrome (Evans, 2024).

Large panels or single gene tests can be used to identify a TP53 pathogenic variant. For example, Invitae has developed a test which analyzes only the TP53 gene with a three mL whole blood sample; this test has a turnaround time of 10-21 days (Invitae, 2024). Blueprint Genetics has developed a similar one gene panel test which also analyzes the TP53 gene in three to four weeks (BluePrint, 2022).

It is common to find TP53 mutations during tumor profiling, but germline mutations are very rare. Germline testing is not recommended if somatic mutations in TP53 are

found unless there is a defined personal or family history indicative of Li-Fraumeni syndrome (Peshkin, 2024).

Clinical Utility and Validity

The reported percentage of LFS due to TP53 mutation varies between studies and criteria used. According to (Schneider et al., 2013), approximately 80 percent of individuals with features of LFS will have an identifiable TP53 mutation. Families that have clinical features of LFS without TP53 mutation are more likely to have a different hereditary cancer syndrome (Schneider et al., 2013). Some studies have reported that 70% to 80% of families meeting the classic LFS criteria have the TP53 mutation (Nagy et al., 2004; Varley, 2003). However, Gonzalez et al. (2009) reported that a slightly lower positive predictive value for the p53 mutation rate using the classic criteria among 341 patients (56%), with high specificity of 91% but low sensitivity (40%). Chompret et al. (2001) reported TP53 mutations can be found in 20% of cases using the Chompret criteria. Gonzalez et al. (2009) reported a higher positive predictive value for LFL syndrome using Chompret criteria (35%) than Birch (16%) or Eeles (14%).

Gonzalez et al. (2009) used a clinical testing cohort to understand the spectrum of tumors associated with germline p53 mutations. Mutations were identified in 17% (91 of 525) of patients submitted for testing. All families with a p53 mutation had at least one family member with a sarcoma, breast, brain, or adrenocortical carcinoma. Overall, 75 patients with a p53 mutation had an adequate family history, and out of these 75, 71 fulfilled the classic LFS or Chompret criteria. When the classic LFS and Chompret criteria were used together, the testing sensitivity was 95%, and the specificity was 52% (Gonzalez et al., 2009).

Villani et al. (2011) assessed the feasibility and clinical impact of a comprehensive surveillance protocol in asymptomatic TP53 mutation carriers in eight families with LFS. A total of 33 TP53 mutation carriers were identified, 18 of whom underwent surveillance. In the surveillance group, 10 tumors developed in seven patients, and all seven patients were alive after a median follow-up of 24 months. In the non-surveillance group, 12 tumors developed in 10 patients, and only two were alive after 24 months. The authors reported a three-year overall survival of 100% in the surveillance group compared to 21% in the non-surveillance group (Villani et al., 2011).

Bougeard, Renaux-Petel, Flaman, Charbonnier, Fermey, Belotti, Gauthier-Villars, Stoppa-Lyonnet, Consolino, Brugieres, et al. (2015) evaluated the genetic spectrum of LFS. The authors identified 415 TP53 mutation carriers with 133 different TP53 mutations. A total of 322 of these carriers were affected and eventually developed 552 tumors. In childhood, the LFS tumor spectrum was as follows: “osteosarcomas, adrenocortical carcinomas, central nervous system (CNS) tumors, and soft tissue

sarcomas (STS) observed in 30%, 27%, 26%, and 23% of the patients, respectively." Adults presented with breast carcinomas in 79% of females and with soft tissue sarcomas in 27% of overall patients. Age of onset varied according to type of mutation; carriers with dominant-negative missense mutations had a mean onset of 21.3 years, carriers with loss of function mutations had a mean onset of 28.5 years, and carriers with genomic rearrangements had a mean onset of 35.8 years. The authors suggested that stratifying clinical management of LFS by class of mutation may be useful (Bougeard, Renaux-Petel, Flaman, Charbonnier, Fermey, Belotti, Gauthier-Villars, Stoppa-Lyonnet, Consolino, Brugieres, et al., 2015).

In 2016, Villani et al. (2016) updated their assessment of a prospective observational study and modified the surveillance protocol. Out of the 89 carriers of TP53 pathogenic variants in 39 unrelated families, 40 (45%) agreed to surveillance and 49 (55%) declined surveillance. The authors reported a five year overall survival was 88.8% in the surveillance group and 59.6% in the non-surveillance group (Villani et al., 2016).

Rana et al. (2018) compared the histories of patients whose TP53 mutations (TP53+) were identified by panel testing to those whose mutations were identified by single-gene testing. A total of 126 TP53+ patients were identified with panel testing, and 96 were identified with single-gene testing. The patients who were identified with panel testing were older at "first cancer identification" and at cancer diagnosis. Established LFS testing criteria were met less often in patients in the panel testing cohort, and phenotypes of the panel testing cohort were often different from those in the single-gene cohort (Rana et al., 2018).

Bakhuizen et al. (2019) completed a nation-wide analysis in the Netherlands which measured TP53 germline mutations in early-onset breast cancer cases. This study included data from 370 individuals diagnosed with breast cancer between 2005 and 2016 who were younger than 30 years at the time of diagnosis. All individuals included in the study were tested for TP53 genetic mutations. A total of eight of these individuals were found to carry a likely pathogenic TP53 sequence (less than one percent), showing the rarity of a TP53 mutation in breast cancer cases. However, the researchers note that TP53 mutation prevalence was similar or greater in other studies which included patients with an older age of onset, questioning whether an early age of onset is necessary as a TP53 genetic testing criterion (Bakhuizen et al., 2019).

Lincoln et al. (2020) studied the yield and utility of germline genetic testing following tumor DNA sequencing in patients with cancer. Germline testing was performed on 2023 patients and the prevalence of pathogenic germline variants (PGVs) was calculated. PGVs were found in 617 of the 2023 patients associated with cancers of the breast, colorectal, renal, lung, and bladder. About 82% of the patients identified with a

PGV met the criteria for follow-up testing and 8.1% of PGVs were missed by tumor sequencing. Only four percent of pathogenic TP53 variants were germline, but 64% of the germline TP53 carriers did not meet the Chompret criteria for germline TP53 testing. It was found that genes which frequently acquire somatic mutations were a challenge because clinicians assumed TP53 to be somatic, so TP53 variants identified by tumor germline sequencing were underreported. The authors conclude that although the yield of germline findings of the TP53 gene is relatively low, the clinical impact can be substantial. Therefore, they recommend broader germline testing for these genes despite the low yield (Lincoln et al., 2020).

Terradas et al. (2021) studied TP53 variants that were detected in colorectal cancer patients without a LFS phenotype. A total of 473 patients with colorectal cancer were assessed for TP53 pathogenic variants. Pathogenic variants were identified in 0.05% of the control and 0.26% of the colorectal cancer patients, none of whom fulfilled the clinical criteria for TP53 testing. The authors conclude that "TP53 pathogenic variants should not be unequivocally associated with LFS. Prospective follow-up of carriers of germline TP53 pathogenic variants in the absence of LFS phenotypes will define how surveillance and clinical management of these individuals should be performed" (Terradas et al., 2021).

Yamamoto et al. (2020) performed an analysis of 194 patients with advanced cancer who had undergone next-generation sequencing (NGS) performed only on tumor specimens. The goal was to identify variants that had the potential to be secondary findings. Out of 194 patients, 120 were identified with possible secondary findings. The gene with the highest incidence was TP53, with a total of 97 variants identified among 91 patients. Of these patients, nine had additional germline testing performed, with 14 variant genes involved (BRCA1, n = 1; BRCA2, n = 2; PTEN, n = 2; RB1, n = 1; SMAD4, n = 1; STK11, n = 1; TP53, n = 6). Those persons identified with TP53 variants were confirmed as somatic variants, as opposed to germline. The authors concluded, "We analyzed 24 patients with TP53 variants who underwent a paired tumor–normal NGS assay. As expected, all TP53 variants were confirmed to be somatic variants. A total of 30 patients were tested for germline variants in TP53, but none of them resulted in true SFs, suggesting the low prevalence of SFs in this gene" (Yamamoto et al., 2020).

Patel et al. (2022) studied the clinical utility of widespread germline testing of cancer patients outside of guidelines. The goal of the study was to diversify the research area, as past studies on cancer screening have "skewed towards wealthier socioeconomic populations that lack ethnic diversity." The authors conducted a single center prospective study on germline testing, aiming to "understudied real-world populations." The study included 67 patients, reported as "African American (14), White (50), or Asian American (3)." All patients were outside of guideline concordance for

genetic testing due to either young age, rare tumors, or recurrent or multiple malignancies. There were 11 pathogenic or likely pathogenic variants that increased susceptibility to cancer, including rare germline findings and LFS. The authors concluded that "current practice of guidelines and genetic counselor recommended testing should be re-examined for broader testing for all incoming cancer patients in a more inclusive manner" (Patel et al., 2022).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN maintains guidelines for the diagnosis and management of Li-Fraumeni Syndrome (NCCN, 2024).

NCCN recommends testing for Li-Fraumeni Syndrome in the following situations:

- Individual from a family with a known *TP53* pathogenic/likely pathogenic variant
- Classic Li-Fraumeni syndrome criteria
- Chompret criteria
- Personal or family history of pediatric hypodiploid acute lymphoblastic leukemia
- In individuals with cancer with a pathogenic/likely pathogenic TP53 variant identified on tumor only genomic testing, germline testing should be considered for:
    1. Those meeting one or more of the other LFS testing criterion above after reevaluation of personal and family history
    2. Those diagnosed age <30 with any cancer
    3. Those with clinical scenario not meeting these criteria but warranting germline evaluation per clinician discretion

The classic Li-Fraumeni syndrome criteria are as follows:

- "Combination of an individual diagnosed age <45 y with a sarcoma AND
- A first-degree relative diagnosed age <45 y with cancer AND
- An additional first- or second-degree relative in the same lineage with cancer diagnosed <45 y, or a sarcoma at any age" (NCCN, 2024).

The Chompret criteria are as follows:

- "Individual with a tumor from LFS tumor spectrum (eg, soft tissue sarcoma, osteosarcoma, CNS tumor, breast cancer, adrenocortical carcinoma [ACC]) before 46 y of age, AND at least one first- or second-degree relative with any of the aforementioned cancers (other than breast cancer if the proband has breast cancer) before the age of 56 y or with multiple primaries at any age OR

- Individual with multiple tumors (except multiple breast tumors), two of which belong to LFS tumor spectrum with the initial cancer occurring before the age of 46 y OR
- Individual with adrenocortical carcinoma, or choroid plexus carcinoma or rhabdomyosarcoma of embryonal anaplastic subtype, at any age of onset, regardless of family history OR
- Breast cancer before age 31 years" (NCCN, 2024)

If these criteria are fulfilled, the *TP53* gene may be tested. If the familial pathogenic variant of *TP53* is known, that variant may be tested for. If it is unknown, a comprehensive *TP53* test may be done.

Reproductive options:

- "For patients of reproductive age, advise about options for prenatal diagnosis and assisted reproduction including pre-implantation genetic diagnosis and donor gametes. Discussion should include known risks, limitations, and benefits of these technologies" (NCCN, 2024).

For relatives:

- "Advise about possible inherited cancer risk to relatives, and options for risk assessment, testing, and management.
- Counselor should discuss the importance of genetic counseling and testing for relatives who also may be at increased risk " (NCCN, 2024).

Children (under 18 years):

- "Genetic testing is generally not recommended when results would not impact medical management"(NCCN, 2024).

American College of Medical Genetics and Genomics (ACMG)

The ACMG has noted *TP53* as a gene whose secondary findings should be reported if found (Kalia et al., 2017). In 2021, a joint ACMG/AMP variant interpretation guideline was published for germline *TP53* variants; the authors note that "intense" cancer surveillance for those patients with *TP53* germline pathogenic variants can lead to "reduced cancer-related mortality" (Fortuno et al., 2021).

Li-Fraumeni Syndrome Association (LFSA)

The LFSA notes certain criteria that can be used to determine if genetic testing should be performed. The classic LFS criteria, Chrompret criteria, Birch definition of Li-

Fraumeni-like syndrome, and Eeles definition of Li-Fraumeni-syndrome may all be fulfilled to consider genetic testing (LFSA, 2024). The association goes on to add that the potential of genetic testing (and the implications of the results) should always involve discussions with a genetic counselor, medical providers, and family.

National Organization of Rare Diseases (NORD)

The NORD states that "Li-Fraumeni syndrome is diagnosed based on the presence of a so called pathogenic or likely pathogenic variant in the *TP53* gene."; further, "The potential of genetic testing (and the implications of the results) should always involve discussions with a genetic counselor, medical providers, and family" (NORD, 2021). The NORD also notes that genetic testing can be considered based on classic LFS criteria, Chrompret criteria, the Birch definition of Li-Fraumeni-like syndrome, and the Eeles definition of Li-Fraumeni-syndrome.

American Society of Breast Surgeons (ASBrS)

The ASBrS have published consensus guidelines on genetic testing for hereditary breast cancer. These guidelines state that "Increased access to testing would likely lead to more patients pursuing testing and improving rates of identification of gene carriers. Breast surgeons are well positioned to be a resource for patients who may benefit from testing. Breast surgeons can identify individuals who are suitable for testing, inform patients of the risks and benefits, provide access to genetic testing, and also discuss risk management strategies for those patients who test positive. For patients with less common mutations, strong consideration should be given to consultation with cancer genetics specialists. Hereditary mutations to be considered include *BRCA 1&2*, *PALB2*, and other hereditary breast cancer syndromes, which include but are not limited to Li-Fraumeni syndrome (*TP53* pathogenic variant), Cowden syndrome (*PTEN* pathogenic variant), hereditary diffuse gastric cancer syndrome (*CDH1* pathogenic variant), and Peutz-Jeghers syndrome (*STK11* pathogenic variant)" (Manahan et al., 2019).

European Reference Network (ERN) GENTURIS

The ERN provides recommendations on cancer patients who should be tested for *TP53* germline mutations. They recommend testing the following patients (Frebourg et al., 2020):

- Patients who meet the Chompret Criteria. These include those with familial presentation, multiple primitive tumors, rare tumors such as adrenocortical carcinoma, choroid plexus carcinoma, or rhabdomyosarcoma, or very early-onset breast cancer (Breast cancer before 31 years, irrespective of family history)

- Patients who are children or adolescents presenting with hypodiploid acute lymphoblastic leukemia, unexplained sonic hedgehog-driven medulloblastoma, or Jaw osteosarcoma.
- Patients who develop a second primary tumour, within the radiotherapy field of a first core *TP53* tumor which occurred before 46 years, should be tested for germline *TP53* variants
- Children with any cancer from southern and south-eastern Brazilian families should be tested for the p.R337H Brazilian founder germline *TP53* variant.

The ERN does not recommend testing "patients older than 46 years presenting with breast cancer without personal or familial history fulfilling the 'Chompret Criteria'." If a patient with isolated breast cancer does not fulfill the Chompret Criteria but has a *TP53* variant, the patient should be referred to an expert multidisciplinary team for discussion (Frebourg et al., 2020).

The ERN also provides testing recommendations for pre-symptomatic individuals. They recommend that:

- "Adult first-degree relatives of individuals with germline disease causing TP53 variants should be offered testing for the same germline TP53 variant.
- Testing in childhood of first-degree relatives of individuals with germline disease-causing TP53 variants should be systematically offered, if database shows that the variant can be considered as a high cancer risk TP53 variant conferring a high cancer risk in childhood" (Frebourg et al., 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by

the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81351	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; full gene sequence
81352	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; targeted sequence analysis (eg, 4 oncology)
81353	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; known familial variant

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Lipoprotein(a) Variant(s) as a Decision Aid for Aspirin Treatment and/or CVD Risk Assessment

Policy Number: AHS – M2082 – Genetic Testing for Lipoprotein(a) Variant(s) as a Decision Aid for Aspirin Treatment and/or CVD Risk Assessment	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Lipoprotein(a) (Lp(a)) is a type of low-density lipoprotein (LDL) that consists of a cholesterol bearing LDL – like particle (apolipoprotein B-100) bound to the plasminogen-like glycoprotein apolipoprotein(a) (apo(a)) (Lu et al., 2015; Schmidt et al., 2016) and has been associated with increased risk for cardiovascular disease (CVD) (Tsimikas et al., 2018). Genetic variants of the Lp(a) gene, *LPA*, (rs3798220 and rs10455872) have been significantly associated with Lp(a) levels (Lu et al., 2015) and could serve as indicators of CVD risk (Lee et al., 2017). The genetic variant rs3798220 was found to have a higher risk for thrombosis and therefore may derive more benefit from the anti-thrombotic properties of aspirin (Chasman et al., 2009). As a result, testing for the rs3798220 variant has been proposed as a method of stratifying benefit from aspirin treatment (Shiffman et al., 2012).

This policy only addresses the detection of specific genetic variants of Lp(a) as a decision aid for aspirin therapy or CVD risk.

For information on serum measurement of Lp(a) levels see AHS-G2050-Cardiovascular Disease Risk Assessment.

II. Related Policies

Policy Number	Policy Title
AHS-M2180	Genetic Markers for Assessing Risk of Cardiovascular Disease

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

1) Genetic testing for *LPA* variant(s) (e.g., LPA-Aspirin Check® and Cardio IQ® LPA Aspirin Genotype) **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
AACE	American Association of Clinical Endocrinologists
ACC	American College of Cardiology
ACE	American College of Endocrinology
AHA	American Heart Association
apo(a)	Apolipoprotein(A)
APOE	*Apolipoprotein E*
AS	Aortic stenosis
ASCP	American Society for Clinical Pathology
ASCVD	Atherosclerotic cardiovascular disease
BMI	Body mass index
CAC	Coronary artery calcification
CAVD	Calcific aortic stenosis
CAVD	Calcific aortic valve disease
CHD	Coronary heart disease
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid
CNVs	Copy number variants
CV	Cardiovascular
CVD	Cardiovascular Disease
DNA	Deoxyribonucleic acid
EAS	European Atherosclerosis Society
ESC	The European Society for Cardiology
FDA	Food and Drug Administration

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

FH	Familial hypercholesterolemia
HDL	High-density lipoprotein
KIV	Kringle (five cysteine-rich domains) IV
LDL	Low-density lipoprotein
LDL-C	Low-density lipoprotein cholesterol
LDT	Laboratory developed test
LDTs	Laboratory-developed tests
LPA	Lipoprotein(a)
Lp(a)	Lipoprotein(a)
MI	Myocardial infarctions
NHLBI	National Heart, Lung, and Blood Institute
NLA	The National Lipid Association
PCI	Percutaneous coronary intervention
PCSK9	Proprotein convertase subtilisin/kexin type 9
PSA	Prostate specific antigen
SNP	Single nucleotide polymorphism
SNPs	Single nucleotide polymorphisms
USPSTF	United States Preventive Services Task Force

V. Scientific Background

Cardiovascular disease (CVD) is a leading cause of morbidity and mortality; with over 11.5% of American adults (27.6 million) diagnosed with heart disease, it claims more lives each year than cancer and chronic lower respiratory disease combined (Benjamin et al., 2018). While progression of CVD is multifactorial, pathophysiological, and epidemiological, genetic studies have provided substantial evidence that Lp(a) is a causal risk factor contributing to CVD (Rosenson et al., 2024). Lp(a) is also elevated in heterozygous familial hypercholesterolemia, further increasing atherosclerotic CVD risk in that disease setting (Rosenson et al., 2024). The physiological role of Lp(a) is to bind and transport proinflammatory oxidized phospholipids in plasma, but its key relation to CVD has been the involvement in atherothrombosis, from the formation of an atherosclerotic plaque through inducing expression of inflammatory mediators and increasing foam formation, to thrombosis following plaque rupture (Fras, 2020). Independent of any other risk factors, Lp(a) was positively associated with increased risk of myocardial infarctions (MI) as well (Paré et al., 2019).

Since first described by Berg (1963) as a genetic trait increased in patients with coronary heart disease (Berg et al., 1974), Lp(a) has been characterized as a type of LDL consisting of apolipoprotein B-100 covalently bound to apolipoprotein(a) (Steyrer et al., 1994). Lipoprotein(a) levels are 75% to 95% heritable and predominately

determined by single-nucleotide variants at the LPA gene and copy number variants (CNVs) in the kringle IV type 2 domain (Trinder et al., 2021). The plasma level and size of Lp(a) are regulated through strict genetic control by the apo(a) gene (*LPA*) on chromosome 6q26-27 with some influence from the *APOE* locus (Erhart et al., 2018; Lu et al., 2015; Moriarty et al., 2017). The *LPA* gene is highly polymorphic based on the number of kringle (five cysteine-rich domains) IV (KIV) repeats, therefore encoding >40 apo(a) isoforms (Marcovina et al., 1996) of varying molecular weights (Rosenson et al., 2024).

As it is genetically controlled, the concentration of Lp(a) is generally stable, correlates inversely with molecular size (smaller size correlating with higher serum levels), and is minimally influenced by age, weight, and diet (Enkhmaa et al., 2016; Tregouet et al., 2009). Genetic variants of apo(a) have been found to have predictive value in coronary heart disease (CHD) (Anderson et al., 2013; Cairns et al., 2017; Helgadottir et al., 2012; Lee et al., 2017; Zekavat et al., 2018; Zewinger et al., 2017). Beyond CHD, genetically lowered Lp(a) is also associated with a lower risk of peripheral vascular disease, stroke, heart failure, and aortic stenosis (Emdin et al., 2016).

The prevalence and association of these genetic variants with apo(a) size and Lp(a) levels are highly variable and ethnicity-specific. Out of 118 single nucleotide polymorphisms (SNPs) identified, rs3798220 is most prevalent in Hispanics (42.38%), rs10455872 in Whites (14.27%), and rs9457951 in Blacks (32.92%). In Hispanics, the rs3798220 variant was associated with large isoforms and lower Lp(a) levels, but in Whites, this variant was associated with very small isoforms and higher Lp(a) levels (Lee et al., 2017). In a separate study that analyzed the relationship between Lp(a) concentration and risk of MI, Paré et al. (2019) found that the clinical use of Lp(a) concentrations for interventions to reduce MI risk would be useful among diverse populations, especially South Asians and Latin Americans, but not Africans or Arabs since there was an insignificant association between high Lp(a) concentration and MI risk in these populations (Paré et al., 2019).

Although its biology and pathophysiology are still incompletely understood (Tsimikas et al., 2018), Lp(a) is recognized as both atherogenic (Grainger et al., 1993; Hajjar et al., 1989; Helgadottir et al., 2012) and thrombogenic (Caplice et al., 2001; Marcovina & Koschinsky, 2003), possibly due to its structural homology with plasminogen (Hancock et al., 2003; McLean et al., 1987). It is thought that Lp(a) could compete with plasminogen for fibrin binding, ultimately resulting in impaired fibrinolysis (Hervio et al., 1995).

A specific SNP in the *LPA* gene (rs3798220) results in an isoleucine-to-methionine substitution within the inactive protease domain, triggering a smaller number of

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

kringle IV repeats, elevated Lp(a) levels, and a greater risk for CVD (Clarke et al., 2009; Helgadottir et al., 2012; Luke et al., 2007). This amino acid substitution (I4399M) has been studied for its effects on coagulation, fibrinolysis, and overall fibrin cloth structure (Scipione et al., 2017).

Carriers of either the rs3798220 or rs10455872 variant were found to have no difference in plasminogen concentration or clot lysis time (Wang et al., 2016). The I4399M variant was found to accelerate the coagulation of plasma clots *in vitro*, therefore suggesting that those with this variant may benefit from the anti-thrombotic properties of aspirin (Scipione et al., 2017). Further, a difference in phenotypic expression between different ethnic groups has been found. Among non-Caucasians, carriers of the rs3798220 variant had increased clot permeability and shorter lysis time, whereas among Caucasians, the trend was for decreased permeability and longer lysis time (Rowland et al., 2014). A correlation was identified between the I4399M variant and both elevated plasma Lp(a) levels and an increased risk of CHD; carriers of this variant in population studies also showed an increased benefit of aspirin therapy (Scipione et al., 2017).

Clinical Utility and Validity

The additional information obtained from the testing for Lp(a) genotype may aid physicians in better estimating the benefit/risk of aspirin therapy and therefore aid in deciding whether to prescribe aspirin for individual patients. *LPA* genotyping in the context of the aspirin use guidelines for primary prevention of CVD was found to be potentially cost-effective (Shiffman et al., 2012). However, traditional plasma-based hemostasis-thrombosis laboratory testing may be more effective at managing venous thrombotic disease than a single DNA variant with a small effect size and no established mechanism linking aspirin with Lp(a) (Nagalla & Bray, 2016).

After a randomized trial of low-dose aspirin, the authors found that rs3798220 was associated with elevated Lp(a) and doubled CVD risk that could be attenuated by aspirin; carriers appeared to benefit more from aspirin than non-carriers (Chasman et al., 2009).

Ozkan et al. (2019) have recently shown that Lp(a) gene polymorphisms play a role in the development of calcific aortic stenosis or calcific aortic valve disease (CAVD). Blood samples were taken from 75 patients previously diagnosed with CAVD and 77 healthy controls, and results showed that "A significant association among smoking, elevated LDL level and creatinine, low albumin levels, Lp(a) level, rs10455872, and rs3798220 polymorphisms may be considered genetic risk factors for the development of calcific aortic stenosis" (Ozkan et al., 2019). However, even with a strong statistically significant relationship between the Lp(a) gene polymorphisms (rs10455872 and rs3798220) and

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

CAVD, this study contained a relatively small sample size, suggesting that more research needs to be completed to validate these results. This research has been corroborated by Pechlivanis et al. (2020) who demonstrated that the rs10455872 SNP has a statistically significant association with coronary artery calcification, a predictor of coronary artery disease (Pechlivanis et al., 2020).

A large-scale study with 44,703 participants of European descent was completed, and a relationship was identified between two Lp(a) variants (rs10455872 and rs3798220) and aortic stenosis (AS) development (Chen et al., 2018). While a relationship between both of these Lp(a) variants has already been established in regard to circulating Lp(a) plasma levels and a high Lp(a) risk score, these data seem to confirm the association between these Lp(a) variants and valvular or cardiac disease events. Final results from this study showed that the participants with these two high-risk alleles had a twice or greater chance of developing AS; however, it must be noted that participants with AS were on average older than the controls, meaning that some controls could still develop AS (Chen et al., 2018).

Mu-Han-Ha-Li et al. (2018) conducted a study with 1,863 Chinese patients with very high CVD risk (as identified on coronary angiography) to analyze the connection between Lp(a) levels and the risks of CVD and diabetes. Researchers concluded that a high number of *LPA* KIV type 2 repeats, and therefore lower serum Lp(a) levels, is associated with an increased risk of type 2 diabetes in a Chinese population with high CVD risk. This data suggests that a large Lp(a) isoform size, and thus low Lp(a) concentration, can have a causal effect on type 2 diabetes (Mu-Han-Ha-Li et al., 2018). With this novel association, it becomes essential for genetic testing of *LPA* gene variants to not only follow up on CVD risk to assess benefit from aspirin therapy, but for the possible latter development of comorbidities like type two diabetes.

Additional researchers have identified a potential relationship between Lp(a) SNPs and a high inflammatory response that may result in an increased CVD risk in pregnant individuals. Tuten et al. (2019) analyzed data from 200 pregnant Turkish individuals, evaluating 14 different Lp(a) SNPs. Results found that two of the Lp(a) SNPs, rs9355296 and rs3798220, were identified as risk factors for preeclampsia, and that rs9355296 carriers reported higher vascular inflammatory rates (Tuten et al., 2019). These results suggest that specific Lp(a) variants may possibly be used as biomarkers for future cardiovascular events and inflammation.

Moreover, Wang and Zhang (2019) showed that high Lp(a) levels are associated with adverse clinicopathological features in prostate cancer patients. Patients with a prostate specific antigen (PSA) level ≥ 100 ng/ml had significantly higher Lp(a) levels; this was believed to be a result of compensatory mechanisms to chronic inflammation

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

caused by tumor aggressiveness and invasion. The researchers also found that the percentage of metastases increased with elevation in Lp(a) level, while body mass index (BMI) decreased with the Lp(a) elevation. The increased metastasis in the setting of high Lp(a) levels was believed to be due to facilitated formations of fibrin networks (apo(a), a part of Lp(a), has structural homologues to kringle IV in plasminogen, which normally induces fibrinolysis) and thrombus formation that allowed for cancer cell adhesion (Wang & Zhang, 2019). Genetic testing for Lp(a) may not only benefit CVD risk assessment with aspirin therapy considerations, but also may have implications for cancer development and treatment.

Pechlivanis et al. (2020) studied the association of *LPA* gene variants (rs10455872 and rs3798220) and IL1F9 (rs13415097) with coronary artery calcification (CAC). LPA levels from 3799 patients were analyzed using linear regression models to explore the association between the variants and CAC. The LPA SNP rs10455872 showed a statistically significant association with CAC. The results of this study show that "rs10455872, mediated by Lp(a) levels, might play a role in promoting the development of atherosclerosis leading to cardiovascular disease events" (Pechlivanis et al., 2020).

In a prospective study, Yoon et al. (2021) studied the association of LPA with recurrent ischemic events after percutaneous coronary intervention (PCI). Baseline LPA levels from 12,064 patients who underwent PCI were studied. A total of 3,747 (31.1%) patients had high Lp(a) (>30 mg/dL) and 8,317 (68.9%) patients had low Lp(a) (≤30 mg/dL). After a seven-year follow-up, 2.0 per 100 person-years in the high-LPA group experienced CV death, spontaneous myocardial infarction, and ischemic stroke compared to 1.6 per 100 person-years in the low-Lp(a) group. Overall, the authors conclude that "Elevated levels of Lp(a) were significantly associated with the recurrent ischemic events in patients who underwent PCI" which provides a rationale to test LPA lowering therapy for secondary prevention in patients undergoing PCI (Yoon et al., 2021).

Murdock et al. (2021) developed a panel test for genes associated with CVD that included an evaluation of *LPA* polymorphisms. The authors studied 709 patients from cardiology clinics. In total, "32% of patients had a genetic finding with clinical management implications." *LPA* polymorphisms were found in 20% of patients, which lead to "diet, lifestyle, and other changes." The authors concluded that the results "support the use of genetic information in routine cardiovascular health management" (Murdock et al., 2021). Familial hypercholesterolemia (FH) and elevated plasma Lp(a) are both inherited conditions associated with ASCVD. Chakraborty et al. (2022) studied the detection of elevated Lp(a) during cascade testing of relatives of people diagnosed with FH. The authors used an immunoassay to test for FH and Lp(a) in 162 people. The

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

prevalence of FH and elevated Lp(a) was 60.5% in adults (n=136) and 41.1% in children (n=26). The proportion of relatives with elevated Lp(a) was higher when they had relatives with Lp(a) ≥100 mg/dL than relatives with Lp(a) between 50 and 99 mg/dL. The authors concluded that dual testing of families for FH and high Lp(a) from appropriate relatives can detect new cases of FH, and elevated Lp(a) with or without FH. Lastly, the authors note that "the findings accord with the co-dominant and independent heritability of FH and Lp(a)" (Chakraborty et al., 2022).

Gu et al. (2022) investigated whether elevated Lp(a) and two corresponding *LPA* polymorphisms played a role in the prediction of cardiovascular events. The authors enrolled 2766 individuals from Peking University People's Hospital. The study included a cohort with coronary heart disease and a separate control group. The authors demonstrated that Lp(a) level and the amount of *LPA* SNPs were associated with the risk and severity of coronary heart disease. The rs6415084 and rs12194138 polymorphisms were particularly associated with serum Lp(a) levels. The authors concluded via univariate logistic regression analysis and multiple logistic regression analysis that, "These data together indicated that the level of Lp(a) and the prevalence of LPA SNPs rs6415084 (CT/TT) and rs12194138 (AT/TT) is positively correlated with the severity of CHD" (Gu et al., 2022).

VI. Guidelines and Recommendations

American Association of Clinical Endocrinologists (AACE) and American College of Endocrinology (ACE)

The AACE/ACE published guidelines for the management of Dyslipidemia and Prevention of Cardiovascular Disease (Jellinger et al., 2017) which state:

"Testing for lipoprotein(a) is therefore not generally recommended, although it may provide useful information to ascribe risk in Caucasians with ASCVD, those with an unexplained family history of early ASCVD, or those with unknown family history such as adopted individuals."

In 2020, the AACE and ACE released a consensus statement for the management of Dyslipidemia and Prevention of Cardiovascular Disease and provided recommendations for the assessment and management of elevated Lipoprotein (a). Within this statement, they recommend measuring Lp(a) in patients with a family history of premature ASCVD and/or increased Lp(a) and all patients with premature or recurrent ASCVD despite LDL-C lowering (Handelsman et al., 2020).

Genetic screening for Lp(a) variants is not mentioned.

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

National Heart, Lung, and Blood Institute (NHLBI)

The NHLBI published Working Group Recommendations to Reduce Lipoprotein(a)-Mediated Risk of Cardiovascular Disease and Aortic Stenosis (Tsimikas et al., 2018) which endorsed the European Society of Cardiology/European Atherosclerosis Society, Canadian Cardiovascular Society, and National Lipid Association Guidelines while making additional specific recommendations to facilitate basic, mechanistic, preclinical, and clinical research on Lp(a).

Genetic screening for Lp(a) variants is not mentioned (Tsimikas et al., 2018).

American College of Cardiology (ACC)/American Heart Association (AHH)

In 2019, the ACC and AHA released guidelines on the primary prevention of CVD. The guidelines list "Risk-Enhancing Factors for Clinician–Patient Risk Discussion" which include Lp(a) as a "lipid/biomarker associated with increased atherosclerotic cardiovascular disease risk." The guidelines note, "elevated Lp(a): A relative indication for its measurement is family history of premature ASCVD. An Lp(a) ≥50 mg/dL or ≥125 nmol/L constitutes a risk-enhancing factor, especially at higher levels of Lp(a)" (Arnett et al., 2019).

In 2022, the AHA released a scientific statement about Lp(a) that supports the ACC/AHH joint guidelines. The statement also includes recommendations on how and when Lp(a) testing should be performed. "At present, the evidence in favor of screening for Lp(a) is the strongest for those with a family or personal history of ASCVD, with consideration of cascade screening in appropriate individuals" (Reyes-Soffer et al., 2022).

Genetic screening for Lp(a) variants is not mentioned (Reyes-Soffer et al., 2022).

The National Lipid Association (NLA)

The NLA considers Lp(a) to be an important clinical biomarker and risk factor for atherosclerotic cardiovascular disease. It is stated that a main obstacle towards the clinical use of Lp(a) is that measurements and various other targeted levels have not yet been standardized in the industry; for example, several of the available assays are reporting results in differing units, such as in mass instead of concentration (Wilson et al., 2019). Based on current data, Wilson et al. (2019) has stated that Lp(a) testing in clinical practice is reasonable for select individuals with the qualifications listed below:

- Adults older than 20 years with a family history of premature atherosclerotic cardiovascular disease (ASCVD)

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

- "Individuals with premature ASCVD (55y of age in men; 65y of age in women), particularly in the absence of traditional risk factors
- Individuals with primary severe hypercholesterolemia (LDL-C ≥ 190 mg/dL) or suspected FH
- Individuals at very-high-risk of ASCVD to better define those who are more likely to benefit from PCSK9 inhibitor therapy"

Wilson et al. (2019) also stated that Lp(a) testing may be reasonable in patients with:

- "Intermediate (7.5%–19.9%) 10-y ASCVD risk when the decision to use a statin is uncertain, to improve risk stratification in primary prevention
- Borderline (5%–7.4%) 10-y ASCVD risk when the decision to use a statin is uncertain, to improve risk stratification in primary prevention
- Less-than-anticipated LDL-C lowering, despite good adherence to LDL-C lowering therapy
- A family history of elevated Lp(a)
- Calcific valvular aortic stenosis
- Recurrent or progressive ASCVD, despite optimal lipid-lowering therapy"

In 2022 scientific statement, the NLA writes:

- "Lp(a) testing is reasonable to refine risk assessment for ASCVD events in adults with:
  - First-degree relatives with premature ASCVD (<55 y of age in men; <65 y of age in women).
  - A personal history of premature ASCVD.
  - Primary severe hypercholesterolemia (LDL-C ≥190 mg/dL) or suspected FH.
- Lp(a) testing may be reasonable in adults:
  - To aid in the clinician-patient discussion about whether to prescribe a statin in those aged 40-75 y with borderline (5%-7.4%) 10-y ASCVD risk.
  - To identify a possible cause for a less-than-anticipated LDL-C lowering to evidence-based LDL-C-lowering therapy.
  - To use in cascade screening of family members with severe hypercholesterolemia.
  - To identify those at risk for progressive [valvular aortic stenosis]" (Wilson et al., 2022)

In 2024, the NLA released a focused update to the 2019 NLA scientific statement that included recommendations for Lp(a) testing in clinical practice (Marlys L. Koschinsky et al., 2024):

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

1. "Adults (aged ≥18 y): Measurement of Lp(a) in all adults is reasonable to refine risk assessment for ASCVD events
2. Youth (aged <18 y): Selective screening of Lp(a) is recommended in high-risk patients (e.g., clinically suspected or genetically confirmed FH, ischemic stroke of unknown cause, first-degree relatives with a history of premature ASCVD [age <55 years in men, <65 years in women], or first-degree relatives with elevated Lp(a))
3. When Lp(a) levels are used for ASCVD risk assessment, it is reasonable to use measurements ≥125 nmol/L (≥50 mg/dL) as levels suggesting high risk, levels <75 nmol/L (<30 mg/dL) as low risk, and levels between as intermediate risk" (Marlys L. Koschinsky et al., 2024)

Genetic screening for Lp(a) variants was mentioned in the most recent NLA guideline update (Marlys L. Koschinsky et al., 2024). "While genetic risk scores incorporating genetic variants at or near the LPA locus are increasingly accurate for identifying individuals likely to have elevated Lp(a) and to develop CVD, Lp(a) genetic risk score appears to add no incremental value for CVD risk classification compared with Lp(a) concentrations alone. Additionally, the generalizability of genetic risk scores to groups with non-White ancestry remains uncertain. Therefore, at this time, Lp(a) measurement is preferable for risk ascertainment; all the necessary information for appraisal of Lp(a)-attributable cardiovascular risk is embodied in the measurement of plasma Lp(a) concentration itself, mandating increased screening to identify individuals with elevated Lp(a) and high risk for CVD" (Marlys L. Koschinsky et al., 2024).

The European Atherosclerosis Society (EAS)

In a 2022 update, the European Atherosclerosis Society recommends testing Lp(a) concentration at least once per lifetime in adults. The EAS also suggests measurement of Lp(a) in youth with a (1) history of ischemic stroke or a (2) family history of premature ASCVD or (3) elevated Lp(a) level and no other known risk factors.

The consensus statement suggests other testing may have value under certain conditions. "Cascade testing has potential value in familial hypercholesterolaemia, or with family or personal history of (very) high Lp(a) or premature ASCVD. Without specific Lp(a)-lowering therapies, early intensive risk factor management is recommended, targeted according to global cardiovascular risk and Lp(a) level" (Kronenberg et al., 2022).

Under a subtitle posing the question "Is there a role for genetic testing?" the authors write: "Measurement of Lp(a) concentration is sufficient for Lp(a)-related risk estimation without the need for genotyping, polygenic risk scores, or investigation of expressed apo(a) isoform sizes" (Kronenberg et al., 2022).

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

The European Society for Cardiology (ESC) and European Atherosclerosis Society (EAS) Joint Guideline

The ESC and EAS published a joint guideline for the Management of Dyslipidemias which recommends:

- "Lp(a) measurement should be considered at least once in each adult person's lifetime to identify those with very high inherited Lp(a) levels > 180mg/dL (>430 nmol/L) who may have a lifetime risk of ASCVD equivalent to the risk associated with heterozygous familial hypercholesterolaemia (Level of Recommendation: C)
- Lp(a) should be considered in selected patients with a family history of premature CVD, and for reclassification in people who are borderline between moderate and high-risk (Level of Recommendation: C)" (Mach et al., 2019).

Genetic screening for Lp(a) variants is not mentioned (Mach et al., 2019).

HEART UK Medical, Scientific, and Research Committee

HEART UK published guidelines for Lp(a) measurement in specific adult populations. HEART UK recommends that Lp(a) is measured in adults as follows: "1) those with a personal or family history of premature atherosclerotic CVD; 2) those with first-degree relatives who have Lp(a) levels >200 nmol/l; 3) patients with familial hypercholesterolemia; 4) patients with calcific aortic valve stenosis and 5) those with borderline (but <15%) 10-year risk of a cardiovascular event" (Cegla et al., 2019).

On genetic testing for Lp(a) levels, the guideline also noted, "Genetic testing for SNPs associated with serum Lp(a) levels is not currently advocated for in routine clinical practice" (Cegla et al., 2019).

U.S. Preventive Services Task Force (USPSTF)

The USPSTF 2022 guidelines on aspirin use to prevent cardiovascular disease do not mention Lp(a) or genetic screening for Lp(a) (Guirguis-Blake et al., 2016; USPSTF, 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-

Confidential and Proprietary Information of Avalon Health Services, LLC, d/b/a Avalon Healthcare Solutions. All Rights Reserved.

database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

The LPA-Aspirin Check® detects the presence of the rs3798220 allele and is considered a laboratory developed test (LDT); this test is developed, validated, and performed by individual laboratories.

The Cardio IQ® LPA Aspirin Genotype test is able to detect individuals who are at risk of high plasma Lp(a) levels, which may suggest an increased risk of cardiovascular events; this assay may also assist in determining if the patient's cardiovascular disease risk may be lowered by low-dose aspirin therapy (Quest Diagnostics, 2019). This test has not been cleared or approved by the FDA.

VIII. Applicable CPT/HCPCS Procedure Codes

Genetic Testing for Neurodegenerative Disorders

Policy Number: AHS – M2167 – Genetic Testing for Neurodegenerative Disorders	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Neurodegenerative diseases are characterized by progressive loss of neurons along with deposition of misfolded proteins throughout the body, leading to clinical symptoms such as cognitive decline and movement problems. Conditions that fall within this classification include Parkinson Disease, dystonia, ataxia, and more (Kovacs, 2016).

This policy does not address Alzheimer Disease or ataxia due to mitochondrial disorders. For information on these conditions, please see AHS-M2038 Genetic Testing for Alzheimer Disease or AHS-M2085 Genetic Testing of Mitochondrial Disorders.

For guidance on preconception screening for spinal muscular atrophies, please refer to AHS-M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title
AHS-	Genetic Testing for *FMR1* Mutations
AHS-	Genetic Testing for Familial Alzheimer Disease
AHS-	Genetic Testing for Diagnosis of Inherited Peripheral Neuropathies
AHS-	Genetic Testing of Mitochondrial Disorders
AHS-	General Genetic Testing, Germline Disorders
AHS-	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic counseling **IS REQUIRED** for individuals prior to and after undergoing genetic testing for diagnostic, carrier, and/or risk assessment purposes.

Amyotrophic Lateral Sclerosis (ALS)

2) For diagnosis in individuals with suspected ALS **and** a first-degree **or** second-degree relative (see Note 1) with ALS or frontotemporal dementia, genetic testing for ALS, including the genes *C9ORF72, SOD1, TARDBP,* and *FUS*, **MEETS COVERAGE CRITERIA**.

Ataxias, including Friedreich ataxia

3) For individuals with sporadic ataxia **or** a family history compatible with an inherited cerebellar ataxia with no known deleterious familial mutation, single gene testing (when a specific ataxia is suspected) or multi-gene panel testing (when a specific ataxia is not suspected) **MEETS COVERAGE CRITERIA.**

4) To confirm a diagnosis in individuals with suspected ataxia-telangiectasia, genetic testing for *ATM* **MEETS COVERAGE CRITERIA**.

Dystonias

5) Genetic testing of *TOR1A* (formerly *DYT1)* **MEETS COVERAGE CRITERIA** in the following situations:
   a) In individuals with limb-onset, primary dystonia before the age of 30 years.
   b) In individuals with limb-onset, primary dystonia with onset after age 30 when there is a family history compatible with early-onset dystonia.

6) Genetic testing of *THAP1* (formerly *DYT6)* **MEETS COVERAGE CRITERIA** in the following situations:
   a) In individuals with an early-onset dystonia or familial dystonia with cranio-cervical predominance.
   b) In individuals with early-onset dystonia after exclusion of *TOR1A*-associated dystonia.

7) To aid in the diagnosis of symptomatic individuals with familial paroxysmal nonkinesigenic dyskinesia (PNKD), genetic testing of *PNKD* **MEETS COVERAGE CRITERIA.**

8) In individuals with paroxysmal exercise-induced dyskinesia, genetic testing of *SLC2A1* (formerly *GLUT1)* **MEETS COVERAGE CRITERIA** if the individual has at least one of the following:

   a) A history of epileptic seizures.

   b) Hemolytic anemia.

   c) A low CSF/serum glucose ratio.

9) In asymptomatic individuals, genetic testing of *TOR1A* **DOES NOT MEET COVERAGE CRITERIA**.

Hereditary Spastic Paraplegia (HSP)

10) To confirm clinical diagnosis and to determine the genetic type of Hereditary Spastic Paraplegia (HSP), genetic testing for HSP **MEETS COVERAGE CRITERIA**.

Huntington disease (HD)

11) Genetic testing for Huntington disease **MEETS COVERAGE CRITERIA** in the following situations:

   a) When an adult patient presents with an otherwise unexplained clinical syndrome of a progressive choreatic movement disorder and neuropsychiatric disturbances.

   b) In an adult patient with a positive family history of the disease.

   c) In a juvenile patient with the following:

      i) A known familial history of HD.

      ii) Presenting with two or more of the following:

         (a) Declining school performance
         (b) Seizures
         (c) Oral motor dysfunction
         (d) Rigidity
         (e) Gait disturbance

Parkinsonism, including Parkinson disease

12) Genetic testing of *SNCA* **MEETS COVERAGE CRITERIA** for an individual only if there is a family history with multiple affected members in more than one generation suggestive of dominant inheritance.

13) Genetic testing of *LRRK2* **MEETS COVERAGE CRITERIA** in the following situations:

    a) In symptomatic individuals with a positive family history suggestive of dominant inheritance.

    b) In symptomatic individuals belonging to a population with known high mutation frequencies of the *LRRK2* gene (i.e., Ashkenazi Jews, Imazighen, and Euskaldunak).

14) Genetic testing of the *PRKN* (formerly *PARK2* or *parkin*) *PINK1*, and *PARK7* (formerly *DJ-1)* genes **MEETS COVERAGE CRITERIA** in the following situations:

    a) In individuals with an onset of disease by the age of 50 years with a positive family history suggestive of recessive inheritance.

    b) In individuals with an onset of disease by the age of 40 years regardless of family history.

15) Genetic testing of the *ATP13A2, PLA2G6,* and *FBXO7* genes **MEETS COVERAGE CRITERIA** only when **all** of the following conditions are met:

    a) With onset of disease by the age of 40 years

    b) Prior testing of *PRKN*, *PINK1,* and *PARK7* genes was negative for known pathogenic variants.

Spinal Muscular Atrophies (SMA)

16) To diagnose individuals suspected of having SMA, genetic testing for SMA (*SMN1* deletion/mutation and *SMN2* copy number) **MEETS COVERAGE CRITERIA**.

Wilson disease (WD)

17) Genetic testing of *ATP7B* **MEETS COVERAGE CRITERIA** in the following situations:

    a) To confirm a diagnosis of Wilson disease in a symptomatic individual.

    b) In a first-degree relative (see Note 1) of an individual with known *ATP7B* mutation to guide potential therapy.

NOTES:

Note 1: First-degree relatives include parents, full siblings, and children of the individual. Second-degree relatives include grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings of the individual.

Note 2: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ACOG	American College of Obstetricians and Gynecologists
ACP33	*SPG21 abhydrolase domain containing, maspardin*
ADAR	*Adenosine deaminase RNA specific*
ADCK3	AARF domain containing kinase 3
ADCY5	Adenylate cyclase 5
ADHSP	Autosomal dominant hereditary spastic paraplegia
AFG3L2	*AFG3 like matrix AAA peptidase subunit 2*
ALDH18A1	*Aldehyde dehydrogenase 18 family member A1*
ALDH3A2	*Aldehyde dehydrogenase 3 family member A2*
ALS	Amyotrophic lateral sclerosis
ALSA	Amyotrophic Lateral Sclerosis Association
AMPD2	*Adenosine monophosphate deaminase 2*
ANO3	*Anoctamin 3*
AP4B1	*Adaptor related protein complex 4 subunit beta 1*
AP4M1	*Adaptor related protein complex 4 subunit mu 1*
AP4S1	*Adaptor related protein complex 4 subunit sigma 1*
AP5Z1	*Adaptor related protein complex 5 subunit zeta 1*
APTX	Ataxia with oculomotor apraxia
ARHSP	Autosomal recessive hereditary spastic paraplegia
AT	Ataxia-telangiectasia
ATAD3A	*ATPase family AAA domain containing 3A*
ATL1	*Atlastin GTPase 1*
ATLD	Ataxia telangiectasia-like disorder
ATM	Ataxia-telangiectasia mutated
ATN1	*Atrophin 1*
ATP	Adenosine triphosphate
ATP13A2	*ATPase cation-transporting 13A2*
ATP2B4	*ATPase plasma membrane Ca2+ transporting 4*

ATP7B	*ATPase copper transporting beta*
ATXN1/2/3/7/8/10	*Ataxin 1/2/3/7/8/10*
ATXN8OS	*Ataxin 8 opposite strand lncRNA*
B4GALNT1	*Beta-1,4-N-acetyl-galactosaminyltransferase 1*
BEAN1	*Brain expressed associated with NEDD4 1*
BICD2	*BICD cargo adaptor 2*
BSCL2	*BSCL2 lipid droplet biogenesis associated, seipin*
C12orf65	*Mitochondrial translation release factor in rescue*
C19orf12	*Chromosome 19 open reading frame 12*
C9ORF72	*Chromosome 9 Open Reading Frame 72*
CACNA1A	*Calcium Voltage – Gated Channel Subunit Alpha 1 A*
CCDC88C	*Coiled-coil domain containing 88C*
CLIA	Clinical Laboratory Improvement Amendments
CMS	Centres for Medicare and Medicaid Services
CMT	Charcot Marie-Tooth Neuropathy
CPT1C	*Carnitine palmitoyltransferase 1C*
CSF	Cerebrospinal fluid
CYP2U1	*Cytochrome P450 family 2 subfamily U member 1*
CYP7B1	*Cytochrome P450 family 7 subfamily B member 1*
DD	Developmental delay
DDHD1/2	*DDHD domain containing ½*
DI-CMT	Dominant intermediate Charcot Marie-Tooth neuropathy
DJ-1	*Parkinsonism associated deglycase*
DNA	Deoxyribonucleic acid
DNM2	*Dynamin 2*
DRPLA	Dentatorubral-pallidoluysian atrophy
DYT1	*Dystonia 1/6/8/11*
EEF2	*Eukaryotic translation elongation factor 2*
EFNS	European Federation of Neurological Societies
EHDN	Working Group on Genetic Counselling and Testing of the European Huntington's Disease Network
ELOVL5	*Elongation of very long chain fatty acid elongase 5*
ENMC	European Neuromuscular Center
ENS	European Neurological Society
ENTPD1	*Ectonucleoside triphosphate diphosphohydrolase 1*
ERLIN1/2	*ER lipid raft associated ½*
ESPGHAN	Hepatology Committee of the European Society for Paediatric Gastroenterology, Hepatology and Nutrition
FA	Friedreich's ataxia

FA2H	*Fatty acid 2-hydroxylase*
FALSA	Familial amyotrophic lateral sclerosis
FARA	Friedreich's Ataxia Research Alliance
FGF14	*Fibroblast growth factor 14*
FMR1	*Fragile X mental retardation 1*
FRDA	*Frataxin*
FUS	*FUS RNA binding protein*
FXN	*Frataxin*
FXTAS	Fragile X Associated Tremor and Ataxia Syndrome
GAA	*Alpha glucosidase*
GAD1	*Glutamate decarboxylase 1*
GAK- DGKQ	*Cyclin G associated kinase-diacylglycerol kinase theta*
GBA	*Glucocerebrosidase*
GBA2	*Glucocerebrosidase beta 2*
GCH1	*GTP cyclohydrolase 1*
GJC2	*Gap junction protein gamma 2*
GLUT1	*Glucose transporter protein type 1*
GRID2	*Glutamate ionotropic receptor delta type subunit 2*
H2O2	Hydrogen peroxide
HD	Huntington disease/Huntington's disease
HDL4	Huntington disease like 4
HLA	*Human leukocyte antigen*
HMN	Hereditary motor neuropathy
HSP	Hereditary spastic paraplegia
HSPD1	*Heat shock protein family D (Hsp60) member 1*
HTT	*Huntingtin*
ICARS	International cooperative ataxia rating scale
ID	Intellectual disability
ITALSGEN	Italian Amyotrophic Lateral Sclerosis Genetic consortium
ITPR1	*Inositol 1,4,5-trisphosphate receptor type 1*
KCND3	*Potassium voltage-gated channel subfamily D member 3*
KIAA1096	*Proline-rich coiled-coil 2C*
KIF1A/1C/5A	*Kinesin family member 1A/1C/5A*
KLC2/4	*Kinesin light chain 2/4*
L1CAM	*L1 cell adhesion molecule*
LDTs	Laboratory developed tests
LRRK2	Leucine rich repeat kinase-2
MARS1	*Methionyl-tRNA synthetase 1*

MDS	International Parkinson and Movement Disorder Society
MDS-ES	Movement Disorder Society – European Section
MELAS	Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes
MERRF	Myoclonus epilepsy, ragged-red-fibers
MHC	*Major histocompatibility complex*
MR1	*Major histocompatibility complex, class I-related*
MRE11A	*MRE11 homolog, double strand break repair nuclease*
mRNA	Messenger ribonucleic acid
MT-ATP6	*Mitochondrially encoded ATP synthase membrane subunit 6*
NAF	National Ataxia Foundation
NARP	Neuropathy, ataxia, and retinitis pigmentosa
NIPA1	*NIPA magnesium transporter 1*
NOP56	*NOP56 ribonucleoprotein*
NORD	National Organization for Rare Disorders
NT5C2	*5'-nucleotidase, cytosolic II*
O2	Oxygen
PARK1/2/4/7/8	*Parkinson disease ½/4/7/8*
PD	Parkinson disease
PDYN	*Prodynorphin*
PGAP1	*Post-GPI attachment to proteins inositol deacylase 1*
PINK1	*PTEN induced kinase 1*
PKND	Paroxysmal dyskinesia with dystonia
PLA2G6	*Phospholipase A2 group VI*
PLP1	*Proteolipid protein 1*
PNKD	Paroxysmal nonkinesigenic dyskinesia
PNPLA6	*Patatin like phospholipase domain containing 6*
POLG	*DNA polymerase gamma, catalytic subunit*
PPP2R2B	*Protein phosphatase 2 regulatory subunit B beta*
PRKCG	*Protein kinase C gamma*
REEP1/2	*Receptor accessory protein ½*
RTN2	*Reticulon 2*
SACS	*Sacsin molecular chaperone*
SARA	Scale for the assessment and rating of ataxia
SCA	Spinocerebellar ataxia
SCAR9	Spinocerebellar ataxia 9
SGCE	*Sarcoglycan epsilon*
SLC2A1	*Solute carrier family 2, member 1*
SLC16A2	*Solute carrier family 16, member 2*

SLC33A1	*Solute carrier family 33, member 1*
SMA	Spinal muscular atrophies
SMN1/2	*Survival of motor neuron ½*
SNCA	*Alpha-synuclein*
SNP	Single nucleotide variant
SOD1	*Superoxide dismutase 1*
SPAST	Spastin
SPG1 – 74	*Spastic paraplegia 1 – 74*
SPTBN2	*Spectrin beta, non-erythrocytic 2*
STR	Short tandem repeat
TARDBP	*TAR DNA binding protein*
TBP	*TATA-binding protein*
TECPR2	*Tectonin beta-propeller repeat containing 2*
TFG	*Trafficking from ER to golgi regulator*
TGM6	*Transglutaminase 6*
THAP1	*THAP domain containing 1*
TOR1A	*Torsin family 1 member A*
TRPC3	*Transient receptor potential cation channel subfamily C member 3*
TTBK2	*Tau tubulin kinase 2*
TTPA	*Alpha tocopherol transfer protein*
TUBB4A	*Tubulin beta 4A class Iva*
UBQLN2	*Ubiquilin 2*
UPDRS	Unified Parkinson's Disease Rating Scale
USP8	*Ubiquitin specific peptidase 8*
WASHC5	*WASH complex subunit 5*
WD	Wilson Disease/Wilson's Disease
WDR48	*WD repeat domain 48*
ZFYVE26/27	*Zinc finger FYVE-type containing 26/27*

V. Scientific Background

Neurodegenerative diseases are characterized by progressive loss of neurons along with deposition of misfolded proteins throughout the body. These misfolded proteins have altered biochemical properties, causing dysfunction. Clinical symptoms may include cognitive decline (primarily dementia) and movement problems (cerebellar dysfunction, hyper- or hypo-kinesia, etc.). The molecular spectrum of these disorders may vary, but typically involve oxidative or neuroinflammatory damage (Kovacs, 2016).

Ataxias (including Friedreich ataxia)

Ataxias encompass the set of conditions that are characterized by "motor incoordination resulting from dysfunction of the cerebellum and its connections" (Opal & Zoghbi, 2024b). This policy focuses on progressive and degenerative ataxias, which are further subdivided into autosomal dominant, autosomal recessive, and X-linked forms.

Friedreich ataxia is the most common hereditary ataxia and is inherited in an autosomal recessive manner. Most cases are caused by mutations in the frataxin gene (*FXN*), which is responsible for transport and management of iron. The frataxin mutation is typically an expanded trinucleotide (van de Warrenburg et al.) repeat in the first intron of the frataxin gene, which reduces expression of frataxin. Severity of phenotype varies with the number of repeats; larger repeats are generally more severe. Impaired iron management leads to a variety of clinical symptoms, such as neurological problems (progressive ataxia, dysphagia, motor weakness, loss of tendon reflexes, etc.), cardiomyopathy, diabetes mellitus, and skeletal deformities. Clinical findings may suggest Friedreich ataxia, but diagnosis is generally confirmed through genetic testing (Opal & Zoghbi, 2023).

Another autosomal recessive ataxia is ataxia-telangiectasia (AT). AT is caused by a defective gene on chromosome 11q22.3, leading to faulty DNA repair mechanisms. This gene (designated AT "M" for mutated) primarily regulates the cell cycle and prevents the cell cycle from progressing if there is DNA damage. When this gene fails, somatic mutations may accumulate. Symptoms such as immune deficiency, cerebellar ataxia, unusual eye movements, and other neurologic abnormalities are characteristic of ataxia-telangiectasia. Ataxia is one of the first clinical symptoms of patients with AT, but other organ systems are usually affected, such as the skin and circulatory system. Similarly, ataxia-telangiectasia-like disorder (ATLD) can affect individuals similarly to AT; however, ATLD is due to mutations within the *MRE11A* gene involved in double-strand DNA break recognition and repair. The rate of neurodegeneration in ATLD is typically slower than AT. ATLD is more rare than AT; however, "it is estimated that as many as 5 percent of AT cases may be incorrectly diagnosed and actually have ATLD, given the similarity in clinical manifestations and coding sizes of the two affected genes" (Opal, 2024).

Spinocerebellar ataxias (SCAs) are the most common autosomal dominant ataxias. At least 30 types of SCAs with varying phenotypes occur, although, cerebellar ataxia is a primary feature of each type. For example, SCA1 is characterized by dysarthria and bulbar dysfunction whereas SCA2 is characterized by "slow saccadic eye movements." Several SCA types have a signature CAG repeat beyond what is present in the wildtype; this expansion is pathogenic. As with Friedreich ataxia, larger number of repeats usually lead to more severe symptoms. The four most common SCAs are SCA1, 2, 3,

and 6, and each type is caused by a different pathogenic mutation. Below is a table displaying each SCA, its distinguishing features, and its primary associated gene (Opal & Zoghbi, 2024a).

Disorder	Distinguishing features	Gene
SCA1	Pyramidal signs, peripheral neuropathy	*ATXN1*
SCA2	Slow saccades; less often myoclonus, areflexia	*ATXN2*
SCA3 (MJD)	Slow saccades, persistent stare, extrapyramidal signs, peripheral neuropathy	*ATXN3*
SCA4	Sensory neuropathy	*16q22.1*
SCA5	Early onset but slow progression	*SPTBN2*
SCA6	May have very late onset, mild, may lack family history, nystagmus	*CACNA1A*
SCA7	Macular degeneration	*ATXN7*
SCA8	Mild disease	*ATXN8, ATXN8OS*
SCA9	Not assigned	
SCA10	Generalized or complex partial seizures	*ATXN10*
SCA11	Mild disease	*TTBK2*
SCA12	Tremor, dementia	*PPP2R2B*
SCA13	Mental retardation	*KCNC3*
SCA14	Intermittent myoclonus with early onset disease	*PRKCG*
SCA15/16	Slowly progressive	*ITPR1*
SCA17 (or HDL4)[1]	Gait ataxia, dementia	*TBP*
SCA18	Pyramidal signs, weakness, sensory axonal neuropathy	*7q22-q32*
SCA19/22	Predominantly cerebellar syndrome, sometimes with cognitive impairment or myoclonus	*KCND3* gene
SCA20	Palatal tremor and dysphonia	*11q12*
SCA21	Mild to severe cognitive impairment	*TMEM240*
SCA23	Distal sensory deficits	*PDYN*
SCA24	Recessive inheritance; redesignated as SCAR4	*1p36*
SCA25	Sensory neuropathy, facial tics, gastrointestinal symptoms	*2p21-p13*
SCA26	Pure cerebellar ataxia	*EEF2*
SCA27	Cognitive impairment	*FGF14*
SCA28	Ophthalmoparesis and ptosis	*AFG3L2*

Disorder	Distinguishing features	Gene
SCA29	Early onset, nonprogressive ataxia; may be an allelic variant of SCA15	*3p26*
SCA30	Slowly progressive, relatively pure ataxia	*4q34.3-q35.1*
SCA31	Decreased muscle tone	*BEAN*
SCA32	Cognitive impairment; affected individuals with azoospermia and testicular atrophy	*7q32-q33*
SCA33	Not assigned	
SCA34	Skin lesions consisting of papulosquamous erythematous ichthyosiform plaques	*ELOVL4*
SCA35	Late onset, slowly progressive gait and limb ataxia	*TGM6*
SCA36	Late onset, truncal ataxia, dysarthria, variable motor neuron disease and sensorineural hearing loss	*NOP56*
SCA37	Late onset, falls, dysarthria, clumsiness, abnormal vertical eye movements	*1p32*
SCA38	Slowly progressive pure cerebellar phenotype	*ELOVL5*
SCA39	Not assigned	
SCA40	Hyperreflexia and spasticity	*CCDC88*
DRPLA	Chorea, seizures, myoclonus, dementia	*ATN1*
[1]SCA17 is synonymous with HDL4 (Huntington disease-like 4) (Toyoshima et al., 2012).		

Jacobi et al. (2015) described the disease progression of SCAs 1, 2, 3, and 6. A total of 462 patients were evaluated on the Scale for the Assessment and Rating of Ataxia (SARA). Annual SARA score increase was 2.11 for SCA1 patients, 1.49 for SCA2, 1.56 for SCA3, and 0.80 for SCA6. The increase of non-ataxia signs plateaued in types 1, 2, and 3. SCA6 symptoms were found to increase more slowly than the other three types. Factors associated with a faster increase of SARA score across all types were short duration of follow-up, older age at inclusion (per additional year), and longer repeat expansions (per additional repeat unit) (Jacobi et al., 2015).

Reetz et al. (2015) examined the effect of the number of GAA repeats in the *FXN* gene on clinical symptoms of Friedreich's Ataxia (FA). A total of 592 patients with FA were sequenced and evaluated. The authors found that with every 100 GAA repeats, the age of onset was 2-3 years earlier. Disease progression was also found to be faster in patients with more repeats; the annual worsening of the Scale for the Assessment and Rating of Ataxia (SARA) score was 1.04 points per year and 1.37 points per year for early and intermediate onset (≤14 and 15-24 years, respectively), compared to 0.56 points per year for late-onset patients (≥25 years) (Reetz et al., 2015).

Leotti et al. (2021) examined the contribution that the expanded CAG repeat length has on the rate of disease progression in spinocerebellar ataxia type 3/Machado-Joseph disease (SCA3/MJD). Expanded CAG repeat in ATXN3 is the mutation that causes SCA3/MJD, and the length of CAG repeat can determine the age of onset of clinical symptoms. The authors studied 82 patients with SCA3/MJD over 15 years using the International Cooperative Ataxia Rating Scale (ICARS) and found that "The length of the CAG repeat was positively correlated with a more rapid ICARS progression, explaining 30% of the differences between patients." The authors concluded that the length of CAG repeat in ATXN3 has major influence over clinical symptoms (Leotti et al., 2021).

Schuermans et al. (2023) performed an observational study to assess the diagnostic value of exome sequencing and multigene panel analysis for adult-onset neurologic disorders, including ataxias. In 2019, 6 diagnostic gene panels were introduced at the center for Medical Genetics of the Ghent University Hospital to diagnose patients with neurologic disorders. One of these panels was for ataxia and spasticity and included 390 genes. While the most common ataxia genes were not included in this panel, only 33% of the diagnosed patients had first been tested for SCAs, Friedrich ataxia, or fragile X tremor/ataxia syndrome. The panels included single nucleotide variants, small indels, and copy number variants. Of the panels and targeted patient populations examined by the authors, the multi-gene panel for ataxia and spasticity had the highest diagnostic yield, identifying the causal pathogenic variant (s) in 19% of the assessed patients (70 of 365) (Schuermans et al., 2023).

Dystonias

Dystonias are a class of movement disorders characterized by "sustained or intermittent muscle contractions causing abnormal, often repetitive movements, postures, or both" (Deik & Comelia, 2023). Movements are typically twisting or patterned and are often worsened by voluntary action. The basic neurochemistry of dystonia is unknown (and without consistent findings), and cell degeneration is typically not seen. However, some types of dystonia (particularly early-onset versions) have clear associations with certain genes. For example, *TOR1A* and *THAP1* both carry pathogenic mutations for early-onset dystonia. *TOR1A* (*DYT1*) encodes a protein that binds to ATP (torsin A) while *THAP1* (*DYT6*) encodes a transcription regulator for torsin A (Deik & Comelia, 2023).

Dystonias are divided into classes or types. They can be focal (involving a single site), multifocal segmental (involving region(s) of the body), generalized (involving the trunk and at least two additional sites), or hemidystonia (affecting only one side of the body). The etiology of the disorder can be either idiopathic or of known causation. Dystonias

can be due to trauma or may be inherited. Those forms of proven genetic origin can be inherited in different inheritance patterns, including autosomal dominant, autosomal recessive, X-linked recessive, or even mitochondrial inheritance. The most common inherited form of dystonia is DYT-TOR1A (or DYT1) dystonia. DYT-TOR1A accounts for approximately 40-65% of early-onset generalized dystonia in populations other than the Ashkenazi Jewish population. Within the latter population, DYT-TOR1A is estimated to account for 90% of these cases (Deik & Comelia, 2023). Even though DYT-TOR1A dystonia is inherited in an autosomal dominant pattern, the penetrance is only 30% (Bressman, 2004; Deik & Comelia, 2023; Ozelius & Lubarr, 2016). Paroxysmal dyskinesia with dystonia (PKND) is a special class of dystonia that involves spontaneous episodes of dystonia. Several environmental factors have been proposed to precipitate these episodes, such as stress, caffeine, and fatigue. The primary gene associated with PKND is *MR1*, or *DYT8*. Another special class of dystonia is myoclonus-dystonia, which is characterized by short, involuntary movements of the neck or arms in addition to normal dystonia symptoms. The main established type of myoclonus-dystonia is caused by mutations in the *SGCE* (*DYT11*) gene (Deik & Comelia, 2023).

Zech et al. (2017) performed whole exome sequencing on 16 patients with "genetically undefined early-onset generalized dystonia." Six patients had mutations of known dystonia-related genes. The mutated genes were *GCH1, THAP1, TOR1A, ANO3*, and *ADCY5*. The authors noted *GCH1, THAP1*, and *TOR1A* as associated with isolated, generalized dystonia and *ANO3* and *ADCY5* associated with a combined myoclonus-dystonia phenotype (Zech et al., 2017).

Parkinsonism (Parkinson Disease, PD)

Parkinsonism is a constellation of symptoms with "any combination of bradykinesia, rest tremor, rigidity, and postural instability." The most common form of parkinsonism is Parkinson disease (PD), a progressive neurodegenerative disorder characterized by degeneration of dopaminergic neurons in the brain (Chou, 2024b). The pathogenesis of PD is driven by loss of dopamine from the basal ganglia in the brain; though a number of compensatory mechanisms may mitigate this loss of dopamine, the progression of disease eventually leads to clinical symptoms (Jankovic, 2024). The "cardinal" features of PD are "tremor, bradykinesia, and rigidity"; postural instability is commonly considered a defining feature, yet it typically manifests late in the course of disease. Other motor symptoms such as dysphagia, blurred vision, shuffling, are common; these secondary motor symptoms are commonly derived from the cardinal features. Nonmotor symptoms include cognitive deterioration, dementia, and other mood disorders (Chou, 2024a).

The exact cause of PD is unknown, but several genetic factors have been Identified. These genes do not imply a particular phenotype, and each mutation vary in severity of symptomology. Genes associated with PD are *SNCA (PARK1/4), LRRK2 (PARK8), PINK1, PARK2, DJ-1 (PARK7)*, and *GBA* (Jankovic, 2024).

GBA- (glucocerebrosidase) associated PD is coupled with the lysosomal storage condition known as Gaucher disease, which is commonly seen in Ashkenazi Jews (Jankovic, 2024). Sidransky et al. (2009) compared PD patients with a *GBA* mutation to those with PD but without a *GBA* mutation, and they found that the patients with a *GBA* mutation had an earlier age of onset and greater chance of cognitive impairment, albeit with less pronounced cardinal features (Sidransky et al., 2009).

SNCA encodes alpha-synuclein. Although its exact role is not well understood, it is thought to function in synaptic plasticity and makes up as much as one percent of total central nervous system protein. Observations suggest a role for mutated alpha-synuclein in the pathogenesis of PD; for example, Lewy bodies, the primary pathologic hallmark of PD, have insoluble, aggregated alpha-synuclein as a major component. It may also be possible for misfolded alpha-synuclein to be transmitted from diseased neurons to healthy ones. *PARK1* refers to a missense mutation in *SNCA* whereas *PARK4* refers to a multiplication (Jankovic, 2024).

LRRK2 (*leucine-rich repeat kinase-2*) encodes a protein called dardarin. Dardarin is thought to function as a kinase for phosphorylation of certain proteins, such as alpha-synuclein and microtubule-associated protein tau. Dardarin may also be implicated in membrane and protein transport. The phenotype of *LRRK2* mutations is noted to be less severe than other genotypes of PD; patients have been observed to respond to levodopa, have a later age of onset, and less severe cognitive deterioration (Jankovic, 2024).

PARK2 encodes a protein called parkin. This protein is associated with degradation of certain proteins in wild-type genes; the mutated version of parkin cannot clear proteins, allowing them to aggregate in the neuron. This mutation typically leads to an early-age onset of PD and clinical symptoms, although the severity of these early symptoms does not appear to be significantly worse than other genotypes (Jankovic, 2024).

DJ-1 and *PINK1* are both associated with autosomal recessive inheritance and early age of onset (under 50 for *PINK1* mutations, under 40 for *DJ-1* mutations). *PINK1* mutations are possibly associated with mitochondrial dysfunction whereas *DJ-1* mutations may lead to increased neuro-oxidative stress (Jankovic, 2024).

Nalls et al. (2014) performed a meta-analysis of genome-wide association studies on PD. A common set of 7893274 variants with 13708 cases and 95282 controls were evaluated. Thirty-two loci were identified as having genome-wide significant association. These 32 loci were re-tested in an independent set of 5353 cases and 5551 controls, and 24 of these loci replicated their significance. Four loci (*GBA, GAK-DGKQ, SNCA, HLA* region) were considered to have a "secondary independent risk variant." The authors noted that the effect of each individual loci was small, but cumulative risk was "substantial" (Nalls et al., 2014).

Maple-Grødem et al. (2021) studied the significance of *glucocerebrosidase* gene (*GBA*) carrier status on motor impairment in patients with incident PD. The authors studied 528 patients with PD, using genomic DNA assessment and the Unified Parkinson's Disease Rating Scale (UPDRS). *GBA* carriers had a faster annual increase in UPDRS score than non-carriers. The authors conclude that "*GBA* variants are linked to a more aggressive motor disease course over 7 years from diagnosis in patients with PD" (Maple-Grødem et al., 2021).

Amyotrophic Lateral Sclerosis (ALS)

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder that causes significant motor neuron degeneration all over the body. This causes a variety of neuromuscular problems, such as spasticity, weakness, atrophy, hyperreflexia, cognitive impairment, and eventual death. ALS is divided into two categories: sporadic (90% of cases) and familial (10%) (Elman et al., 2023).

The primary genes tested in ALS cases are superoxide dismutase (*SOD1*) and chromosome 9 open reading frame 72 (*C9ORF72*), both of which lead to familial ALS. The enzyme SOD1 catalyzes toxic superoxide radicals to O2 and H2O2. The mutation thought to be the primary cause of *SOD1*-mediated toxicity is a gain-of-function mutation, creating many reactive oxygen species. Other hypotheses of *SOD1*-mediated toxicity include misfolded proteins caused by *SOD1* mutations and production of protein aggregates that damage motor neurons (Maragakis, 2023).

C9ORF72 expansions are another common cause of familial ALS. This mutation is a hexanucleotide repeat (GGGGCC) that forms a structure called the G-quadruplex. The exact pathogenic mechanism is unknown, but some hypotheses include creation of defective RNA transcripts and creation of toxic dipeptide proteins that cause RNA processing to falter (Maragakis, 2023).

Chiò et al. (2012) evaluated the genetic landscape of ALS in an Italian cohort. A total of 475 patients were examined, and 51 were noted to carry a mutation associated with ALS. Familial ALS was found in 46 of these patients, and 31 of these 46 were found to

have a genetic mutation (leaving 20 mutations in the remaining 429 sporadic cases). After performing a logistic regression, the authors found that the chance to carry a genetic mutation was related to the presence of comorbid frontotemporal dementia by an odds ratio of 3.5 (Chiò et al., 2012).

Vajda et al. (2017) evaluated clinician opinion on genetic testing in ALS. Responses from 167 clinicians in 21 countries were analyzed. Approximately 90.2% of respondents were found to have offered genetic testing to patients they defined as having familial ALS and 49.4% to patients with sporadic ALS. The four main genes tested were *SOD1, C9ORF72, TARDBP*, and *FUS*. Further, 42% of respondents did not offer genetic testing to asymptomatic family members of patients with familial ALS (Vajda et al., 2017).

Bandres-Ciga et al. (2019) used publicly available genome-wide association studies to identify shared polygenic risk genetic factors and casual associations in 20,806 ALS cases and 59,804 controls. Positive associations were found with smoking and moderate physical activity levels, and negative associations were found with higher education, cognitive performance, and light physical activity levels. Further, the authors report that "hyperlipidemia is a causal risk factor for ALS and localized putative functional signals within loci of interest" (Bandres-Ciga et al., 2019).

Wilson Disease (WD)

Wilson disease (WD) is a condition caused by defective copper transport. This leads to accumulation of copper in several organs, such as the brain, eyes, and liver. Eventually, the liver becomes cirrhotic, while other neurological conditions may develop. The primary gene handling hepatocyte copper transport is *ATP7B*. Normally, this gene mediates the transport of copper into apoceruloplasmin, which is then secreted into the bloodstream. Mutations in this gene cause impaired binding of copper to the protein, causing copper accumulation in the hepatocyte and eventually the bloodstream (Schilsky, 2024).

Dong et al. (2016) evaluated the genetic spectrum of WD in Chinese patients. A total of 632 patients with WD were compared against 503 controls. Further, 161 variants were found in the WD patents, and 142 were considered pathogenic or "likely pathogenic." The authors concluded that 569 of the 632 patients (90%) could be diagnosed with two or more "likely pathogenic" or worse variants. Finally, the 14 most common variants were found at least once in 537 of the 569 (94%) genetically diagnosed patients (Dong et al., 2016).

Huntington Disease (HD)

Huntington disease (HD) is a progressive, neurodegenerative disorder characterized by choreiform (brief, abrupt, and involuntary) movements, psychiatric disorders, and eventual dementia. During the early stages of the disease, patients may be able to function day-to-day and perform typical tasks; however, as the disease progresses, patients lose their ability to function independently and require assistance. In the late stages of the disease, patients often become bedridden as cognitive and motor ability continues to decline, with death occurring 10 to 40 years after onset. Currently there is no cure, and the disorder is inherited in an autosomal dominant fashion (Suchowersky, 2023).

Huntington disease is primarily caused by a trinucleotide repeat expansion. A cytosine-adenine-guanine "repeat" encodes for polyglutamine tracts in the *huntingtin* (*HTT*) gene, and the "expansion" refers to additional repeats of this trinucleotide side. Approximately 6-26 CAG repeats is considered wild-type, 27-35 repeats is considered intermediate (i.e., typically do not cause disease but may expand in future generations), and ≥36 repeats is considered diagnostic of HD. CAG repeat length is considered to correlate with both rate of disease progression and severity of neurological changes. The CAG repeat expansion leads to a toxic "gain-of-function" of the *HTT* protein, and although the exact function of this huntingtin protein is unknown, it interacts with several different proteins, implying that it has a function in several cellular events. Mutant huntingtin is seen to disrupt transcription, activation of proteases, synaptic transmission, and more (Zoghbi & Orr, 2023).

Baig et al. (2016) reviewed 22 years of predictive testing performed by the UK's Huntington Consortium. A total of 9407 predictive tests were performed over 23 testing centers, with 8441 tests on individuals considered at 50% predictive risk. Of these 8441, 4629 were mutation negative and 3790 were mutation positive (with 22 tests as "uninterpretable"). A prevalence figure of 12.3×10^{-5} was used to evaluate the "cumulative uptake" of predictive testing at the 50% risk level; this amount was calculated to be 17.4% (the number of individuals at 50% risk that had undergone predictive testing). The authors concluded that the majority of individuals at risk for HD had not undergone predictive testing (Baig et al., 2016).

Spinal Muscular Atrophies (SMA)

Spinal muscular atrophy (SMA) disorders encompass the set of disorders that are characterized by the degeneration of anterior "horn" cells in the spinal cord and motor nuclei in the lower brainstem. This leads to muscle weakness and atrophy, although cognition is unaffected. There are currently five main types of SMA, types 0 to 4. These types are organized by age of onset and clinical presentation, with types 0 and 1 presenting earliest and with the most severe symptoms and type 4 as the least severe

phenotype. For example, type 0 presents prenatally and death occurs by six months, whereas type 4 patients usually remain ambulatory and have a normal lifespan (Bodamer, 2023).

The primary gene mutation occurs in the survival motor neuron 1 (*SMN1*) gene. This gene encodes a protein that appears to play a role in mRNA synthesis. The most common mutation in *SMN1* is a deletion of exon 7, representing up to 94% of SMA patients. Another gene, *SMN2*, may cause phenotypic changes in *SMN1* due to its effect as a gene modifier. *SMN2* encodes an extremely similar protein to *SMN1* (only one nucleotide difference), and it may compensate for *SMN1* loss. Severity of SMA correlates inversely with amount of *SMN2* gene copy numbers, which varies from 0 to 8 (Bodamer, 2023).

Zarkov et al. (2015) evaluated the association between clinical symptoms and *SMN2* gene copy numbers. Forty-three patients with SMA were examined, and 37 of them had homozygous deletions of *SMN1* exon 7. The genetic characterization of these 37 patients were as follows: "One had SMA type I with 3 SMN2 copies, 11 had SMA type II with 3.1 +/- 0.7 copies, 17 had SMA type III with 3.7 +/- 0.9 copies, while 8 had SMA type IV with 4.2 +/- 0.9 copies." The authors concluded that "a higher SMN2 gene copy number correlated with less severe disease phenotype," but they noted that potential other phenotype modifiers could not be ignored (Zarkov et al., 2015).

Hereditary Spastic Paraplegia (HSP)

Hereditary spastic paraplegia (HSP) represents a group of genetic neurodegenerative diseases characterized by increased spasticity of the lower limbs over time (Shribman et al., 2019). Spastic gait is often the only, or main, feature of the syndrome; bladder dysfunction is a common clinical finding as well. More than 70 types of HSP have been identified, and are often due to axon degeneration, leading to progressive degeneration of the corticospinal tracts (Fink, 2014; Opal & Ajroud-Driss, 2022). The classification of HSP may be based on age of onset, rate of progression, degree of spasticity, and genetics with more than 55 loci related to the disease (Opal & Ajroud-Driss, 2022). Some of the more common autosomal dominant forms of HSP may be caused by mutations in the *ATL1, SPAST, KIAA1096, KIF5A,* and *REEP1* genes; additional genes are associated with autosomal recessive forms, x-linked forms, and mitochondrial forms of HSP (Opal & Ajroud-Driss, 2022).

Dong et al. (2018) performed next-generation sequencing on 149 genes associated with HSP in a cohort of 99 individuals. A retrospective study on other patients with HSP was also completed. Different genetic mutations cause different subtypes of HSP such as SPG4, SPG3A, and SPG6. The researchers note that "In ADHSP [autosomal dominant

HSP], we found that SPG4 (79%) was the most prevalent [subtype], followed by SPG3A (11%), SPG6 (4%) and SPG33 (2%)… In ARHSP [autosomal recessive HSP], the most common subtype was SPG11 (53%), followed by SPG5 (32%), SPG35 (6%) and SPG46 (3%)" (Dong et al., 2018).

In 2018, GeneReview published an updated overview of HSP. This overview was last updated in 2021. This document states the following regarding genetic testing:

- "Concurrent or serial single-gene testing can be considered if clinical findings and/or family history indicate that involvement of a particular gene or small subset of genes is most likely (see Tables 1, 2, 3, and 4)"
- "A multigene panel that includes some or all of the genes listed in Table 1 is most likely to identify the genetic cause of the condition at the most reasonable cost while limiting identification of variants of uncertain significance and pathogenic variants in genes that do not explain the underlying phenotype"
- "Comprehensive genomic testing (which does not require the clinician to determine which gene[s] are likely involved) may be considered. Exome sequencing is most commonly used; genome sequencing is also possible. Exome array (when clinically available) may be considered if exome sequencing is not diagnostic"
- "Recommendations for the evaluation of parents of a proband with an apparent *de novo* pathogenic variant include molecular genetic testing of both parents for the pathogenic variant identified in the proband" (Hedera, 2021).

GeneReviews has published four tables (below) which show the genes associated with autosomal dominant HSP, autosomal recessive HSP, X-linked HSP, and maternal (mitochondrial) HSP.

Table 1: Hereditary Spastic Paraplegia: Genes and Distinguishing Clinical Features – Autosomal Dominant Inheritance (Hedera, 2021)

Gene[1]	HSP	Type of HSP	Onset	Distinguishing Clinical
ADAR	Not assigned	Uncomplicated	Early childhood	Abnormal pattern of interferon expression determined by reverse transcription PCR assay
ALDH18A1	SPG9A	Complicated	Adolescence to adulthood (1 subject w/infantile onset)	Cataracts Gastroesophageal reflux Motor neuronopathy Variably present: Dysarthria

Gene[1]	HSP	Type of HSP	Onset	Distinguishing Clinical
				Ataxia Cognitive impairment
ATAD3A	Not assigned	Complicated	Early onset	Amyotrophy Hyperkinetic movements May be confused w/hyperkinetic cerebral palsy
ATL1	SPG3A	Uncomplicated	Infantile to childhood (rarely adult onset)	Progression may be minimal w/static course. May present as spastic diplegic cerebral palsy Complicated phenotype w/peripheral neuropathy or autonomic failure reported
BICD2	Not assigned	Complicated	Childhood or adult	Infantile onset associated w/SMA w/variable upper motor signs & contractures Adult onset associated w/mild amyotrophy
BSCL2 [2]	SPG17	Complicated	Adulthood	Distal amyotrophy affecting hands & feet Motor neuropathy Can be indistinguishable from ALS
CPT1C	SPG73	Uncomplicated	Early adulthood	Foot deformity may be present.
DNM2 [3]	Not assigned	Complicated	Before age 20 years	Axonal polyneuropathy may be present. Mild distal amyotrophy in feet
ERLIN2	SPG18 [4]	Uncomplicated	Juvenile to adulthood	None
HSPD1	SPG13	Uncomplicated	Adulthood	Mild distal amyotrophy
KIF5A	SPG30	Uncomplicated (for AD inheritance)	Juvenile to adulthood	Some individuals have mild ID.

Gene[1]	HSP	Type of HSP	Onset	Distinguishing Clinical
				Optic nerve atrophy, epilepsy can be rarely seen in AD SPG30.
KIF5A [4]	SPG10	Complicated	Juvenile or adulthood	Polyneuropathy Pes cavus
NIPA1	SPG6	Uncomplicated	Adulthood (infantile onset rare)	Severe weakness & spasticity Rapidly progressive Rarely, complicated by epilepsy or variable peripheral neuropathy
***ATP2B4* (*PMCA4*)**	Not assigned	Uncomplicated	Adulthood	None
REEP1	SPG31	Uncomplicated	Variable from 2nd to 7th decades	Mild amyotrophy variably present.
REEP2	SPG72	Uncomplicated	Very early, average age 4 years	Musculoskeletal problems Mild postural tremor
RTN2	SPG12	Uncomplicated	Before age 20 years	None
SLC33A1	SPG42	Uncomplicated	Early adulthood	Slowly progressive Mild *pes cavus*
SPAST	SPG4	Uncomplicated	Variable from infancy to 7th decade	Cognitive decline & dementia common Distal amyotrophy variably present Complicated phenotype w/ataxia variably present
SPG7	SPG7	Uncomplicated or complicated	Juvenile or adulthood	Dysarthria Ataxia Optic atrophy Supranuclear palsy Mitochondrial abnormalities on skeletal muscle biopsy
WASHC5	SPG8	Uncomplicated	Adulthood (rare infantile onset reported)	Severe motor deficit in some individuals

Gene[1]	HSP	Type of HSP	Onset	Distinguishing Clinical
TUBB4A [5]	Not assigned	Complicated	Juvenile	Cerebellar ataxia MRI evidence of hypomyelination
ZFYVE27	SPG33	Uncomplicated	Adulthood	Mild pes cavus

AD = autosomal dominant; AR = autosomal recessive; ALS = amyotrophic lateral sclerosis; CMT = Charcot-Marie-Tooth neuropathy; DI-CMT = dominant intermediate Charcot-Marie-Tooth neuropathy; HMN = hereditary motor neuropathy; HSP = hereditary spastic paraplegia; SMA = spinal muscular atrophy

Table 2: Hereditary Spastic Paraplegia: Genes and Distinguishing Clinical Features – Autosomal Recessive Inheritance (Hedera, 2021)

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
SPG21 (ACP33)	SPG21	Complicated	Childhood	Ataxia Adult-onset dementia & parkinsonism Polyneuropathy Akinetic mutism seen in advanced cases	Rare, first described in Old Order Amish population (later identified in various ethnic groups) Also known as Mast syndrome
ALDH18A1	SPG9B	Complicated	Adolescence to adulthood (one subject w/infantile onset)	Cataracts Gastroesophageal reflux Motor neuronopathy Variably present: Dysarthria Ataxia Cognitive impairment	Rare Allelic w/AD HSP (SPG9A)

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
ALDH3A2	Not assigned	Complicated	Childhood	Congenital ichthyosis Macular dystrophy Leukodystrophy Seizures in ~40% of patients	Rare Most common in people of Swedish ancestry Known as Sjögren-Larsson syndrome
AMPD2 [2]	SPG63	Complicated	Infancy	Short stature Thin corpus callosum White matter changes	Rare
AP4B1	SPG47	Complicated	Infancy	Severe ID Facial dysmorphism Seizures Stereotypic laughter w/tongue protrusion	Rare
AP4E1	SPG51	Complicated	Infancy	Severe ID Facial dysmorphism Seizures Stereotypic laughter w/tongue protrusion	Rare
AP4M1	SPG50	Complicated	Infancy	Severe ID Facial dysmorphism Seizures Stereotypic laughter w/tongue protrusion	Rare
AP4S1	SPG52	Complicated	Infancy	Severe ID Facial dysmorphism Seizures Stereotypic laughter w/tongue protrusion	Rare

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
AP5Z1	SPG48	Uncomplicated	Typically adulthood; rarely infancy	Urinary incontinence Parkinsonism Dystonia Thin corpus callosum Leukodystrophy Severe DD in infantile onset	Single family
ATL1	SPG3A	Uncomplicated	Infantile to childhood (rarely adult onset)	Progression may be minimal w/static course May present as spastic diplegic cerebral palsy Complicated phenotype w/peripheral neuropathy or autonomic failure reported	AR inheritance is very rare.
B4GALNT1	SPG26	Complicated	Juvenile	Amyotrophy Dysarthria Ataxia DD Dystonia	Rare
BICD2	Not assigned	Complicated	Childhood	Amyotrophy Contractures	Rare
C12orf65	SPG55	Complicated	Childhood	DD Visual loss Polyneuropathy Arthrogryposis Signs of mitochondrial encephalomyopathy, some classified as Leigh syndrome	Rare

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
C19orf12	SPG43	Complicated	Childhood	Amyotrophy Dysarthria Multiple contractures Neurodegeneration w/brain iron accumulation in some	Rare
CYP2U1	SPG56	Complicated	Infancy	Severe DD Dystonia Polyneuropathy Calcification of basal ganglia	Rare
CYP7B1	SPG5A	Uncomplicated or complicated	Juvenile to early adulthood	Ataxia Polyneuropathy Extrapyramidal signs MRI signs of leukodystrophy	SPG5A was diagnosed in 9 of 172 families w/histories consistent w/AR inheritance of HSP. [3]
DDHD1	SPG28	Uncomplicated	Childhood	Scoliosis	Rare
DDHD2	SPG54	Complicated	Infancy	Severe DD Optic atrophy Thin corpus callosum Leukodystrophy	Rare
ENTPD1	SPG64	Complicated	Infancy	Mild cognitive disability Behavioral disturbances White matter changes	Rare

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
ERLIN1	SPG62	Complicated	Childhood	Amyotrophy Ataxia Phenotype consistent w/juvenile onset of ALS reported	Rare
ERLIN2	SPG18	Complicated (rarely pure AR HSP reported)	Childhood	DD Seizures Contractures Juvenile primary lateral sclerosis phenotype reported Allelic w/AD pure HSP	Rare
FA2H [4]	SPG35	Complicated	Childhood	Seizures Dystonia Parkinsonism w/iron accumulation in basal ganglia	Rare
GAD1	Not assigned	Complicated	Childhood	Moderate to severe ID Single reported family was described as having AR cerebral palsy	Rare (single family reported)
GBA2	SPG46	Complicated	Childhood	DD Ataxia Hearing loss Polyneuropathy	Rare
GJC2 [5]	SPG44	Complicated	Childhood	Febrile seizures Deafness Episodic spasms Variable degree of leukodystrophy	Rare
GRID2 [6]	Not assigned	Complicated	Childhood	Amyotrophy Ataxia	Rare

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
IBA57 [7]	SPG74	Complicated	Childhood	Optic atrophy Peripheral neuropathy	Rare
KIF1A [8]	SPG30	Complicated	Childhood	Spastic ataxia Polyneuropathy	Rare
KIF1C	SPG58	Complicated	Childhood	Spastic ataxia Dystonia	Rare
KLC2	Not assigned	Complicated	Childhood	Optic atrophy Neuropathy Contractures in later stages Cognition remains intact	Rare Also known as spastic paraplegia optic atrophy, & neuropathy (SPOAN)
KLC4	Not assigned	Complicated	Childhood	Ataxia Multiple contractures Variable degree of leukodystrophy	Rare
MARS1 [9]	SPG70	Complicated	Infancy	Nephrotic syndrome, polyneuropathy Mild ID Late onset of CMT2 (axonal) type also reported	Rare
NT5C2	SPG45	Complicated	Childhood	Optic atrophy Nystagmus Strabismus ID Hypoplastic corpus callosum	Rare
PGAP1 [10]	SPG67	Complicated	Infancy	Severe DD Tremor Agenesis of corpus callosum Hypomyelination	Rare

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
PNPLA6 [11]	SPG39	Complicated	Childhood	Amyotrophy Endocrine abnormalities w/short stature or hypogonadotropic hypogonadism Chorioretinal dystrophy	Rare
REEP2	SPG72	Uncomplicated	Early childhood	Musculoskeletal problems Mild postural tremor	Rare Inheritance can be dominant or recessive.
SPART	SPG20	Complicated	Juvenile	Distal amyotrophy Short stature Kyphoscoliosis Multiple limb contractures	Rare Mostly seen among Old Order Amish
SPG7	SPG7	Uncomplicated or complicated	Juvenile or adulthood	Dysarthria Ataxia Optic atrophy Supranuclear palsy Mitochondrial abnormalities on skeletal muscle biopsy	5%-12% of AR HSP AD inheritance suggested for some pathogenic variants; this remains controversial
SPG11	SPG11	Complicated	Childhood or early adulthood	DD Optic atrophy Ataxia Pseudobulbar signs Polyneuropathy Levodopa-responsive parkinsonism Hypoplastic or absent corpus callosum	5% of AR HSP 75% of HSP w/DD & hypoplasia of corpus callosum

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
TECPR2	SPG49	Complicated	Childhood	Central apnea Severe DD Microcephaly Dysmorphic features	Rare
TFG	SPG57	Complicated	Childhood	Optic atrophy Severe polyneuropathy	Rare
USP8	SPG59	Uncomplicated	Childhood	None	Rare
WDR48	SPG60	Complicated	Infancy	Polyneuropathy DD	Rare
ZFYVE26	SPG15	Complicated	Childhood or early adulthood	DD Optic atrophy Ataxia Central retinal degeneration Polyneuropathy	1%-2% of AR HSP

AD = autosomal dominant; AR = autosomal recessive; ALS = amyotrophic lateral sclerosis; DD = developmental delay; HSP = hereditary spastic paraplegia; ID = intellectual disability

Table 3: Hereditary Spastic Paraplegia: Genes and Distinguishing Clinical Features – X-Linked Inheritance (Hedera, 2021)

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
L1CAM [2]	SPG1	Complicated	Infancy	ID Adducted thumbs Corpus callosum hypoplasia Aphasia Obstructive hydrocephalus	Rare

Gene [1]	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features	Other
PLP1 [3]	SPG2	Complicated	Early-childhood to juvenile onset (in manifesting XX heterozygotes: onset in 4th – 7th decade)	Pure HSP phenotype present in early stages; later, other signs emerge Nystagmus Optic atrophy Dysarthria ID Variable degree of leukodystrophy on MRI	Rare In heterozygous XX individuals: variable phenotype w/relatively late onset & mild clinical manifestations
SLC16A2	SPG22	Complicated	Early childhood	Severe ID Infantile hypotonia Progressive spasticity Ataxia Dystonia ↑ T3 & normal to mildly ↑ TSH ↓ T4 hypomyelination on neuroimaging	Rare SPG22 is a proposed designation. [4] Also referred to as Allan-Herndon-Dudley syndrome [5]

AD = autosomal dominant; AR = autosomal recessive; DD = developmental delay; HSP = hereditary spastic paraplegia; ID = intellectual disability

Table 4: Hereditary Spastic Paraplegia: Gene and Distinguishing Clinical Features – Maternal (Mitochondrial) Inheritance (Hedera, 2021)

Gene	HSP Designation	Type of HSP	Onset	Distinguishing Clinical Features
MT-ATP6	Not assigned	Complicated	Adult	Cardiomyopathy, diabetes mellitus, sensory polyneuropathy

VI. Guidelines and Recommendations

Amyotrophic Lateral Sclerosis (ALS)

Italian Amyotrophic Lateral Sclerosis Genetic (ITALSGEN) Consortium

The following guidelines were created as a result from a workshop on ALS genetic testing.

- "All ALS patients who have a first-degree or second-degree relative with ALS, frontotemporal dementia or both, should be offered genetic testing. At present, however, we do not recommend offering genetic testing to sporadic ALS patients, outside research protocols."
- "Genetic testing at present is not indicated in asymptomatic at-risk subjects and, therefore, should not be proposed."
- The guidelines also note that "two-thirds of mutations are found in four genes, *C9ORF72, SOD1, TARDBP* and *FUS*." Therefore, they state that these genes should be "considered" for routine diagnostic protocol. Furthermore, they note that *C9ORF72* testing is "worthwhile" in sporadic patients. If these four genes are negative, other ALS-related genes may be tested. Finally, *UBQLN2* is a gene that should be tested if there is suspicion of an X-linked dominant inheritance (Chio et al., 2014).

ALS Association

The ALS Association published information on genetic testing on their website. They state that "Knowing whether your ALS is connected to a specific gene mutation could make you eligible for ongoing clinical trials testing treatments targeted at specific genes." The guidelines go on to state that "if genetic testing identifies a disease-causing genetic mutation in a person with ALS, their family members generally have the option to pursue testing themselves" but note that this is a personal decision with significant costs and benefits (ALSA, 2024).

Ataxias (including Friedreich ataxia)

European Federation of Neurological Societies (EFNS) and European Neurological Society (Schuermans et al.)

The EFNS-ENS released joint guidelines on diagnosis and management of chronic ataxias in adulthood. Their genetic testing guidelines are listed below:

"In the case of a family history that is compatible with an autosomal dominant cerebellar ataxia, screening for SCA1, 2, 3, 6, 7 and 17 is recommended (level B). In Asian patients, DRPLA should also be tested for."
"If mutation analysis is negative, we recommend contact with or a referral to a specialized clinic for reviewing the clinical phenotype and further genetic testing (good practice point)."

In the case of a family history compatible with an autosomal recessive cerebellar ataxia, they recommend a three-step diagnostic approach.

Step 1 includes mutation analysis of the FRDA gene for Friedreic''s ataxia (although one can refrain from this in the case of severe cerebellar atrophy).
Step 2 includes mutation analysis of the *SACS*, *POLG*, Aprataxin (*APTX*) and *SPG7* genes (taking into account specific phenotypes).
Step 3 includes "referral to a specialized centre, e.g. for skin or muscle biopsy targeted at diagnoses such as Niemann−Pick type C, recessive ataxia with coenzyme Q deficiency [aarF domain containing kinase 3 (ADCK3)/autosomal recessive spinocerebellar ataxia 9 (SCAR9)] and mitochondrial disorders, or for extended genetic screening using gene panel diagnostics."
"In the case of sporadic ataxia and independent from onset age, we recommend routine testing for SCA1, SCA2, SCA3, SCA6 and DRPLA (in Asian patients) (level B)"(van de Warrenburg et al., 2014).

Friedreich''s Ataxia Research Alliance (FARA)

The FARA notes genetic diagnostic information on their website.

They state that in "more than 95% of abnormal alleles, the mutation is expansion of naturally occurring GAA repeat in first intron (non-coding region) of the frataxin or FRDA gene."
"Genetic testing results in ~98% detection in symptomatic individuals. In rare cases, analysis of frataxin protein levels can be helpful to confirming or ruling out a diagnosis…Carrier testing is recommended for anyone with a positive family history of Friedreich ataxia and for partners of known carriers. Presymptomatic testing for at-risk siblings/relatives is available, however genetic counseling is strongly recommended to assist individuals/families in considering the risks vs benefits for testing an untreatable genetic condition" (FARA, 2022).

An expert working group was convened to review and provide guidelines for FA. This working group reviewed guidelines from a variety of different societies, and drafted their own guidelines based off their review. Their genetic testing items are as follows:

"Any individual in whom the diagnosis of FRDA is considered should undergo genetic testing for FRDA."
"Referral to a clinical geneticist or genetic counselor should be considered on diagnosis of FRDA."
"Requests for pre-symptomatic genetic testing are best managed on a case-by-case basis; there is no evidence to support the routine provision or refusal of pre-symptomatic genetic testing for FRDA."
"The committee did not reach consensus on the issue of whether it is appropriate to conduct presymptomatic testing in a minor. Where a request for presymptomatic testing in a minor occurs, the individual/family should be referred to a team with expertise in this field for discussion about pre-symptomatic genetic testing in which the risks and benefits of pre-symptomatic genetic diagnosis are put forward. The risks and benefits from both the child's and parents' perspectives should be carefully reviewed during the pre-test assessment."
"All patients identified pre-symptomatically and their families would benefit from immediate post-test counseling and psychosocial support and referral for appropriate neurological and cardiac surveillance."
"Carrier testing should be first undertaken on the closest relative" (Corben et al., 2014).

For Friedreich Ataxia due to compound heterozygosity for a *FXN* Intron 1 GAA expansion and point mutation/insertion/deletion:

"If a person compound heterozygous for a *FXN* GAA expansion and a point mutation/insertion/deletion has a similar phenotype to those with FRDA due to homozygosity for GAA expansions, they should be managed as per the guidelines in this document."
"If spastic ataxia is the predominant phenotype, then the main management issue is that of spasticity and the guidelines for management of spasticity should be followed" (Corben et al., 2014).

Ataxia UK

Genetic tests are recommended as part of the secondary care regimen for ataxia. The secondary care is divided into "first line" and "second line" for adults.

The first line genetic tests are for: FRDA, SCA1, 2, 3, 6, 7 (12, 17), and FXTAS. The second line genetic tests are for any remaining genes (de Silva et al., 2019). The guidelines list genes associated with types of ataxia (Bonney et al., 2016).

Spinocerebellar ataxias:

Type (MacLeod et al.)	Gene
1	*ATXN1*
2	*ATXN2*
3	*ATXN3*
5	*SPTBN2*
6	*CACNA1A*
7	*ATXN7*
8	*ATXN8OS*
10	*ATXN10*
11	*TTBK2*
12	*PPP2R2B*
13	*KCNC3*
14	*PRKCG*

40	*CCDC88C*
41	*TRPC3*

The guidelines note that the clinical validity of genetic testing for SCA8 by CAG repeat sizing has not been determined. Therefore, SCA8 should not be offered as a routine test if family history is unknown. However, testing may be appropriate in "large pedigrees where the expansion has been proven to be segregating with the disease" (Bonney et al., 2016).

SCAs are considered autosomal dominant ataxias. Autosomal dominant ataxias also include GSS, DRPLA, POLG1, and EA types 1 and 2.

Autosomal reccessive ataxia genes include *FXN* (Frederich's Ataxia), *APTX, SETX, SACS, SPG7, ATM*, and *TTPA* (Ataxia with Vitamin E deficiency).

Mitochondrial Ataxias include NARP, MELAS, and MERRF.

X-Linked Ataxias include FXTAS (Fragile X associated Tremor and Ataxia Syndrome).

For children, second-line diagnostic tests for chronic ataxias include DNA testing for the *FXN* gene is recommended for suspected Frederich's Ataxia, *ATM* testing is recommended for suspected ataxia-telangiectasia, and general DNA testing is recommended for "other conditions." Finally, "genetic testing of asymptomatic 'at-risk' minors is not generally recommended, but should be considered on a case-by-case basis" (Bonney et al., 2016).

National Ataxia Foundation (NAF)

The National Ataxia Foundation published a "Frequently Asked Questions" document regarding genetic testing for hereditary ataxias. For diagnostic testing, they noted that in sporadic ataxia cases (no prior family history of ataxia), genetic testing should only be done after non-genetic causes of ataxia have been excluded. For predictive testing, a patient "must" know what type of ataxia is present in their family to be eligible (NAF, 2015).

Dystonias

European Federation of Neurological Societies (EFNS)

The EFNS has released guidelines on the genetic testing of dystonias, which are listed below:

"Genetic testing should be performed after establishing the clinical diagnosis. Genetic testing is not sufficient to make a diagnosis of dystonia without clinical features of dystonia (level B). Genetic counselling is recommended."
"*DYT1* testing is recommended for patients with limb-onset, primary dystonia with onset before age 30 (level B), as well as in those with onset after age 30 if they have an affected relative with early-onset dystonia (level B)."
"In dystonia families, *DYT1* testing is not recommended in asymptomatic individuals (good practice point)."
"*DYT6* testing is recommended in early-onset dystonia or familial dystonia with cranio-cervical predominance or after exclusion of *DYT1* (good practice point)."
"Individuals with early-onset myoclonus affecting the arms or neck, particularly if positive for autosomal-dominant inheritance and if triggered by action, should be tested for the *DYT11* gene (good practice point). If direct sequencing of the SGCE gene is negative, gene dosage studies increase the proportion of mutation-positives (level C)."
"Diagnostic testing for the PNKD gene (*DYT8*) is recommended in symptomatic individuals with PNKD (good practice point)."
"Gene testing for mutation in *GLUT1* is recommended in patients with paroxysmal exercise-induced dyskinesias, especially if involvement of *GLUT1* is suggested by low

CSF/serum glucose ratio, epileptic seizures or haemolytic anaemia (good practice point)" (Albanese et al., 2011).

The EFNS also released guidelines on the diagnosis of Huntington's Disease. In it, they recommend that "diagnostic testing for HD is recommended (Level B) when a patient presents with an otherwise unexplained clinical syndrome of a progressive choreatic movement disorder and neuropsychiatric disturbances with or without a positive family history of the disease" (Harbo et al., 2009).

Hereditary Spastic Paraplegia (HSP)

National Organization for Rare Disorders (NORD)

NORD has published a webpage on HSP. This page states that "Individuals seeking genetic counseling for HSP are recommended to consult a genetic counselor or medical geneticist for specific information"; further, "Genetic testing is often helpful in confirming the clinical diagnosis of HSP and in determining the genetic type of HSP. Results of genetic testing can be used, together with clinical information, to provide genetic counseling" (NORD, 2017).

Regarding genetic testing for a HSP diagnosis, NORD states that "Testing for HSP genes is available and performed for individual HSP genes, for panels containing dozens of HSP genes, and by analysis of all genes (whole exome and whole genome analysis). Genetic testing is often helpful to confirm the clinical diagnosis of HSP. Genetic testing is most often able to find causative gene mutations for subjects with HSP who have a family history of a similarly affected first-degree relative. Despite discovery of more than 60 genes in which mutations cause various types of HSP, many individuals with HSP do not have an identified gene mutation… at present, genetic testing results very rarely influence treatment which is largely directed toward reducing symptoms" (NORD, 2017).

Huntington Disease (HD)

Working Group on Genetic Counselling and Testing of the European Huntington's Disease Network (EHDN)

This Working Group was convened to provide guidelines for diagnostic genetic testing for HD. The guidelines list four groups that "should be considered" for genetic testing.

- The first group is "the patient with a positive family history and specific motor symptoms." The authors note that diagnosis of this group is "not difficult" and that the test may be "little more than a formality."

- The second group is "the patient with no family history, but specific symptoms likely to be HD." The authors consider diagnostic testing of this group to be "most clinically useful."
- The third group is "the patient with a positive family history and prodromal symptoms, which suggest the impending onset of HD." The authors state that the motor abnormalities are part of the diagnostic criteria, but other symptoms such as behavioral changes or other mental conditions may present in HD.
- The fourth group"is "the child with a family history of HD and features of juvenile HD." The authors note this group as challenging to diagnose, and alludes to diagnostic criteria set forth by Nance, which are as follows:
    - "a known family history of HD (often, but not exclusively, the father)
    - and two or more of
        - declining school performance
        - Seizures
        - oral motor dysfunction
        - Rigidity
        - gait disturbance" (Craufurd et al., 2015)

Another Working Group was convened to evaluate the predictive testing guidelines for HD in 2013. In those guidelines, they noted that HD testing should not be part of routine blood work and that patients under 18 should not be tested. However, they state that genetic counseling should be offered to those desiring to take the test (MacLeod et al., 2013). MacLeod et al. (2013) was affirmed by the American Association of Neurology on January 14, 2014 (AAN, 2014).

The EDHN performed a literature review of scientific and consensual guidelines in 2019. The only major change had to do with deutetrabenazine (Grade A) as a treatment. Other studies were in agreement wiuth previously noted guidelines and recommendations (Bachoud-Lévi et al., 2019).

Parkinsonism (Parkinson Disease, PD)

European Federation of Neurological Societies (EFNS) and Movement Disorder Society–European Section (MDS-ES)

These guidelines were created by a Task Force comprised of members from both societies. Their genetic testing recommendations for Parkinson disease are listed below:

- "Testing for *SNCA* point mutations and gene multiplications is recommended only in families with multiple affected members in more than one generation suggestive of dominant inheritance, with early- or late-onset PD."
- "*LRRK2* genetic testing for counselling purposes, specifically directed at known pathogenic variants is recommended in patients with a clinical picture of typical PD and a positive family history suggestive of dominant inheritance."
- "In sporadic patients, genetic testing should be limited to the search for known *LRRK2* founder mutations in the appropriate populations (i.e. with known high mutation frequencies)."
- "Genetic testing for *GBA* gene mutations is recommended in patients with typical PD with or without a positive family history, limited to the known founder mutations of established pathogenic role in the appropriate populations."
- "Genetic testing of the *parkin, PINK1* and *DJ-1* genes for counselling purposes is recommended in patients with typical PD and positive family history compatible with recessive inheritance, particularly when the disease onset is before the age of 50 years. For sporadic cases, *parkin, PINK1* and *DJ-1* genetic testing is recommended when onset is very early, particularly before the age of 40."
- "Testing of the *ATP13A2, PLA2G6* and *FBXO7* genes might be considered in cases with very-early-onset PD, if no mutation in *parkin, PINK1* and *DJ-1* gene has been found."

For recommendation III, the guideline lists Ashkenazi Jews, North African Arabs, and Basques as examples of high mutation frequency populations (Berardelli et al., 2013).

Spinal Muscular Atrophies (SMA)

218th European Neuromuscular Centre (ENMC) International Workshop

Researchers, industry representatives, and other representatives from SMA Europe convened to review the current knowledge on the standards of care for SMA. Regarding genetic testing, they noted that "there was consensus that genetic testing is the first line investigation when this condition is suspected in a typical case and that muscle biopsy or electromyography should not be performed in a typical presentation. There was also consensus that, at variance with previous recommendations, the current gold standard is *SMN1* deletion/mutation and *SMN2* copy number testing, with a minimal standard of *SMN1* deletion testing. Other areas concerning the value of *SMN2* copy number were more controversial and a further Delphi round was planned to complete the task" (Finkel et al., 2017).

"Diagnostic testing for HD is recommended (Level B) when a patient presents with an otherwise unexplained clinical syndrome of a progressive choreatic movement disorder

and neuropsychiatric disturbances with or without a positive family history of the disease" (Finkel et al., 2017).

American College of Obstetricians and Gynecologists (ACOG)

ACOG recommended SMA screening for all individuals "considering pregnancy or are currently pregnant." ACOG also noted that if one parent had a family history of SMA, the other parent should be tested for *SMN1* deletion if molecular reports for the first parent were not available. These guidelines were reaffirmed in 2023 (ACOG, 2017).

Wilson Disease (WD)

Hepatology Committee of the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN)

ESPGHAN has published a position paper regarding Wilson disease in children. The genetic testing-relevant items are listed below:

The paper stated that the scoring system used for diagnosis of Wilson's Disease included identification of a pathogenic mutation, which was considered one point (the scoring system is as follows: 0-1: unlikely, 2-3: probable, 4+, highly likely). The paper also notes that if biochemical and clinical symptoms are present, only one mutation needs to be identified to diagnose Wilson disease. If the patient is asymptomatic, two mutations must be identified to diagnose "with certainty." The diagnostic protocol calls for biochemical (copper metabolism testing), liver (ALT/AST, bilirubin, et al), and clinical evaluation before proceeding to molecular testing, and *ATP7B* is the primary gene mutation mentioned in evaluation of Wilson disease.

"Genetic counseling is essential for families of patients with WD, and screening first-degree relatives is recommended by both European and American guidelines."
"It is essential to screen siblings of any patient newly diagnosed with WD because the chance of being a homozygote and developing clinical disease is 25%. Assessment should include physical examination, serum ceruloplasmin, liver function tests, and molecular testing for *ATP7B* mutations or haplotype studies if not available. Newborn screening is not warranted and screening may be delayed until 1 to 2 years of age" (Socha et al., 2018).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the

determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81177	ATN1 (atrophin 1) (eg, dentatorubral-pallidoluysian atrophy) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81178	ATXN1 (ataxin 1) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81179	ATXN2 (ataxin 2) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81180	ATXN3 (ataxin 3) (eg, spinocerebellar ataxia, Machado-Joseph disease) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81181	ATXN7 (ataxin 7) (eg, spinocerebellar ataxia) gene analysis, evaluation to det ect abnormal (eg, expanded) alleles
81182	ATXN8OS (ATXN8 opposite strand [non-protein coding]) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81183	ATXN10 (ataxin 10) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81184	CACNA1A (calcium voltage-gated channel subunit alpha1 A) (eg, spinocerebellar ataxia) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81185	CACNA1A (calcium voltage-gated channel subunit alpha1 A) (eg, spinocerebellar ataxia) gene analysis; full gene sequence
81186	CACNA1A (calcium voltage-gated channel subunit alpha1 A) (eg, spinocerebellar ataxia) gene analysis; known familial variant

CPT	CPT Description
81243	FMR1 (fragile X messenger ribonucleoprotein 1) (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81244	FMR1 (fragile X messenger ribonucleoprotein 1) (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; characterization of alleles (eg, expanded size and promoter methylation status)
81271	HTT (huntingtin) (eg, Huntington disease) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81274	HTT (huntingtin) (eg, Huntington disease) gene analysis; characterization of alleles (eg, expanded size)
81284	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; evaluation to detect abnormal (expanded) alleles
81285	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; characterization of alle les (eg, expanded size)
81286	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; full gene sequence
81289	FXN (frataxin) (eg, Friedreich ataxia) gene analysis; known familial variant(s)
81329	SMN1 (survival of motor neuron 1, telomeric) (eg, spinal muscular atrophy) gen e analysis; dosage/deletion analysis (eg, carrier testing), includes SMN2 (survival of motor neuron 2, centromeric) analysis, if performed
81343	PPP2R2B (protein phosphatase 2 regulatory subunit Bbeta) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81344	TBP (TATA box binding protein) (eg, spinocerebellar ataxia) gene analysis, evaluation to detect abnormal (eg, expanded) alleles
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP] by techniques such as restriction enzyme digestion or melt curve analysis)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)

CPT	CPT Description
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons
81407	Molecular pathology procedure, Level 8 (eg, analysis of 26-50 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of >50 exons, sequence analysis of multiple genes on one platform)
81408	Molecular pathology procedure, Level 9 (eg, analysis of >50 exons in a single gene by DNA sequence analysis)
81479	Unlisted molecular pathology procedure
0136U	ATM (ataxia telangiectasia mutated) (eg, ataxia telangiectasia) mRNA sequence analysis (List separately in addition to code for primary procedure) (Use 0136U in conjunction with 81408) Proprietary test: +RNAinsight™ for ATM Lab/Manufacturer: Ambry Genetics
0231U	CACNA1A (calcium voltage-gated channel subunit alpha 1A) (eg, spinocerebellar ataxia), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, short tandem repeat (STR) gene expansions, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® CACNA1A Analysis Lab/Manufacturer: Variantyx Inc
0233U	FXN (frataxin) (eg, Friedreich ataxia), gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, short tandem repeat (STR) expansions, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® FXN Analysis Lab/Manufacturer: Variantyx Inc
0236U	SMN1 (survival of motor neuron 1, telomeric) and SMN2 (survival of motor neuron 2, centromeric) (eg, spinal muscular atrophy) full gene analysis, including small sequence changes in exonic and intronic regions, duplications and deletions, and mobile element insertions Proprietary test: Genomic Unity® SMN1/2 Analysis Lab/Manufacturer: Variantyx Inc

Genetic Testing for Neurofibromatosis and Related Disorders

Policy Number: AHS – M2134 – Genetic Testing for Neurofibromatosis and Related Disorders	Prior Policy Name and Number, as applicable: • M2134-Genetic Testing for Neurofibromatosis
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Neurofibromatoses are a group of three clinically and genetically distinct disorders that cause tumors to form on nerve tissue. Neurofibromatosis type 1 (NF1) is caused by autosomal dominant mutations in the neurofibromin (*NF1*) gene and is characterized by multiple café-au-lait macules and neurofibromas (Korf et al., 2024). Neurofibromatosis type (NF2) is caused by autosomal dominant mutations in the merlin, also known as schwannomin, (*NF2*) gene, and is characterized by multiple tumors of the nervous system, including the more common bilateral vestibular schwannomas as well as intracranial and spinal meningiomas, intrinsic ependymomas, and other spine tumors (Evans, 2023b). Schwannomatosis is caused by inactivating mutations in *SMARCB1* and *LZTR* and is characterized by multiple schwannomas and pain arising in adulthood (Bergner & Yohay, 2024).

Legius syndrome is an NF1-like disorder caused by autosomal dominant mutations in the sprout-related EVH1 [enabled/vasodilator-stimulated phosphoprotein homology 1] domain-containing protein 1 (*SPRED1*) gene, resulting in café-au-lait macules. Constitutional mismatch repair-deficiency syndrome (CMMR-D), caused by mutations in mismatch repair genes, can also result in café-au-lait macules, axillary freckling, and Lisch nodules similar to NF1; however, unlike NF1, CMMR-D can also result in a variety of different malignancies, including glioblastoma and colorectal cancer (Korf et al., 2024).

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Prior to genetic testing for neurofibromatosis, *NF2-*, *SMARCB1-*, or *LZTR1*-related schwannomatosis, Legius Syndrome, **or** constitutional mismatch repair deficiency (CMMRD), genetic counseling **IS REQUIRED.**

2) For individuals who are clinically suspected of having neurofibromatosis type 1 (NF1), but for whom a definitive diagnosis cannot be made without genetic testing, genetic testing for *NF1* mutations **MEETS COVERAGE CRITERIA** when **one** of the following signs of NF1 is present:
   a) Individual has six or more café-au-lait macules (over 5 mm in greatest diameter in pre-pubertal individuals; over 15 mm in greatest diameter in post-pubertal individuals).
   b) Individual has two or more neurofibromas of any type or one plexiform neurofibroma.
   c) Individual has freckling in the axillary or inguinal regions.
   d) Individual has optic glioma.
   e) Individual has two or more Lisch nodules (iris hamartomas).
   f) Individual has a distinctive osseous lesion, such as sphenoid dysplasia, anterolateral bowing of the tibia, or pseudarthrosis of the long bone.
   g) Individual has a first-degree relative (see Note 1) with NF1 as defined by the above criteria.

3) For asymptomatic individuals who have a close blood relative (see Note 1) with a deleterious *NF1* or *NF2* gene mutation, the following testing **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial mutation.
   b) Comprehensive genetic testing when the specific familial mutation is unknown (i.e., family member is unavailable for testing or testing results are unavailable).

4) For individuals who have a clinical diagnosis of neurofibromatosis and who are planning to conceive, preconception screening for *NF1* or *NF2* gene mutations, when

the individual has not previously received genetic screening for a pathogenic mutation, **MEETS COVERAGE CRITERIA.**

5) For individuals who are clinically suspected of having *NF2*-related schwannomatosis, but for whom a definitive diagnosis and classification cannot be made without genetic testing, genetic testing for *NF2* gene mutations **MEETS COVERAGE CRITERIA** when **one** of the following signs of *NF2*-related schwannomatosis is present:
    a) Individual has bilateral vestibular schwannomas (VS)
    b) Individual has either two major or one major and two minor criteria:
        i) Major criteria:
            (a) Unilateral VS
            (b) First-degree relative (see Note 1) other than a sibling) with *NF2*-related schwannomatosis
            (c) Two or more meningiomas (note that a single meningioma qualifies as minor criteria)
        ii) Minor criteria:
            (a) Can count >1 of a type (e.g., 2 distinct schwannomas would count as 2 minor criteria): Ependymoma, schwannoma (note that if the major criterion is unilateral VS, at least 1 schwannoma must be dermal in location)
            (b) Can count only once (e.g., bilateral cortical cataracts count as a single minor criterion): Juvenile subcapsular or cortical cataract, retinal hamartoma, epiretinal membrane in a person aged <40 years, meningioma (because multiple meningiomas qualify as a major criteria).

6) For individuals who are negative for *NF2* mutations **and** who have one or more pathologically confirmed schwannoma or hybrid nerve sheath tumor, genetic testing for mutations in *SMARCB1* and *LZTR1* **MEETS COVERAGE CRITERIA**.

7) For individuals who are clinically suspected of having Legius Syndrome, genetic testing of *SPRED1* **MEETS COVERAGE CRITERIA** when **one** of the following conditions is met:
    a) The individual has six or more café-au-lait macules (over 5 mm in greatest diameter in pre-pubertal individuals; over 15 mm in greatest diameter in post-pubertal individuals).
    b) The individual has freckling in the axillary or inguinal regions.

c) The individual has symptoms of NF1, but genetic test results for NF1 were negative.

8) For individuals 25 years and younger who have at least two hyperpigmented skin patches (café-au-lait macules), who have tested negative for *NF1* and *SPRED1* mutations, **and** for whom neither parent has diagnostic signs of NF1 (if known), genetic testing for CMMRD (*MLH1, MSH2, MSH6,* and *PMS2*) **MEETS COVERAGE CRITERIA** when **one** of the following risk factors is present:

   a) Risk factors in the patient include:

      i) Atypical café-au-lait macules (irregular borders and/or pigmentation).
      ii) Hypopigmented skin patches.
      iii) One or more pilomatricoma(s).
      iv) Agenesis of the corpus callosum.
      v) Non-therapy-induced cavernoma.
      vi) Multiple developmental vascular abnormalities (cerebral venous angiomas) in separate regions of the brain.

   b) Familial risk factors include:

      i) Consanguineous parents.
      ii) A genetic diagnosis of Lynch syndrome in one or both of the parental families.
      iii) A sibling with diagnostic NF1 sign(s).
      iv) A sibling, living or deceased, with any type of childhood malignancy.
      v) A first- or second-degree relative (see Note 1) diagnosed before the age of 60 years with one of the following carcinomas from the Lynch syndrome spectrum: colorectal cancer, endometrial cancer, ovarian cancer, gastric cancer, small bowel cancer, cancer of the bile duct or gall bladder, pancreatic cancer, or urothelial cancer.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

9) For all other situations not meeting the criteria outlined above, genetic testing for neurofibromatosis **DOES NOT MEET COVERAGE CRITERIA**

NOTES:

Note 1: Close blood relatives include 1st-degree relatives (e.g., parents, siblings, and children), 2nd-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews,

grandchildren, and half-siblings), and 3rd-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins), all of whom are on the same side of the family.

Note 2: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AACR	American Association for Cancer Research
AAP	American Academy of Pediatrics
ACMG	American College of Medical Genetics and Genomics
BVS	Bilateral vestibular schwannoma
C4CMMRD	Care for constitutional mismatch repair deficiency
CALM	Café au lait macule
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMMRD	Constitutional mismatch repair deficiency
CMS	Centers for Medicare and Medicaid Services
EANO	European Association of Neuro-Oncology
EVH1	*Enabled/vasodilator-stimulated phosphoprotein homology 1*
FDA	Food and Drug Administration
LDT	Laboratory-developed test
LZTR1	*Leucin-zipper-like transcriptional regulator 1*
MMR	Measles, mumps, and rubella
MRI	Magnetic resonance imaging
NCCN	National Comprehensive Cancer Network
NF1	Neurofibromatosis type 1
NF2	Neurofibromatosis type 2
NGS	Next-generation sequencing
NSD	Noonan spectrum disorders
SMARCB1	*SWI/SNF related, matrix associated, actin dependent regulator of chromatin, subfamily B, member 1*
SPRED1	*Sprout-Related EVH1 Domain-Containing Protein 1*
sVS	Sporadic vestibular schwannoma
VS	Vestibular schwannoma

V. Scientific Background

Neurofibromatosis type 1

Neurofibromatosis type 1 is relatively common, affecting approximately one in 3,000 individuals (Korf et al., 2024). Almost half of these cases are *de novo* mutations, resulting from the unusually high (~1:10,000) mutation rate in the *NF1* tumor suppressor gene primarily in paternally derived chromosomes (Stephens et al., 1992).

The GTPase protein product of the *NF1* gene, neurofibromin, is expressed in many tissues, including brain, kidney, spleen, and thymus leading to a wide spectrum of clinical manifestations. NF1 typically presents as café-au-lait macules, followed by axillary and/or inguinal freckling, and later Lisch nodules (iris hamartomas), and neurofibromas (Korf et al., 2024). Ocular, neurologic, musculoskeletal, vascular, cardiac, and malignant manifestations have been reported (Hirbe & Gutmann, 2014).

NF1 mutations are highly penetrant and inherited dominantly; however, NF1 is variably expressed resulting in significant clinical variability, not only between unrelated individuals and among affected individuals within a single family but even within a single person with NF1 at different times in life (Friedman, 2023). Despite thousands of *NF1* mutations identified, few genotype/phenotype correlations have been observed (Shofty et al., 2015). Recent reports indicate the growing utility of next generation sequencing to provide solutions for problems like genetic heterogeneity, overlapping clinical manifestations, or the presence of mosaicism, and interactions between *SPRED1* and neurofibromin provide functional insight that will help in the interpretation of pathogenicity of certain missense variants identified in NF1 and Legius syndrome patients (Fisher et al., 2018).

NF1 is diagnosed clinically using the criteria developed by the National Institutes of Health (NIH, 1988), which are both highly specific and sensitive in all but very young children. Approximately 46% of sporadic NF1 cases fail to meet the NIH Diagnostic Criteria by one year of age. Nearly all (97%; 95% confidence interval: 94-98) NF1 patients meet the criteria for diagnosis by eight years old, and all do so by 20 years old (DeBella et al., 2000).

Molecular testing for NF1 includes sequencing of all the coding exons as well as deletions/rearrangements due to the large size of the gene and the heterogeneity of mutations. reported identification of the causative DNA mutation in 64 of 67 patients with a clinical diagnosis of NF1. Korf et al. (2024) states that molecular testing is reported to identify approximately 95 percent of causative mutations. However, a positive *NF1* mutation test does not predict the severity or complications of the disorder (Korf et al., 2024).

Molecular genetic testing is indicated for individuals in whom NF1 is suspected but who do not fulfill the NIH diagnostic criteria (Friedman, 2023). Additionally, there is increasing use of genetic testing in the diagnosis of NF1 for patients who meet only these two NIH criteria; moreover, individuals with only one NIH criterion as a positive genetic test may shorten the period of diagnostic uncertainty, allowing the initiation of appropriate screening evaluations (Korf et al., 2024). Further examples of clinical utility that justify molecular testing include: a young child with a serious tumor (e.g., optic glioma) in whom establishing a diagnosis of NF1 immediately would affect management, an adult with NF1 if prenatal or preimplantation genetic diagnosis in a current or future pregnancy is anticipated (Friedman, 2023).

Prenatal testing is available through direct mutation testing of fetal DNA taken from CVS or from amniocentesis to diagnose *NF1* pathogenic variants in the fetus. An additional option is assessing DNA markers in families with two or more affected individuals; however, many partners do not perform a prenatal assessment because of "the inability to determine disease severity" in the fetus (Ferner et al., 2007). Because the time for prenatal diagnosis is limited, it is common for families to detect pathogenic *NF1* alleles through linkage analysis as a more "rapid and useful" method for diagnosis (Terzi et al., 2009). Additionally, detection of pathogenic *NF1* mutations can be complex and challenging because of wide phenotypic variability and an absence of genotype-phenotype correlation (Terzi et al., 2009).

Preimplantation genetic diagnosis is also available to assist individuals who want to avoid a later termination of a pregnancy. Preimplantation genetic diagnosis occurs using cells removed from an embryo (available at the approximately 3-day mark of embryo development). This helps individuals determine which embryos do not carry the NF1 mutation in order to transfer unaffected embryos for implantation. Additionally, NF1 experts recommend that all NF1 pathogenic mutation affected individuals should receive genetic counseling prior to conception (Ferner et al., 2007).

Lastly, some rare variants of NF1, including spinal NF1, are known to produce a phenotype in which affected individuals may not meet the NIH diagnostic criteria. In this case, molecular testing is indicated for at-risk relatives (Burkitt-Wright et al., 2013).

Neurofibromatosis type 2

Neurofibromatosis type 2 refers to what was originally thought to be a rare subtype of neurofibromatosis type 1, but rather is a distinct entity, both genetically and clinically (Evans, 2023b). It is characterized by bilateral vestibular schwannomas with associated symptoms of tinnitus, hearing loss, and balance dysfunction resulting from mutation in the *NF2* gene. Affected individuals may also develop schwannomas of other cranial and peripheral nerves, meningiomas, ependymomas, and, very rarely, astrocytomas.

Typical age of onset is 18 to 24 years, with almost all affected individuals developing bilateral schwannomas by the age of 30 (Evans, 2023b). The prevalence is about 1:60,000 with a birth incidence of 1:33,000 (Evans et al., 2010). Skin tumors and ocular findings often are the first manifestations and have been underrecognized in children (Ruggieri et al., 2005).

The protein encoded by the *NF2* gene, merlin or schwannomin, is a cell membrane-related tumor suppressor (Evans, 2023b). Inactivation of both alleles is necessary for tumor development. Variable expressivity of *NF2* results in varying size, location, and number of tumors. Despite that these tumors are not malignant, their number and anatomical location contribute significantly to morbidity and mortality with the average age of death being 36 (Baser et al., 2002). However, advances in molecular diagnosis, imaging, and treatment of NF2-associated tumors have resulted in lower mortality (Hexter et al., 2015).

Clinical criteria for NF2 were initially established with those for *NF1* (NIH, 1988), and they were modified as the Manchester criteria to include molecular diagnostics and increase specificity without affecting sensitivity (Evans, 2023b). Most recently, the identification of *LZTR1* as a cause of schwannomatosis reduces the specificity of these more inclusive criteria and even the presence of bilateral VS is now no longer sufficient to be certain that an individual has NF2 (Smith et al., 2017), resulting in further modification of the Manchester criteria.

Detailed molecular testing is reported to identify mutations in NF2 in 93% of families with multiple members affected by NF2 (Evans, 2023b). Early diagnosis of individuals with NF2 facilitates treatment and reduction of mortality (Hexter et al., 2015); however, genetic testing and management is complicated by the well-documented risk of mosaicism (Evans et al., 2012). More so than with *NF1*, the stronger genotype/phenotype correlations in mutations of NF2 (Baser et al., 2004; Baser et al., 2005), high frequency of de novo mutations, and presentation of patients before clinical diagnostic criteria are fulfilled have provided a stronger rationale for the clinical utility of molecular testing than for *NF1*.

Molecular testing approaches can differ for NF2 based on the clinical picture. Patients with the distinctive phenotypic and laboratory findings suggestive of NF2 are likely to be diagnosed using gene-targeted testing (75%), whereas those where the diagnosis of NF2 has not been considered or had met the diagnostic criteria (such as children) are diagnosed after exome sequencing (Evans, 2023a).

Schwannomatosis

Schwannomatosis is an uncommon form of neurofibromatosis characterized by predisposition to develop multiple schwannomas and, less frequently, meningiomas. Its estimated prevalence is 1:70,000 (Dhamija et al., 2018) but is thought to be underestimated (Koontz et al., 2013). Although there is clinical overlap with NF2, schwannomatosis is caused by the concomitant mutational inactivation of two or more tumor suppressor genes. Germline mutations of either the *SMARCB1* or *LZTR1* tumor suppressor genes have been identified in 86% of familial and 40% of sporadic schwannomatosis patients (Kehrer-Sawatzki et al., 2017). *LZTR1* encodes leucin-zipper-like transcriptional regulator 1 and *SMARCB1* (also known as INI1) encodes a subunit of the SWI/SNF chromatin remodeling complex, and both act as tumor suppressors. Biallelic inactivation of these tumor suppressor genes leads to schwannomatosis (Radhika Dhamija, 2023).

The median age of symptom onset is 30 years with pain being the most common presenting symptom in 57 percent of patients. In others (41 percent), a mass was the presenting symptom (Merker et al., 2012). Other symptoms reported at presentation vary based on the location of the tumors, but they can include focal numbness, weakness, and muscle atrophy (Bergner & Yohay, 2024). Peripheral and spinal schwannomas are common in schwannomatosis patients. Severe pain is difficult to treat in these patients and often associated with anxiety and depression (Merker et al., 2012).

Diagnostic criteria for schwannomatosis was first set forth by MacCollin et al. (2005) but has been revised with the addition of molecular diagnostic criteria (Plotkin et al., 2013). More recently combined clinical and molecular criteria from Kehrer-Sawatzki et al., have been proposed (Kehrer-Sawatzki et al., 2017).

"A combined molecular and clinical diagnosis may be made with ≥ 2 tumors with 22q LOH and different somatic *NF2* mutations AND ≥ 2 pathologically confirmed schwannomas or meningiomas"

OR

"Germline *SMARCB1* or *LZTR1* pathogenic mutation AND one pathologically confirmed schwannoma or meningioma"

"A strictly clinical diagnosis may be made with ≥ 2 nonintradermal schwannomas, one pathologically confirmed and no bilateral vestibular schwannoma by high quality MRI (some mosaic NF2 patients will be included in this diagnosis at a young age and some schwannomatosis patients may have unilateral vestibular schwannomas or meningiomas)"

OR

"One pathologically confirmed schwannoma or intracranial meningioma AND an affected first degree relative."

Exclusion criteria for schwannomatosis are as follows:

- Germline pathogenic *NF2* mutation
- First degree relative with NF2
- Fulfillment of diagnostic criteria for NF2
- If schwannomas occur exclusively in a region of previous radiation therapy (Kehrer-Sawatzki et al., 2017)

Kehrer-Sawatzki et al. (2017) also recommended, "Comprehensive mutation analysis of all three genes, *LZTR1*, *SMARCB1,* and *NF2,* in patients with schwannomatosis should be performed to identify the complete mutational spectra and the number of mutational hits that affect these genes. This comprehensive testing may help to classify the tumors according to their mutation-profile. The mutation analysis should also include methods, such as next-generation sequencing, which are well suited to detect somatic mosaicism with mutant cells present in low proportions. This approach should identify tumor heterogeneity and help to distinguish between mosaic NF2 and schwannomatosis, since some NF2 patients with somatic mosaicism for an *NF2* gene mutation fulfil the diagnostic criteria for schwannomatosis" (Kehrer-Sawatzki et al., 2017).

Legius Syndrome

Legius syndrome has similar clinical features to NF1 such as the café-au-lait macules, but does not have the neurofibromas or central nervous system tumors. Furthermore, the primary genetic alteration in Legius syndrome is the sprouty-related EVH1 [enabled/vasodilator-stimulated phosphoprotein homology 1] gene (*SPRED1*) compared to *NF1* for neurofibromatosis 1.

A negative *NF1* mutation test in patients with only café-au-lait macules and axillary freckling should be tested for *SPRED1* mutations followed by the four mismatch repair genes as Legius syndrome, constitutional mismatch repair-deficiency (CMMR-D) syndrome, and Noonan syndrome may present with these indications (Korf et al., 2024).

CMMR-D

Constitutional mismatch repair-deficiency syndrome (CMMR-D) has similar clinical symptoms to neurofibromatosis 1 but leads to different malignancies. Hematologic

malignancies develop in infancy to early childhood, brain tumors (such as glioblastoma) may present in mid-childhood, and colorectal cancer may show up in adolescence or young adulthood (Korf et al., 2024). CMMR-D is a childhood cancer predisposition syndrome that is caused by biallelic pathogenic variants in one of four mismatch repair genes (Hizuka et al., 2021). Individuals with this syndrome may develop hematologic or colorectal malignancies in addition to the neurofibromas seen in NF1 patients (Korf et al., 2024).

One important characteristic of CMMR-D is that it is typically diagnosed in childhood. The Federal Food, Drug, and Cosmetic Act (FD&C Act) defines pediatric patients as persons aged 21 or younger at the time of their diagnosis or treatment and the *Bright Futures* guidelines from the American Academy of Pediatrics identify adolescence as 11 to 21 years of age, dividing the group into early (ages 11–14 years), middle (ages 15–17 years), and late (ages 18–21 years). CMMR-D is most often diagnosed before the age of 18. One collaborative review from the European consortium established the ages of first diagnosis as ranging from 0.4 to 39 years. However, the "vast majority" of patients are diagnosed with a first malignancy before the age of 18 (82% diagnosed before age 18) (Wimmer et al., 2014).

Clinical Utility and Validity

Neurofibromatosis type 1

Giugliano et al. (2019) investigated the clinical and genotypic associations in children with pigmentary features characteristic of a neurocutaneous condition, such as neurofibromatosis type 1. A group of 281 patients were included, with 150 definitively diagnosed with NF1, 95 presenting with only pigmentary features such as café au lait macules (CALMs), and 36 presenting with a clinical suspicion of another "RASopathy" (a condition caused by mutations in the MAPK pathway) or other neurocutaneous disorder. The authors identified the causative pathogenic variant in 239 of 281 cases (leaving 42 undiagnosed). Of the patients diagnosed with NF1, mutations were detected in 98% of cases (147/150) but in patients with only pigmentary features, the detection rate fell to 69.5% (66/95), with *SPRED1* accounting for eight of those cases. In patients presenting with a separate neurocutaneous condition, mutation detection rate was found to be 72.2% (26/36), with pathogenic variants found in 10 genes such as PTPN11. The authors recognized the difficulty of diagnosing these neurocutaneous and concluded that a "combined NGS-based approach can assist clinicians in the diagnosis of NF1 as well as other neurocutaneous disorders and overlapping conditions" (Giugliano et al., 2019).

Castellanos et al. (2020) developed a custom next-generation sequencing (NGS) panel for testing patients with "a clinical suspicion of a RASopathy (n = 48) and children

presenting multiple CALMs [café-au-lait macules] (n = 102)". The authors stated that phenotypic overlaps may exist in children if multiple CALMs are the only clinical symptom present and that genetic testing may differentiate between conditions. Of the 48 patients with clinical suspicion of a RASopathy, 21 were found to harbor a pathogenic mutation (with *NF1* mutations comprising five of 48 cases). Of the patients with multiple CALMs, both *NF1* and *SPRED1* pathogenic mutations were identified. Overall, the authors concluded that "an NGS panel strategy for the genetic testing of these two phenotype-defined groups outperforms previous strategies" (Castellanos et al., 2020).

Witkowski et al. (2020) studied the benefits of adding *NF1* and *SPRED1* sequencing to the Noonan spectrum/ RASopathy NGS panel. Noonan spectrum disorders (NSD) are a group of disorders caused by problems in the MAPK pathway. NSD's are due to gain of function, while NF1 is caused by a loss of function. The study included 28 patients with a negative NSD panel that underwent *NF1* and *SPRED1* sequencing, and a validation panel analyzed 14 RASopathy associated genes in 505 patients. In total, 21% of the 28 patients had disease-causing *NF1/SPRED1* variants. In the validation cohort, only 2% of the patients were found to have disease-causing variants in the *NF1/SPRED1* genes. Adding *NF1* and *SPRED1* to the panel increased the diagnostic yield from 23.5% to 25.7%. The authors concluded that "adding the *NF1* and *SPRED1* genes to Noonan spectrum disorder/RASopathy NGS gene panels modestly increases clinical diagnoses" (Witkowski et al., 2020).

In a retrospective study, Elmas (2022) studied the use of artificial intelligence, Face2Gene, to diagnosis neurofibromatosis type 1. Fourteen patients underwent Face2Gene analysis. As a result, the most detected mutation type was nonsense mutation (42.8%) and suggested NF1 diagnosis for 10 of the 14 patients. The authors concluded that Face2Gene will be used a lot in the routines of medical doctors in the next 10 years (Elmas, 2022).

Neurofibromatosis type 2

Evans et al. (2015) investigated the clinical validity of the primary development of NF2, the bilateral vestibular schwannoma (BVS). The authors observed that out of a database of over 1200 patients, approximately 25% of them over 50 developed a BVS without any other clinical features of NF2. Over 50% of the patients over 70 developed a BVS as well. This lack of other clinical features in addition to the BVS led the authors to suggest that these developments of a BVS were due to chance rather than an NF2 mutation (Evans et al., 2015).

Pathmanaban et al. (2017) analyzed the database of the Manchester Centre for Genomic Medicine to determine the frequency of the known heritable meningioma- or

schwannoma-predisposing mutations in children and young adults presenting with a solitary meningioma or schwannoma. They found that "A significant proportion of young people with an apparently sporadic solitary meningioma or schwannoma had a causative predisposition mutation. This finding has important clinical implications because of the risk of additional tumors and the possibility of familial disease. Young patients presenting with a solitary meningioma or schwannoma should be referred for genetic testing" (Pathmanaban et al., 2017).

Castellanos et al. (2018) recently demonstrated the clinical utility of a careful dermatological inspection and the correct identification of skin plaques in children for an early diagnosis of NF2. Skin plaques from seven patients (four male and three female) were analyzed and histologically characterized as plexiform schwannomas. Genetic analysis of primary Schwann cell cultures derived from them allowed the identification of a constitutional and a somatic NF2 mutation. Genetic testing allowed the early diagnosis of NF2 in a child only exhibiting the presence of skin plaques. Most of the patients with NF2 analyzed had an early presentation of skin plaques and a severe NF2 phenotype. The authors remarked that "Dermatological identification of skin plaque schwannomas in children would facilitate the early diagnosis and treatment of patients with NF2 before development of severe adverse effects" (Castellanos et al., 2018).

A genetic severity score has recently been developed to draw these factors together to enable genotypic data to be routinely factored into clinical and research use. This UK NF2 Genetic Severity Score classifies patients into three categories, which are tissue mosaic (1), classic (2), and severe (3). Within each category are subcategories, which consists of the following in increasing severity: presumed tissue mosaicism (1A), confirmed tissue mosaicism (1B), mild NF2 (2A), moderate NF2 (2B), and severe NF2 (3). These categories are separated by severity of mutation shown below (Halliday et al., 2017).

Genetic Severity	Sub-category	Clinical Characteristics	Definition
1 (Tissue Mosaic)	1A	Presumed tissue mosaicism	Meets clinical criteria for sporadic NF2 but not confirmed molecularly with identical NF2 mutations detected in two separate tissue samples
	1B	Confirmed tissue mosaicism	Mosaic NF2 confirmed molecularly with identical NF2 mutations detected in two or more separate tissue samples

2 (Classic)	2A	Mild NF2	Full or mosaic *NF2* mutation identified in blood excluding those found in group 2B or 3: missense mutations; in-frame deletions and duplications; deletions involving the promoter region or exon 1; splice site mutations in exons 8–15; truncating mutations of exon 1; mosaicism in blood for mutations other than truncating mutations in exons 2–13 Inherited NF2 but no *NF2, SMARCB1* or *LZTR1* mutation identified in blood
	2B	Moderate NF2	Full or mosaic NF2 mutation identified in blood including: splicing mutation involving exons 1–7; large deletion not including the promoter or exon 1; truncating mutations in exons 14–15; mosaic in blood for a truncating mutation in exons 2–13
3 (Severe)	3	Severe NF2	Full *NF2* truncating mutation exons 2–13

Halliday et al. (2017) evaluated the validity of this score in 142 patients (63 in group 1, 35 in group 2, and 19 in group 3 with three with no mutation identified) More severe symptoms such as intracranial meningiomas, BVS, and spinal schwannomas, were more likely to be found in group 3 compared to group 1. For example, BVS and intracranial meningiomas were found in 100% and 94.7% of group 3 patients respectively, compared to 54% and 59% in group 1. Spinal meningiomas were found in 36.8% of group 3 patients compared to 15.3% of group 1, and schwannomas were found in 94.7% of group 3 patients compared to 48.3% of group 1. The authors concluded that "The biggest single factor that determines NF2 severity is the type of mutation, its position within the gene and the proportion of cells carrying it" (Halliday et al., 2017).

Lu et al. (2019) examined the efficacy and safety of bevacizumab for vestibular schwannomas (VS) in neurofibromatosis type 2. The authors included eight articles including 161 patients and 196 VS. The authors identified radiographic response in 41% of cases (termed "partial regression"), no change in 47% of cases, and tumor progression of 7% of cases. Bevacizumab treatment also resulted in hearing improvement in 20% of cases, stability in 69% of cases, and further hearing loss in 6% of cases. Bevacizumab toxicity was observed in 17% of cases, and surgical intervention

was needed in 11% of cases. Overall, the authors concluded that bevacizumab may "arrest" tumor progression and hearing loss in NF2 patients presenting with VS lesions but recommended judicious use of bevacizumab due to serious adverse events (Lu et al., 2019).

Schwannomatosis

Hutter et al. (2014) evaluated the proportion of schwannomatosis cases that come from mutations aside from the germline variants in *SMARCB1* and *LZTR1*. The authors performed whole exome sequencing on 23 patients with sporadic schwannomatosis (without *SMARCB1* mutations) and found only five *LZTR1* or *NF2* mutations. However, since the authors noted the reported frequency of *SMARCB1* mutations to be only 10% in sporadic schwannomatosis patients, they concluded that approximately 65% (or at least the "majority") of sporadic schwannomatosis mutations are caused by an unknown gene (Hutter et al., 2014).

Louvrier et al. (2018) performed targeted next generation sequencing (NGS) to investigate genetic differences between NF2, schwannomatosis, and meningiomatosis. The authors sequenced 196 patients (79 with NF2, 40 with schwannomatosis, 12 with meningiomatosis, and 65 with no clearly established diagnosis) for *NF2, SMARCB1, LZTR1, SMARCE1*, and *SUFU*. The NF2 and schwannomatosis results were as follows: "An NF2 variant was found in 41 of 79 NF2 patients (52%). *SMARCB1* or *LZTR1* variants were identified in 5/40 (12.5%) and 13/40 (~32%) patients in the schwannomatosis cohort. Potentially pathogenic variants were found in 12/65 (18.5%) patients with no clearly established diagnosis. A *LZTR1* variant was identified in 16/47 (34%) NF2/SMARCB1-negative schwannomatosis patients." The authors concluded that targeted NGS was a suitable strategy for identifying NFS mosaicism in blood and for investigation of these tumors (Louvrier et al., 2018).

Sadler et al. (2021) studied which germline pathogenic variants are associated with sporadic vestibular schwannoma (sVS) through genetic analysis of sVS cases of *NF2, LZTR1* and *SMARCB1* genes. NF2 variants were confirmed in 2% of the patients, *LZTR1* was found in 3% of the patients, and there were no pathogenic *SMARCB1* variants identified in this cohort. Therefore, the authors concluded that "loss of *NF2* function is a common event in sVS tumours and may represent a targetable common pathway in VS tumourigenesis. Earlier identification of patients with these syndromes can facilitate more accurate familial risk prediction and prognosis" (Sadler et al., 2021).

Piotrowski et al. (2022) studied the use of targeted massively parallel sequencing to diagnose multiple schwannomas. Thirty-five patients were enrolled in the study and massive parallel sequencing of *LZTR1, SMARCB1*, and *NF2* genomic loci was conducted. The study verified whether any other *LZTR1/SMARCB1/NF2* pathogenic variants could

be found in 16 cases carrying a *SMARCB1* constitutional variant in the 3′-untranslated region. "The 3′-UTR variants c.*17C>T and c.*82C>T showed pathogenicity. Two novel deep intronic *SMARCB1* variants, c.500+883T>G and c.500+887G>A were identified in two individuals. Further resequencing of chromosome 22q in individuals negative for PVs in the *SMARCB1/LZTR1/NF2* demonstrated five potential schwannomatosis-predisposing candidate genes (*MYO18B, NEFH, SGSM1, SGSM3*, and *SBF1*)." The authors conclude that noncoding *SMARCB1/LZTR1* variants are a molecular cause of schwannomatosis, hence it is essential to include them into the molecular diagnostic panel (Piotrowski et al., 2022).

VI. Guidelines and Recommendations

American Academy of Pediatrics (AAP)

In 2008, the AAP committee on genetics published guidelines on health supervision in children with NF1 (Hersh, 2008). The committee stated that genetic consultation and genetic testing should be considered to expedite a diagnosis when there is uncertainty regarding a definitive diagnosis of NF1. The committee also noted that "molecular testing also may represent an option in those instances when a couple in which one person has NF1 is seeking prenatal diagnosis."

This guideline was reaffirmed in 2017.

A Clinical Report from the AAP comments on the role of genetic testing for Neurofibromatosis Type 1. They state that genetic testing:

- "can confirm a suspected diagnosis before a clinical diagnosis is possible;"
- "can differentiate NF1 from Legius syndrome;"
- "may be helpful in children who present with atypical features;"
- "usually does not predict future complications; and"
- "may not detect all cases of NF1; a negative genetic test rules out a diagnosis of NF1 with 95% (but not 100%) sensitivity" (Miller et al., 2019).

American College of Medical Genetics and Genomics (ACMG)

In their guidelines detailing the care of adults with NF1, the ACMG noted that "In most cases, the diagnosis can be easily made based on a history, physical exam, and pedigree review and no additional imaging or NF1 genetic testing is needed". Furthermore, the ACMG stated that genetic testing can quickly establish a diagnosis for children thereby relieving anxiety, but this is not as significant an issue for adults (Stewart et al., 2018).

However, in the ACMG's guidelines for reporting of secondary findings in exome or genome sequencing, mutations in the *NF2* gene were recommended for return as secondary findings related to cancer phenotypes for both pathogenic and likely pathogenic variants (Miller et al., 2021).

European Association of Neuro-Oncology (EANO)

This EANO guideline on "diagnosis and treatment of vestibular schwannoma" comments on neurofibromatosis type 2, stating that NF2 "should be considered when an individual presents with a unilateral vestibular or other sporadic schwannoma at <30 years or meningioma at <25 years. Germline pathogenic variants can be identified in 1-10% of cases. NF2 should also be considered in older patients with two NF2 related tumors (Goldbrunner et al., 2020).

American Association for Cancer Research (AACR) Childhood Cancer Predisposition Workshop

The following recommendations were created based on expert review of the literature and discussion brought to this workshop.

NF1

- "A child who meets one or more clinical criterion should now have NF1 molecular genetic testing (sequencing and deletion/duplication analysis) offered to confirm if NF1 is the correct diagnosis." Genetic testing is especially recommended in children fulfilling only pigmentary features of the criteria.

The clinical diagnostic criteria are as follows:

- Six or more CAL macules, the greatest diameter of which is more than five mm in prepubertal patients and more than 15 mm in post-pubertal patients
- Two or more neurofibromas of any type, or one plexiform neurofibroma
- Axillary or inguinal freckling
- Optic glioma
- Two or more Lisch nodules
- A distinctive osseous lesion such as sphenoid dysplasia or pseudarthrosis
- A first-degree relative with NF1 according to the preceding criteria

The guidelines note that according to the NIH, two or more of these criteria must be present. This contrasts with their own guidelines' statement of only requiring one clinical criterion.

The guidelines summarize their genetic testing recommendations as follows:

- "Children considered at risk of NF1 especially with 6+ CAL macules or diagnosed with NIH criteria should ideally have genetic testing of the *NF1* gene with an RNA-based approach and testing of *SPRED1* if pigmentary features only".
- "Those testing negative should be considered for a panel of genes including *GNAS, MLH1, MSH2, MSH6, NF2, PMS2, PTPN11, SOS1,* and *SPRED1* (if not already tested)" (Evans, Salvador, Chang, Erez, Voss, Schneider, et al., 2017).

NF2

- "All children presenting with either clear diagnostic criteria for NF2, including combined retinal hamartomas, or those with an NF2 tumor (any schwannoma/meningioma) presenting in childhood should undergo genetic testing of *NF2*, ideally in both blood and tumor if available in sporadic cases."

Schwannomatosis

- "Test for mutations in *SMARCB1* and *LZTR1* in children and young adults with one or more non-intradermal schwannoma, including those with VS (vestibular schwannoma) negative for NF2" (Evans, Salvador, Chang, Erez, Voss, Druker, et al., 2017).

European Consortium 'Care for CMMRD'

The C4CMMRD recommends further testing for patients reaching three points on the clinical scoring scale. "Further testing" generally follows the protocols for Lynch syndrome, which involves analysis of microsatellite instability or immunohistochemistry staining of the main mismatch repair proteins (MLH1, MSH2, MSH6 and PMS2). The clinical scoring scale is as follows (K. Wimmer et al., 2014):

Malignancies/premalignancies: one is mandatory; if more than one is present in the patient, add the points.

- Carcinoma from the LS spectrum* at age <25 years 3 points
- Multiple bowel adenomas at age <25 years and absence of APC/MUTYH mutation(s) or a single high-grade dysplasia adenoma at age <25 years 3 points
- WHO grade III or IV glioma at age <25 years 2 points
- NHL (non-Hodgkin's lymphoma) of T-cell lineage or sPNET (supratentorial primitive neuroectodermal tumour) at age <18 years 2 points
- Any malignancy at age <18 years 1 point

Additional features: optional; if more than one of the following is present, add the points

- Clinical sign of NF1 and/or ≥2 hyperpigmented and/or hypopigmented skin alterations Ø>1 cm in the patient 2 points
- Diagnosis of LS in a first-degree or second-degree relative 2 points
- Carcinoma from LS spectrum* before the age of 60 in first-degree, second-degree, and third-degree relative 1 point
- A sibling with carcinoma from the LS spectrum*, high-grade glioma, sPNET or NHL 2 points
- A sibling with any type of childhood malignancy 1 point
- Multiple pilomatricomas in the patient 2 points
- One pilomatricoma in the patient 1 point
- Agenesis of the corpus callosum or non-therapy-induced cavernoma in the patient 1 point
- Consanguineous parents 1 point
- Deficiency/reduced levels of IgG2/4 and/or IgA 1 point

*Colorectal, endometrial, small bowel, ureter, renal pelvis, biliary tract, stomach, bladder carcinoma (K. Wimmer et al., 2014).

The consortium in 2018 issued the selection strategy for CMMR-D testing as follows:

Prerequisites for testing are…

- "Suspicion of NF1 due to the presence of at least one diagnostic NF1 feature, including at least two hyperpigmented skin patches reminiscent of CALMs [café-au-lait macules]
- No *NF1* and *SPRED1* germline mutations detected using comprehensive and highly sensitive mutation analysis protocols.
- Absence of diagnostic NF1 sign(s) in both parents
- Additional features, at least one (either in the family or in the patient) is required
    - In the family
        - Consanguineous parents.
        - Genetic diagnosis of Lynch syndrome in one or both of the parental families.
        - Sibling with diagnostic NF1 sign(s).
        - A (deceased) sibling§ with any type of childhood malignancy.
        - One of the following carcinomas from the Lynch syndrome spectrum: colorectal cancer, endometrial cancer, ovarian cancer, gastric cancer, small bowel cancer, cancer of the bile duct or gall bladder, pancreatic cancer or urothelial cancer before the age of 60 years in first-degree or second-degree relative.
    - In the patient

- Atypical CALMs (irregular borders and/or pigmentation).
- Hypopigmented skin patches.
- One or more pilomatricoma(s) in the patient.
- Agenesis of the corpus callosum.
- Non-therapy-induced cavernoma.
- Multiple developmental vascular abnormalities (also known as cerebral venous angiomas) in separate regions of the brain.

This can be expanded to second-degree and third-degree relatives in populations with a high prevalence of founder mutations" (Suerink et al., 2019).

National Comprehensive Cancer Network (NCCN)

Within the Lynch Syndrome guidelines, the NCCN states, "For patients of reproductive age, advise about the risk of a rare recessive syndrome called CMMRD syndrome… If both partners are a carrier of a pathogenic variant(s) in the same MMR gene, then their future offspring will be at risk of having CMMRD syndrome" (NCCN, 2023).

International consensus group recommendation on neurofibromatosis type 1

An international consensus group revised diagnostic criteria for neurofibromatosis type 1 as well as sought to establish diagnostic criteria for Legius syndrome (Legius et al., 2021). The group involved global experts, advocacy groups, and patient input in a multistep process to establish criteria.

Diagnostic criteria for neurofibromatosis type 1:

> "A: The diagnostic criteria for NF1 are met in an individual who does not have a parent diagnosed with NF1 if two or more of the following are present:
>
> - Six or more café-au-lait macules over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
> - Freckling in the axillary or inguinal region
> - Two or more neurofibromas of any type or one plexiform neurofibroma
> - Optic pathway glioma
> - Two or more iris Lisch nodules identified by slit lamp examination or two or more choroidal abnormalities (CAs)—defined as bright, patchy nodules imaged by optical coherence tomography (OCT)/near-infrared reflectance (NIR) imaging

- A distinctive osseous lesion such as sphenoid dysplasia, anterolateral bowing of the tibia, or pseudarthrosis of a long bone
- A heterozygous pathogenic *NF1* variant with a variant allele fraction of 50% in apparently normal tissue such as white blood cells.

B: A child of a parent who meets the diagnostic criteria specified in A merits a diagnosis of NF1 if one or more of the criteria in A are present" (Legius et al., 2021).

Diagnostic criteria for Legius syndrome:

"A: The diagnostic criteria for Legius syndrome are met in an individual who does not have a parent diagnosed with Legius syndrome if the following CRITERIA are present:

- Six or more café-au-lait macules bilaterally distributed and no other *NF1*-related diagnostic criteria except for axillary or inguinal freckling
- A heterozygous pathogenic variant in *SPRED1* with a variant allele fraction of 50% in apparently normal tissue such as white blood cells

B: A child of a parent who meets the diagnostic criteria specified in A merits a diagnosis of Legius syndrome if one or more of the criteria in A are present" (Legius et al., 2021).

"The diagnostic criteria for mosaic NF1 are met in an individual if any of the following is present:

1. A pathogenic heterozygous *NF1* variant with a variant allele fraction of significantly less than 50% in apparently normal tissue such as white blood cells AND one other NF1 diagnostic criterion (except a parent fulfilling diagnostic criteria for NF1)
2. An identical pathogenic heterozygous *NF1* variant in two anatomically independent affected tissues (in the absence of a pathogenic *NF1* variant in unaffected tissue)
3. A clearly segmental distribution of café-au-lait macules or cutaneous neurofibromas AND
   a. Another NF1 diagnostic criterion (except a parent fulfilling diagnostic criteria for *NF1*)
   or
   b. Child fulfilling diagnostic criteria for NF1
4. Only one NF1 diagnostic criterion from the following list: freckling in the axillary and inguinal region, optic pathway glioma, two or more Lisch nodules or two or

more choroidal abnormalities, distinctive osseous lesion typical for NF1, two or more neurofibromas or one plexiform neurofibroma AND a child fulfilling the criteria for NF1"(Legius et al., 2021).

"The diagnostic criteria for mosaic Legius syndrome are met in an individual if any of the following is present:

1. A heterozygous pathogenic *SPRED1* variant with a variant allele fraction of significantly less than 50% in apparently normal tissue such as white blood cells AND six or more café-au-lait macules
2. An identical pathogenic heterozygous *SPRED1* variant in two independent affected tissues (in the absence of a pathogenic *SPRED1* variant in unaffected tissue)
3. A clearly segmental distribution of café-au-lait macules AND a child fulfilling the criteria for Legius syndrome" (Legius et al., 2021).

International consensus group recommendation on neurofibromatosis type 2 and schwannomatosis

The international consensus group also provided new recommendations on the nomenclature of NF2 and schwannomatosis. Traditionally, NF2 and SWN were identified based on primarily clinical features; however, the group's consensus is that the "phenotype of these diseases spans a continuum without absolute delineation of subtypes phenotypically" leading to the need for an umbrella (Plotkin et al., 2022). The group chose the term "schwannomatosis" (i.e. as the umbrella term) to showcase the overlapping clinical phenotype of related conditions. Additionally, the group recommended that the type of SWN be further classified based on the gene that harbors a PV (identified through molecular analysis). According to this nomenclature, NF2 would be renamed "NF2-related schwannomatosis" and SWN would fall as either "SMARCB1-related schwannomatosis," "LZTR1-related schwannomatosis," or "22q-related schwannomatosis," depending on the location of the inherited pathogenic. For patients who have clinical features of NF2/SWN but have not had molecular analysis, the group recommends "schwannomatosis-not otherwise specified" as the type categorization or "schwannomatosis-not elsewhere classified" for patients in whom molecular analysis did not successfully detect a PV variant (Plotkin et al., 2022).

Updated diagnostic criteria for NF2-related schwannomatosis:

"A diagnosis of NF2-related schwannomatosis (previously termed neurofibromatosis 2, NF2) can be made when an individual has one of the following:

1. Bilateral vestibular schwannomas (VS)

2. An identical *NF2* pathogenic variant in at least 2 anatomically distinct NF2-related tumors (schwannoma, meningioma, and/or ependymoma). (Note: if the variant allele fraction (VAF) in unaffected tissues such as blood is clearly <50%, the diagnosis is mosaic NF2-related schwannomatosis)
3. Either 2 major or 1 major and 2 minor criteria as described in the following:

Major criteria:

- Unilateral VS
- First-degree relative other than sibling with NF2-related schwannomatosis
- 2 or more meningiomas (Note: single meningioma qualifies as minor criteria).
- *NF2* pathogenic variant in an unaffected tissue such as blood (Note: if the VAF is clearly <50%, the diagnosis is mosaic NF2-related schwannomatosis)"

Minor criteria:

Can count >1 of a type (e.g., 2 distinct schwannomas would count as 2 minor criteria)

- Ependymoma, meningioma (Note: multiple meningiomas qualify as a major criteria), schwannoma (Note: if the major criterion is unilateral VS, at least 1 schwannoma must be dermal in location)

Can count only once (e.g., bilateral cortical cataracts count as a single minor criterion)

- Juvenile subcapsular or cortical cataract, retinal hamartoma, epiretinal membrane in a person aged <40 years, meningioma" (Plotkin et al., 2022).

"Pattern of genetic changes in unaffected and tumor tissue in *NF2*-related schwannomatosis"

Gene locus	Unaffected Tissue	Tumor 1	Tumor 2	Comment
NF2				
Allele 1	PV1	PV1	PV1	Shared *NF2* pathogenic variant
Allele 2	WT	LOH or *NF2* or PV2	LOH or *NF2* or PV3	Tumor-specific partial loss of 22q in trans position or a different *NF2* somatic second PV in every anatomically unrelated tumor"(Plotkin et al., 2022)

Diagnostic criteria for *SMARCB1*- and *LZTR1*-related schwannomatosis

"A diagnosis of *SMARCB1*- or *LZTR1*-related schwannomatosis can be made when an individual meets 1 of the following criteria:

- At least 1 pathologically confirmed schwannoma or hybrid nerve sheath tumor and a *SMARCB1* (or *LZTR1*) pathogenic variant in an unaffected tissue such as blood
- A shared *SMARCB1* or *LZTR1* pathogenic variant in 2 schwannomas or hybrid nerve sheath tumors" (Plotkin et al., 2022).

"Pattern of genetic changes in unaffected and tumor tissue in *SMARCB1*- and *LZTR1*-related schwannomatosis"

Gene locus	Unaffected Tissue	Tumor 1	Tumor 2	Comment
SMARCB1/LZTR1				
Allele 1	PV1	PV1	PV1	Shared *SMARCB1* or *LZTR1* pathogenic variant
Allele 2	WT	LOH	LOH	Tumor-specific partial loss of 22q in trans position, LOH typically entails deletion of 22q region encompassing *LZTR1/SMARCB1/NF2*"(Plotkin et al., 2022).

Gene locus	Unaffected Tissue	Tumor 1	Tumor 2	Comment
NF2				
Allele 1	WT	PV2	PV3	Tumor-specific pathogenic *NF2* variant in cis to pathogenic *SMARCB1* variant
Allele 2	WT	LOH	LOH	Tumor-specific partial loss of 22q in trans position, LOH typically entails deletion of 22q region encompassing *LZTR1/SMARCB1/NF2*"(Plotkin et al., 2022).

Diagnostic criteria for 22q-related schwannomatosis

"A diagnosis of 22q-related schwannomatosis can be made when an individual does not meet criteria for *NF2*-related schwannomatosis, *SMARCB1*-related schwannomatosis, or *LTZR1*-related schwannomatosis, does not have a germline *DGCR8* pathogenic variant, and has both of the following molecular features:

- LOH of the same chromosome 22q markers in 2 anatomically distinct schwannomas or hybrid nerve sheath tumors and
- A different *NF2* pathogenic variant in each tumor, which cannot be detected in unaffected tissue" (Plotkin et al., 2022).

"Pattern of genetic changes in unaffected and tumor tissue in 22q-related schwannomatosis"

Gene locus	Unaffected Tissue	Tumor 1	Tumor 2	Comment
SMARCB1/ LZTR1				
Allele 1	WT	None found	None found	No shared pathogenic *LZTR1* or *SMARCB1* variant
Allele 2	WT	LOH	LOH	Tumor-specific partial loss of the same chromosome 22q, LOH typically entails deletion of 22q region encompassing *LZTR1/SMARCB1/NF2"*(Plotkin et al., 2022)"

Gene locus	Unaffected Tissue	Tumor 1	Tumor 2	Comment
NF2				
Allele 1	WT	PV1	PV2	Tumor-specific pathogenic *NF2* variant trans to the 22q deletion
Allele 2	WT	LOH	LOH	Tumor-specific partial loss of the same chromosome 22q, LOH typically entails deletion of 22q region encompassing *LZTR1/SMARCB1/NF2"*(Plotkin et al., 2022)"

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-

database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81292	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81293	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81294	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81295	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81296	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81297	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81298	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81299	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81300	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81301	Microsatellite instability analysis (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) of markers for mismatch repair deficiency (eg,

	BAT25, BAT26), includes comparison of neoplastic and normal tissue, if performed
81317	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81318	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81319	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)
81408	Molecular pathology procedure, Level 9 (eg, analysis of >50 exons in a single gene by DNA sequence analysis)
81479	Unlisted molecular pathology procedure

Genetic Testing for Ophthalmologic Conditions

Policy Number: AHS – M2083 – Genetic Testing for Ophthalmologic Conditions	Prior Policy Name and Number, as applicable: • AHS – M2083 – Genetic Testing for Macular Degeneration
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Genetic eye diseases involve every part of the eye, including the visual system and ocular adnexa (accessory structures attached to the eye, such as the eyelids, extraocular muscles and orbits); conditions within this group of disorders may be rare or common, and they may exhibit a significant impact on vision or may not affect eyesight at all (Lee & Couser, 2016). Many genes involved in ophthalmologic disorders are now mapped and due to this, scientists have developed a greater understanding of how these genes influence vision and eye health (Singh & Tyagi, 2018).

II. Related Policies

Policy Number	Policy Title
AHS-M2144	Genetic Testing for Connective Tissue Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with clinical signs of an inherited retinal degeneration (see Note 1), single gene or multi-gene panel testing **MEETS COVERAGE CRITERIA.**

2) For individuals with clinical findings suggestive of other ophthalmologic disorders with a known causative gene(s) where identification of a genetic variant will affect clinical management, testing of the known causative gene(s) **MEETS COVERAGE CRITERIA.**

3) For individuals with retinal dystrophy, genetic testing of *RPE65* prior to treatment with Luxturna (voretigene neparvovec-rzyl) **MEETS COVERAGE CRITERIA** and **is required.**

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

4) Genetic testing for age-related macular degeneration **DOES NOT MEET COVERAGE CRITERIA**.

5) For individuals with ophthalmologic conditions, whole exome sequencing (WES) **and/or** whole genome sequencing (WGS) **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: The American Academy of Ophthalmology recommends genetic diagnostic testing for the four major types of inherited retinal degenerations (IRDs):

- Rod-cone degenerations (e.g., retinitis pigmentosa)
- Cone-rod degenerations (e.g., achromatopsia)
- Chorioretinal degenerations (e.g., CHM-associated retinal degeneration [choroideremia])
- Inherited dystrophies that involve the macula (e.g., *ABCA4*-associated macular degeneration [Stargardt disease])

Note 2: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AAO	American Academy of Ophthalmology
ABC1	*ATP binding cassette 1*
ABCA4	*ATP binding cassette subfamily A member 4*
ABCG1	*ATP binding cassette subfamily G member 1*
AGBL5	*AGBL Carboxypeptidase 5 gene*

AMD	Age-related macular degeneration
Anti-VEGF	Anti-vascular endothelial growth factor
AOA	American Optometric Association
APE1	*Apurinic/apyrimidinic endonuclease 1 gene*
AREDS	Age-Related Eye Disease Study
ARMS2	*Age-related maculopathy susceptibility 2 gene*
HTRA1	*HtrA Serine Peptidase 1 gene*
ASRS	American Society of Retina Specialists
BAP1	*BRCA1 associated protein 1 gene*
C2	*Complement C2 gene*
C3	*Complement C3 gene*
CALM2	*Calmodulin 2*
CAV1/2	Calcium channel, voltage-dependent, L type, alpha 1C subunit
CBS	*Cystathionine beta-synthase*
CDKN2A	*Cyclin dependent kinase inhibitor 2A gene*
CETP	*Cholesteryl ester transfer protein gene*
CF	Complement factor
CFB	Complement factor B
CFH	Complement factor H
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
C-MET	Tyrosine-protein kinase met
CMS	Centers for Medicare and Medicaid
CNGA1	*Cyclic nucleotide gated channel subunit alpha 1 gene*
COL8A1	*Collagen type VIII alpha 1 chain gene*
CRYAA	*Crystallin alpha A gene*
CRYBB2	*Crystallin beta B2 gene*
Cx50/GJA3 & 8	Connexin α8 (GJA8 or Cx50) and connexin α3
CYP1B1	*Cytochrome P450 family 1 subfamily B member 1 gene*
CYP2C19	Cytochrome P450 2C19
CYP51A1	*Cytochrome P450 family 51 subfamily a member 1 gene*
DDEF1	Development and differentiation enhancing factor 1
DNA	Deoxyribose nucleic acid
EIF1AX	*Eukaryotic translation initiation factor 1A X-Linked gene*
EPHA2	*Ephrin type-A receptor 2 gene*
ERN-EYE	European Reference Network for Rare Eye Diseases
EURETINA	European Society of Retina Specialists
FBN1	*Fibrillin 1 gene*
FDA	Food and Drug Administration

FGD6	*FYVE, rhoGEF and ph domain containing 6 gene*
FOXC1	*Forkhead box C1 gene*
GEMIN4	*Gem nuclear organelle associated protein 4 gene*
GNA11	*G protein subunit alpha 11 gene*
GNAQ	*G protein subunit alpha q gene*
HERC2	*HECT and RLD domain containing E3 ubiquitin protein ligase 2 gene*
HGF	*Hepatocyte growth factor gene*
HK1	*Hexokinase 1 gene*
IGF-1	*Insulin-like growth factor 1 gene*
IL-8	*Interleukin 8 gene*
IRDs	Inherited retinal degenerations
LCD	Local Coverage Determination
LDT	Laboratory-developed test
LOX1	*Lectin-type oxidized LDL receptor 1 gene*
LTBP2	*Latent transforming growth factor beta binding protein 2 gene*
MIP	*Major intrinsic protein of lens fiber gene*
MMP-1/2	*Matrix metalloproteinases 1/2 gene*
MMP-9	*Matrix metalloproteinase 9 gene*
MPP-7	*Membrane protein, palmitoylated 7*
MTHFR	*Methylenetetrahydrofolate reductase gene*
MTR	*5-Methyltetrahydrofolate-homocysteine methyltransferase*
MTRR	*5-Methyltetrahydrofolate-homocysteine methyltransferase reductase*
MVL	Molecular vision tests
MYOC	*Myocilin gene*
NAMD	Neovascular age-related macular degeneration
NGS	Next-gene sequencing
NOS2A	*Nitric oxide synthase 2A gene*
OCA2	*Oculocutaneous Albinism type 2 gene*
OPA1	*Optic atrophy 1 gene*
P14arf	ARF tumor suppressor
P4HA2	*Prolyl 4-Hydroxylase Subunit Alpha 2 gene*
PAX6	*Paired box 6 gene*
PCV	Polypoidal choroidal vasculopathy
PDE6A	*Phosphodiesterase 6A gene*
PDE6B	*Phosphodiesterase 6B gene*
PEDF	*Pigment epithelium-derived factor gene*
PITX2	*Paired like homeodomain 2 gene*
POLR3B	*Ribonucleic acid polymerase III subunit b gene*
PPFIA2	*PTPRF interacting protein alpha 2 gene*

PRPF3	*Pre-MRNA processing factor 3 gene*
PRPF31	*Pre-MRNA processing factor 31 gene*
PRPH2	*Peripherin 2*
PRX	*Periaxin gene*
PTEN	*Phosphatase and tensin homolog gene*
PTPRR	*Protein tyrosine phosphatase receptor type r gene*
RAD51B	*RAD51 paralog b gene*
RDH12	*Retinol dehydrogenase 12 gene*
RED	Rare eye diseases
RHO	*Rhodopsin gene*
RIC1	*RIC1 homolog, RAB6A GEF complex partner 1 gene*
RP	Retinitis pigmentosa
RP1	*RP1 axonemal microtubule associated gene*
RP2	*RP2 activator of ARL3 GTPase gene*
RPE65	*Retinal pigment epithelium-specific 65 gene*
RPGR	*Retinitis pigmentosa GTPase regulator gene*
SERPING1	*Serpin family g member 1 gene*
SF3B1	*Splicing factor 3b subunit 1 gene*
SLC16A8	*Solute carrier family 16 member 8 gene*
Snps	Single nucleotide polymorphisms
STGD	Stargardt Disease
TAF1A	*TATA-Box Binding Protein Associated Factor, RNA Polymerase I Subunit A gene*
TAPT1	*Transmembrane Anterior Posterior Transformation 1 gene*
TEK	*Tyrosine, kinase, endothelial gene*
TGFBR2	*Transforming growth factor beta receptor 2 gene*
TIE2	*TEK receptor tyrosine kinase gene*
TIMP3	*Tissue inhibitor of metalloproteinase 3 gene*
UMODL1	*Uromodulin Like 1 gene*
USH2A	*Usherin gene*
VEGF-A	*Vascular endothelial growth factor A gene*
VEGFR-2	*Vascular endothelial growth factor receptor 2 gene*
WDR87	*WD Repeat Domain 87 gene*
WES	Whole exome sequencing
WGS	Whole genome sequencing
XRCC1	*X-ray repair cross complementing 1 gene*
ZNF350	*Zinc finger protein 350 gene*

V. Scientific Background

Approximately 4,000 diseases or syndromes affect humans, and nearly one-third of these diseases are related to the eyes (Singh & Tyagi, 2018). Several ophthalmologic disorders may be inherited, including age-related macular degeneration, cataracts, glaucoma, inherited optic neuropathies, retinitis pigmentosa and Stargardt's disease (Singh & Tyagi, 2018). Early diagnoses, knowledge of family history and genetic testing can positively influence outcomes and treatment regimens. Inherited retinal diseases (IRDs) affect one in 1380 individuals; it is estimated 36% of healthy people could be considered carriers of at least one IRD-related mutation (Hanany et al., 2020).

Genetic testing for eye disorders is growing in popularity. Further, there is considerable overlap between the clinical phenotypes of many eye disorders, highlighting the importance of genetic testing to determine the cause and most effective treatment avenue (Sangermanoa et al., 2020). To date, genetic tests can identify dozens of ophthalmologic conditions (Stone et al., 2014), and panel tests are already used clinically for early-onset glaucoma, retinal dystrophies, inherited optic neuropathies and more (Wiggs, 2017). Further, many genes have been linked to various human eye diseases and disorders. Table 1 below, adapted from Singh and Tyagi (2018), lists genes and gene variants associated with ten different ophthalmologic conditions. However, it's also important to recognize that there is a broad clinical spectrum of disorders and many involved genes in IRD-related disorders. Over 270 genes have currently been associated with IRD and the number of genes and heterogeneity of disease is compounded by variations in familial inheritance patterns (García Bohórquez et al., 2021).

Ocular gene therapy shows promise for both inherited and acquired retinal pathologies. Adeno-associated viruses (AAVs) are the most common and leading platform used in retinal gene therapy. These vectors deliver gene-specific approaches to promote expression of a healthy copy of a disease-causing gene (Michalakis et al., 2021). A combination of factors has led to the adeno-associated virus method as the primary vector option for IRDs. First, AAVs have smaller risks of mutagenesis because they aren't integrated into the host genome. Second, they have low pathogenicity. Lastly, they can transfer genetic material to multiple retinal cell types (Avalyon, 2021).

Recent advancements in AAV ocular gene therapy have been effective in treating certain types of ophthalmologic conditions. For example, Luxturna – the first Food and Drug Administration approved ocular therapy – is a prescription gene therapy product used to treat patients with inherited retinal degenerations (IRDs) due to mutations in the *RPE65* (retinal pigment epithelium-specific 65) gene; however, genetic testing must first be used to determine a potential mutation in this gene (Luxturna, 2022). Therefore,

accurate genetic diagnoses have become imperative for some ophthalmologic treatments.

Other retinal conditions such as choroideremia, achromatopsia, X-linked retinitis pigmentosa, X-linked retinoschisis and AMD are among those being investigated as potential targets for gene therapies using AAVs. In addition, additional viral vectors and non-viral platforms are in the process of consideration because AAVs are limited in the amount of genetic information they can carry, that is, they cannot carry large therapeutic gene sets. For example, larger gene targets (such as the gene associated with Stargardt disease) present a barrier to AAV-specific gene therapy (Avalyon, 2021).

Table 1: Genes/gene variants linked with common human eye diseases/disorders (Singh & Tyagi, 2018)

Disease	Gene/variant	Age of disease or disorder onset
AMD (age-related macular degeneration)	*NOS2A, CFH, CF, C2, C3, CFB, HTRA1/LOC, MMP-9, TIMP-3, SLC16A8*, etc.	Old
Cataract	*GEMIN4, CYP51A1, RIC1, TAPT1, TAF1A, WDR87, APE1, MIP, Cx50/GJA3 & 8, CRYAA, CRYBB2, PRX, POLR3B, XRCC1, ZNF350, EPHA2,* etc.	Old
Glaucoma	*CALM2, MPP-7, Optineurin, LOX1, CYP1B1, CAV1/2, MYOC, PITX2, FOXC1, PAX6, CYP1B1, LTBP2*, etc.	Over 40 except congenital form that can affect an infant
Inherited optic neuropathies	*Complex I* or *ND* genes, *OPA1, RPE65*, etc.	Young males
Marfan syndrome	*FBN1, TGFBR2, MTHFR, MTR, MTRR*, etc.	Born with disorder but may not be diagnosed until later in life

Myopia	*HGF, C-MET, UMODL1, MMP-1/2, PAX6, CBS, MTHFR, IGF-1, UHRF1BP1L, PTPRR, PPFIA2, P4HA2,* etc.	Typically progresses until about age 20
Polypoidal choroidal vasculopathies	*C2, C3, CFH, SERPING1, PEDF, ARMS2-HTRA1, FGD6, ABCG1, LOC387715, CETP,* etc.	Between ages 50 and 65
Retinitis pigmentosa	*RPGR, PRPF3, HK1, AGBL5,* etc.	Between 10 and 30
Stargardt's disease	*ABC1, ABCA4, CRB1,* etc.	Signs may appear in early childhood to middle age
Uveal melanoma	*PTEN, BAP1, GNAQ, GNA11, DDEF1, SF3B1, EIF1AX, CDKN2A, p14ARF, HERC2/OCA2,* etc.	50 to 80

Age-Related Macular Degeneration (AMD)

Age-Related Macular Degeneration is caused by pathologic changes to the deeper retinal layers of the macula and surrounding vasculature, which can result in central vision loss. There are two main types of AMD: neovascular ("dry" AMD) and nonneovascular ("wet" AMD). Nonneovascular AMD accounts for 80-85% of all cases and generally carries a more favorable visual prognosis, whereas Neovascular AMD affects the remaining 15% to 20% and accounts for approximately 80% of severe vision loss (Thomas et al., 2021).

Age-Related Macular Degeneration is caused by a combination of genetic and environmental factors. The strongest genetic association is due to genes involved in complement pathways. For instance, a major polymorphism of complement factor H (CFH) and CFH related genes (*CFHR1*-5) may predispose an individual to AMD (Cipriani et al., 2020). This polymorphism (histidine in place of tyrosine on position 402, CFH Y402H) on chromosome 1 has been associated with higher risk of AMD. One copy of the polymorphism has been associated with a 2.4-4.6 times higher risk of developing AMD whereas both copies of the allele have been associated with a 3.3-7.4 times higher risk. Single nucleotide polymorphisms (SNPs) such as CYP2C19 (G681A) Rs4244285 and CYP1A2 (-163C>A) Rs762551 may also confer added risk for AMD (Stasiukonyte et al., 2017).

Proprietary Testing

Several genetic tests have been developed to identify ophthalmologic conditions. The MVL Vision Panel (v2) by Molecular Vision tests for 581 genes associated with vision-related inherited conditions (MolecularVision, 2023). GeneDx has developed a Glaucoma Panel which tests for 38 glaucoma-related genes (GeneDx, 2024). Invitae has developed the Inherited Retinal Disorders Panel which tests for 248 genes associated with inherited retinal disorders (Invitae, 2024). Blueprint Genetics has developed 25 different ophthalmology panels which test for over 3,900 genes collectively (Blueprint, 2020). Finally, Prevention Genetics has developed the Stargardt Disease and Macular Dystrophies Panel which tests for 28 relevant genes (PreventionGenetics, 2024).

Clinical Utility and Validity

Lenassi et al. (2019) studied the clinical utility of genetic testing in children with inherited eye disorders. A total of 201 children in preschool (aged 0-5) participated in this study; all participants underwent panel testing. This cohort included "74 children with bilateral cataracts, 8 with bilateral ectopia lentis, 28 with bilateral anterior segment dysgenesis, 32 with albinism, and 59 with inherited retinal disorders" (Lenassi et al., 2019). The diagnostic yield for this study was 64% with testing results leading to altered disease management in 33% of probands (Lenassi et al., 2019).

Fauser and Lambrou (2015) analyzed potential biomarker candidates that could be used in a clinical setting to predict response to anti-vascular endothelial growth factor (anti-VEGF) treatment of neovascular AMD (nAMD). SNPs from 39 publications were evaluated and divided into two categories; those associated with AMD pathogenesis and those targeted by anti-VEGF therapies. The authors found that several studies supported an association between anti-VEGF treatment response and two SNPs, CFH rs1061170 and VEGFA rs699947, but results from randomized controlled trials found no such association (Fauser & Lambrou, 2015).

Chew et al. (2014) determined whether genotypes at two major loci associated with late AMD, complement factor H (CFH) and age-related maculopathy susceptibility 2 (*ARMS2*), influenced the relative benefits of Age-Related Eye Disease Study (AREDS) supplements; the original AREDs formulation contained vitamins C and E, zinc, copper and beta-carotene. A total of 1237 AREDS participants, 385 with late AMD, were genotyped. Both *CFH* and *ARMS2* genotypes were noted to individually associate with progression to late AMD. However, the investigators found that the genotypes at the *CFH* and *ARMS2* loci did not significantly alter the benefits of AREDS supplements. The investigators concluded that "genetic testing remains a valuable research tool, but these analyses suggest it provides no benefits in managing nutritional supplementation for patients at risk of late AMD" (Chew et al., 2014).

Hagstrom et al. (2015) evaluated the pharmacogenetic relationship between genotypes of SNPs in the VEGF signaling pathway and response to treatment with ranibizumab or bevacizumab for nAMD. For each of the measures of visual equity evaluated, there was no association with any of the genotypes or with the number of risk alleles. The investigators concluded that there are no pharmacogenetic associations between the studied *VEGF-A* and *VEGFR-2* SNPs and response to anti-VEGF therapy (Hagstrom et al., 2015).

Cascella et al. (2018) aimed to characterize exudative AMD in the Italian population and to identify the susceptibility/protective factors (genetic variants, age, sex, smoking, and dietary habits) that are specific for the onset of disease. The study involved a cohort of 1976 subjects, including 976 patients affected with exudative AMD and 1000 control subjects who underwent genotyping analysis of 20 genetic variants known to be associated with AMD. This analysis revealed that eight genetic variants (*CFH, ARMS2, IL-8, TIMP3, SLC16A8, RAD51B, VEGFA* and *COL8A1*) were significantly associated with AMD susceptibility. Following a multivariate analysis, considering both genetic and non-genetic data available, age, smoking, dietary habits, and sex, together with the genetic variants, were significantly associated with AMD (Cascella et al., 2018).

Chen et al. (2020) completed a study of 2,343 Chinese and Japanese individuals including patients with neovascular age-related macular degeneration (nAMD), polypoidal choroidal vasculopathy (PCV) and healthy controls. PCV is a disease of the choroidal vasculature in the eye. The *TIE2* (tyrosine kinase, endothelial, *TEK*) gene was the main focus in this study. In the analysis of all participants, a SNP of the *TIE2* gene (rs625767) was significantly associated with nAMD and PCV (Chen et al., 2020).

Strunz et al. (2020) completed a transcriptome-wide association study that included data from 6,144 late-stage AMD cases and 17,832 healthy controls. A total of 10 genes were significantly associated with AMD variants in at least one tissue in this study (27 different human tissues were analyzed). The authors conclude by stating that "our study highlights the fact that expression of genes associated with AMD is not restricted to retinal tissue as could be expected for an eye disease of the posterior pole, but instead is rather ubiquitous suggesting processes underlying AMD pathology to be of systemic nature" (Strunz et al., 2020).

Pontikos et al. (2020) conducted a retrospective study of electronic records in families with molecularly characterized IRD, to investigate proportions with disease attributable to gene variants. It was found that depending on the inheritance pattern, different genes were more likely to be implicated; among all the genes encountered, *ABCA4* was most frequent, but when accounting for types of retinitis pigmentosa (RP), the autosomal recessive type was most frequently caused by *USH2A* whereas autosomal

dominant RP was most linked with *RHO, RP1, and PRPF31*. Additionally, many X-linked retinopathies were the result of variants in *RPGR* (about 40%). More families in the study's pediatric cohort were affected by variants in X-linked genes, likely a result of earlier onset and severity of X-linked pathologies and likelihood of earlier diagnoses. The researchers also noted a weak but statistically significant positive correlation with transcription lengths and number of families affected by eye conditions, as longer transcripts are more likely to contain loss of function or premature termination mutations (Pontikos et al., 2020).

Sheck et al. (2021) reported on the performance of a next-gene sequencing (NGS) panel of 176 retinal genes (NGS 176) in patients with IRD. Among 488 patients, a diagnostic yield of 59.4% was recorded, with younger children being more likely to receive a molecular diagnosis than older adults. The clinical diagnoses were also statistically significantly associated with the diagnostic yield after multivariate analyses. Homogeneous IRD phenotypes of achromatopsia and congenital stationary night blindness, which were associated with six and ten genes, respectively, had diagnostic yields of 100% and 94%, respectively. This study demonstrated the effectiveness of using a new sequencing panel in the UK, and other factors, like age and clinical diagnoses that could correlate with a higher diagnostic yield (Sheck et al., 2021).

García Bohórquez et al. (2021) investigated the genetic basis for IRD in 92 patients using two custom NGS panels. At the time of the study, there were 270 genes associated with IRD. Using NGS, the authors found: among 92 patients, 53 had known gene variants, in 12 patients there was just one mutation in a gene found with a known autosomal recessive pattern of inheritance, and 27 patients (29.3%) had zero specified or identified genes, representing "unsolved" cases. A total of 120 pathogenic or likely pathogenic instances were identified. The most common gene variant was *ABCA4*. The *USH2A* gene was the most frequently found gene amongst patients diagnosed with retinitis pigmentosa. Lastly, a total of 10 families had pathogenic variants in more than one IRD-related gene (García Bohórquez et al., 2021).

VI. Guidelines and Recommendations

American Academy of Ophthalmology (AAO)

In 2014, the American Academy of Ophthalmology (AAO) Task Force on Genetic Testing published recommendations for genetic testing of inherited eye diseases. The Task Force stated that standard clinical diagnostic methods like biomicroscopy, ophthalmoscopy, tonography, and perimetry will be more accurate for assessing a patient's risk of vision loss from a complex disease than the assessment of a small number of genetic loci. The authors also state that "skilled counseling should be provided to all individuals who undergo genetic testing to maximize the benefits and

minimize the risks associated with each test" (Stone et al., 2014). The recommendations include:

- "Offer genetic testing to patients with clinical findings suggestive of a Mendelian disorder whose causative gene(s) have been identified. If unfamiliar with such testing, refer the patient to a physician or counselor who is. In all cases, ensure that the patient receives counseling from a physician with expertise in inherited disease or a certified genetic counselor.
- Use Clinical Laboratories Improvement Amendments– approved laboratories for all clinical testing. When possible, use laboratories that include in their reports estimates of the pathogenicity of observed genetic variants that are based on a review of the medical literature and databases of disease-causing and non–disease-causing variants.
- Provide a copy of each genetic test report to the patient so that she or he will be able independently to seek mechanism-specific information, such as the availability of gene-specific clinical trials, should the patient wish to do so.
- Avoid direct-to-consumer genetic testing and discourage patients from obtaining such tests themselves. Encourage the involvement of a trained physician, genetic counselor, or both for all genetic tests so that appropriate interpretation and counseling can be provided.
- Avoid unnecessary parallel testing— order the most specific test(s) available given the patient's clinical findings. Restrict massively parallel strategies like whole-exome sequencing and whole-genome sequencing to research studies conducted at tertiary care facilities.
- Avoid routine genetic testing for genetically complex disorders like age-related macular degeneration and late-onset primary open-angle glaucoma until specific treatment or surveillance strategies have been shown in 1 or more published prospective clinical trials to be of benefit to individuals with specific disease-associated genotypes. In the meantime, confine the genotyping of such patients to research studies.
- Avoid testing asymptomatic minors for untreatable disorders except in extraordinary circumstances. For the few cases in which such testing is believed to be warranted, the following steps should be taken before the test is performed: (1) the parents and child should undergo formal genetic counseling, (2) the certified counselor or physician performing the counseling should state his or her opinion in writing that the test is in the family's best interest, and (3) all parents with custodial responsibility for the child should agree in writing with the decision to perform the test" (Stone et al., 2014).

In 2019, the AAO published the Age-Related Macular Degeneration Preferred Practice Pattern guidelines and state that "The primary risk factors for the development of

advanced AMD include increasing age, northern European ancestry, and genetic factors… The routine use of genetic testing is not recommended at this time" (AAO, 2019). In 2023, they reaffirmed that the AAO "does not currently recommend genetic testing for AMD" (Mukamal, 2021).

In 2022, the AAO published recommendations on clinical assessment of patients with inherited retinal degenerations (IRDs). These clinical guidelines state that "Genetic testing and genetic counseling are essential components of the management of patients with IRDs as genetic testing may confirm the diagnosis, provide information to optimize management of the patient and family members, and potentially confirm eligibility to participate in clinical trials." They also note that "genetic testing for patients with IRDs can take multiple forms, including single gene analyses, panel-based tests that include many IRD disease genes, or more expansive testing such as whole exome and whole genome sequencing. Because of the genetic heterogeneity of the other phenotypes (>80), next generation sequencing testing using a retinal dystrophy panel provides an efficient first step for genetic testing. Whether the patient has syndromic features or not, testing should include genes known to be associated with syndromic forms of retinal disease, since some patients may only show the syndromic features later. Some 'syndromic genes' can be associated with a non-syndromic retinal degeneration." AAO also reiterates the importance of genetic testing for gene therapy: "patients would need to have genetic testing to determine if they are eligible for the FDA-approved voretigene neparvovec or be considered for any of the numerous clinical trials of gene-based therapies" (AAO, 2022).

European Reference Network for Rare Eye Diseases (ERN-EYE)

The ERN-EYE released a position statement on the need for eliminating gaps in genetic testing, as collectively, rare eye diseases (RED) are the "leading cause of visual impairment and blindness for children and young adults in Europe." There are still critical gaps in the administration of genomic testing that need to be addressed, especially in Europe's smaller countries where no formal genomic testing pathways exist. However, the ERN-EYE emphasizes promoting access to genetic testing to RED and the clinical need and relevance of it with increasing evidence for clinical utility (Black et al., 2021).

American Society of Retina Specialists (ASRS)

The ASRS states that there is no clinical evidence that changing treatment based on genetic risk is beneficial to the patient. At present there is "insufficient data to support the use of genetic testing in patients with AMD prior to recommendation of current Age-Related Eye Disease Study (AREDS) nutritional supplement use" (Csaky et al., 2017).

Italian IRD Working Group

An interdisciplinary panel of IRD experts convened to discuss IRD. They established parameters surrounding eligibility for *RPE65*-associated IRD gene therapy. The working group published "a strong consensus" recommendation for the use of "a targeted multi-gene NGS approach, including all the genes known to be responsible for IRDs, both isolated and syndromic forms." The authors also specify that larger panels such as clinical exome or whole-exome sequencing may also be used. They write, "The use of a larger panel (i.e. either a clinical exome or a whole-exome sequencing) is not excluded but, due to the issue of possible incidental findings, requires a more careful pre-test counselling" (Sodi et al., 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)

81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81408	Molecular pathology procedure, Level 9 (eg, analysis of >50 exons in a single gene by DNA sequence analysis)
81434	Hereditary retinal disorders (eg, retinitis pigmentosa, Leber congenital amaurosis, cone-rod dystrophy), genomic sequence analysis panel, must include sequencing of at least 15 genes, including ABCA4, CNGA1, CRB1, EYS, PDE6A, PDE6B, PRPF31, PRPH2, RDH12, RHO, RP1, RP2, RPE65, RPGR, and USH2A
81479	Unlisted molecular pathology procedure
81599	Unlisted multianalyte assay with algorithmic analysis

Genetic Testing for Polyposis Syndromes

Policy Number: AHS – M2024 – Genetic Testing for Polyposis Syndromes	Prior Policy Name and Number, as applicable: • AHS – M2024 – Familial Adenomatous Polyposis and *MUTYH*-Associated Polyposis
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Familial adenomatous polyposis (FAP) is characterized by development of adenomatous polyps and an increased risk of colorectal cancer (CRC) caused by an autosomal dominant mutation in the *APC* (Adenomatous Polyposis Coli) gene, affecting one in 5,000-10,000 individuals in the United States (Kinzler & Vogelstein, 1996; NORD, 2014). Depending on the location of the mutation in the *APC* gene, FAP can present as the more severe classic FAP with hundreds to thousands of polyps developing at the ages of 10-12 years associated with a significantly increased risk of CRC, or attenuated FAP (AFAP) with fewer polyps, developing later in life with lower risk of CRC (Brosens et al., 2015; Spirio et al., 1993). Two other subtypes of FAP include Gardner syndrome, which causes non-cancer tumors of the skin, soft tissues, and bones, and Turcot syndrome, a rare inherited condition in which individuals have a higher risk of adenomatous polyps and colorectal cancer. In classic FAP, the most common type, patients usually develop cancer in one or more polyps as early as age 20, and almost all classic FAP patients have CRC by the age of 40 if their colon has not been removed (Society, 2023).

MUTYH-associated polyposis (MAP) results from an autosomal recessive mutation of both alleles of the *MUTYH* gene and is characterized by increased risk of CRC with development of adenomatous polyps. This condition, however, may present without these characteristic polyps (Nielsen, 2015).

Two other polyposis syndromes are Juvenile Polyposis Syndrome (JPS) and Peutz-Jeghers Syndrome (PJS). These syndromes are characterized by polyps in the GI tract

and are often associated with *SMAD4* or *BMPR1A* mutations and *STK11* mutations, respectively (Chung, 2023; Chung & Delgado, 2024).

II. Related Policies

Policy Number	Policy Title
AHS-M2004	Lynch Syndrome
AHS-M2026	Testing for Colorectal Cancer Management
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic counseling **IS REQUIRED** for individuals being considered for genetic testing for polyposis syndromes.

2) For individuals (see Note 1) in a family with a pathogenic familial polyposis gene variant, the following testing **MEETS COVERAGE CRITERIA:**
   a) Testing restricted to the known pathogenic familial variant.
   b) Comprehensive genetic testing, including muti-gene panel testing (see Note 2), when the specific familial mutation is unknown.

3) For individuals (see Note 1) who have no known familial pathogenic variant(s), multi-gene panel testing (see Note 2, Note 3) for polyposis syndrome risk factors **MEETS COVERAGE CRITERIA** in **any** of the following situations:
   a) For individuals with a personal history of 10 or more cumulative adenomas.
   b) For individuals with a personal history of 2 or more hamartomatous polyps.
   c) For individuals with multifocal/bilateral or unilateral congenital hypertrophy of retinal pigment epithelium (CHRPE).
   d) For individuals with a personal history of **any** of the following:
      i) Primary brain tumor (e.g., medulloblastoma).
      ii) Desmoid tumor.
      iii) Hepatoblastoma.
      iv) Osteomas.

v) Supernumerary teeth.

e) For individuals who meet the criteria for serrated polyposis syndrome (SPS):

i) Individual has 5 or more serrated lesions/polyps proximal to the rectum, all being greater than or equal to 5 mm in size, with 2 or more being greater than or equal to 10 mm in size.

ii) Individual has greater than 20 serrated lesions/polyps of any size, distributed throughout the large bowel, with 5 or more being proximal to the rectum.

4) In an unaffected reproductive partner of an individual with *MUTYH*-associated polyposis (MAP), comprehensive sequencing of *MUTYH* **MEETS COVERAGE CRITERIA.**

5) Genetic testing of *SMAD4* and *BMPR1A* **MEETS COVERAGE CRITERIA** in **any** of the following situations:

a) For individuals with a known family history of juvenile polyposis syndrome (JPS) or known pathogenic familial *SMAD4* or *BMPR1A* mutations (testing restricted to known pathogenic familial mutation).

b) For individuals with at least five juvenile polyps in the colorectum.

c) For individuals with any number of juvenile polyps in other regions of the GI tract.

6) Genetic testing of *STK11* (formerly known as *LKB1*) **MEETS COVERAGE CRITERIA** in **any** of the following situations:

a) For individuals with a known family history of Peutz-Jeghers syndrome or known pathogenic familial *STK11* mutation (testing restricted to known pathogenic familial mutation).

b) For individuals with mucocutaneous hyperpigmentation of the mouth, lips, nose, eyes genitalia, or fingers.

c) For individuals with two or more histologically proven Peutz-Jeghers-type hamartomatous polyps of the GI tract.

7) For individuals less than 18 years of age who have one biological parent with MAP and one unaffected parent, sequencing of the *MUTYH* gene **DOES NOT MEET COVERAGE CRITERIA**.

8) For all other situations not described above, multi-gene panel testing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: For individuals under 18 years of age, "genetic testing is generally not recommended unless results would impact medical management, such as initiation of early colonoscopy surveillance. Clear exceptions include when familial adenomatous polyposis (FAP), JPS, PHS, or constitutional MMR deficiency (CMMRD) syndrome are suspected or known to be present in a family, in which case testing prior to age 18 is recommended to guide medical management" (NCCN, 2023).

Note 2: Per the NCCN, "multigene panel[s] should include all polyposis and CRC [colorectal cancer] genes" (NCCN, 2023). At minimum, multigene panels should include the following polyposis and CRC risk genes: *APC, ATM, AXIN2, BLM, BMPR1A, CHEK2, EPCAM, GALNT12, GREM1, MBD4, MLH1, MLH3, MSH2, MSH3, MSH6, MUTYH, NTHL1, POLD1, POLE, PMS2, PTEN, RNF43, RPS20, SMAD4, STK11,* and *TP53*.

Note 3: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162-Reimbursement Policy.

WES	Whole exome sequencing

V. Scientific Background

Familial Adenomatous Polyposis (FAP) and MUTYH-Associated Polyposis (MAP)

Inherited syndromes that express adenomatous polyps and confer a significantly increased risk of CRC include familial adenomatous polyposis (FAP) and *MUTYH*-associated polyposis (MAP) (Jasperson et al., 2010). Both FAP and MAP account for less

than one percent of all colorectal cancer cases (Chung & Rodgers, 2024; Grover & Stoffel, 2022).

Familial Adenomatous Polyposis results from mutations in the adenomatous polyposis coli (*APC*) tumor suppressor gene. Mutant or absent *APC* results in increased transcription of cell proliferation genes regulated through the Wnt/β-catenin pathway and the earliest malignancies (microadenomas and other small polyps) have lost the second *APC* allele. The *APC* gene is thought to prevent accumulation of β-catenin, and mutations in this gene result in failure of these β-catenin regulatory domains. β-catenin is thought to regulate the proliferation and differentiation of intestinal epithelial cells, and failure of this regulatory mechanism results in cell proliferation. Somatic mutations of this gene are present in 80% of sporadic CRCs and a single germline mutation of this gene is responsible for FAP (Frucht & Lucas, 2023). The prevalence of FAP is about 1:13,000 (Brosens et al., 2015). More than 300 different mutations have been reported, and the clinical presentation is dependent on the location of the mutation in the *APC* gene (Brosens et al., 2015; Spirio et al., 1993). Mutations in the central part of the gene (Exons 169 to 1393) result in classic FAP characterized by the presence of 100 or more adenomatous colorectal polyps (Chung & Rodgers, 2024). When fully developed, patients can have up to thousands of colorectal adenomas and nearly 100% risk of CRC. About 50% of patients developed adenomas by age 15 and 95% by age 35. If left untreated, FAP patients will develop CRC at an average age of 39 (Brosens et al., 2015). Patients with FAP are also at risk for extracolonic malignancies, such as desmoid tumors, duodenal adenomas, or even brain tumors (Chung & Rodgers, 2024).

In contrast, mutations in either end of the gene predispose to attenuated FAP (AFAP) (Spirio et al., 1993). AFAP is characterized by fewer colorectal adenomas with a later age of onset and an 80% lifetime risk of CRC compared to FAP. The diagnosis should be considered in patients 40-50 years old with 10-100 adenomas cumulatively. Patients with AFAP are diagnosed on average about 14 years later when compared with classic FAP (44 years of age versus 58 years of age, respectively). Overall, AFAP is a milder, but very similar form, of FAP (Chung & Rodgers, 2024).

MUTYH-associated polyposis is caused by biallelic mutations in the *MUTYH* gene base excision repair gene whose protein repairs oxidative damage on the *APC* gene (Sieber et al., 2003). Failure of base excision repair results in transversions in multiple genes, including the *APC* and *KRAS* genes. The two most common mutations in the *MUTYH* gene are Y179C and G396D, but more than 100 unique *MUTYH* gene mutations have been reported. *MUTYH*-associated polyposis is usually characterized by development of between 10 to 100 colorectal polyps by ages 50-60; however, *MUTYH* mutations have been identified in CRC with few or no colorectal polyps. Adenomas are the

primary polyp type in patients with *MUTYH*-associated polyposis, but hyperplastic and sessile serrated polyps have been reported in some patients (Grover & Stoffel, 2022). The genes that are mutated strongly influence the polyposis phenotype with the *KRAS* gene mutation resulting in different phenotypes compared to *MUTYH* (Boparai et al., 2008). Furthermore, the genotype of the condition may also make a difference in the clinical presentation. Multiple studies have suggested that the mutation G396D is less severe than the mutation Y179C, with the patients of the G396D genotype tending to develop polyps later and experiencing a later age of onset for those polyps (Guarinos et al., 2014; Nielsen et al., 2021).

Although both FAP and *MUTYH*-associated polyposis both cause numerous colorectal adenomas, there are notable differences between the two conditions. Mutations of *MUTYH* typically do not result in FAP. FAP is characterized by mutations in the *APC* gene and may be transmitted from parent to child (although 25% of FAP cases are *de novo*), whereas *MUTYH*-associated polyposis is not inherited in this manner. Diagnosis of *MUTYH*-associated polyposis requires identification of biallelic pathogenic germline variants of *MUTYH* (Grover & Stoffel, 2022).

A study of 8676 patients who had undergone mutation analysis of the *APC* and *MUTYH* genes was performed by Grover et al. Of these 8676, 7225 had colorectal adenomas. Overall, 1457 patients had classical FAP, and 3253 had AFAP. The study found *APC* mutations in 80% of patients with ≥1000 adenomas (95/119), 56% of patients with 100-999 adenomas (756/1338), 10% of patients with 20-99 adenomas (326/3253) and five percent of patients with 10-19 adenomas (50/970). *MUTYH* mutations were found in two percent (2/119), seven percent (94/1338), seven percent (233/3253), and four percent (37/970) of patients, respectively. The authors concluded that *APC* mutation rate increased as number of adenomas increased, but *MUTYH* mutation rate was relatively constant over all categories. There were 2098 patients out of 8676 (24%) who had a pathogenic *APC* or *MUTYH* mutation, and 6578 (76%) had a non-pathogenic mutation or no mutation in either gene (Grover et al., 2012).

Ciavarella et al. (2018) investigated genetic causes of unexplained adenomatous polyposis in eight cases of polyposis with no causative germline variant in *APC* or *MUTYH*. They identified *APC* mosaicism in 50% of patients. In three cases mosaicism was restricted to the colon, while in one it also extended to the duodenum and saliva. One patient without *APC* mosaicism carried an *APC* in-frame deletion of uncertain significance and was found to harbor rare germline variants in *OGG1, POLQ,* and *EXO1* genes. The authors concluded that restrictive selection criteria improved the detection of mosaic *APC* patients and that an oligogenic inheritance of rare variants may have a role in sporadic colorectal polyposis (Ciavarella et al., 2018).

Guidelines have been established by several organizations to reduce morbidity and mortality from hereditary forms of polyposis and resulting CRC by identifying individuals at risk and implementing a highly targeted program of cancer surveillance and management guided by the causative mutations identified (Hampel et al., 2015; Hegde et al., 2014; Provenzale et al., 2016; Syngal et al., 2015).

In a study by M. Yang et al. (2020), next-generation sequencing (NGS) panel, multiplex ligation-dependent probe amplification (MLPA), whole-exome sequencing (WES), and Sanger sequencing were used to determine a diagnostic method for variant-negative FAP patients. Although definite pathogenic variants of the *APC* gene are identified in the majority of FAP patients, there are still numerous variant-negative patients. NGS and MLPA did not identify any variants of the *APC* gene; however, WES recognized three patients with a point variant (c.-190G>A) in the noncoding region of the *APC* gene. Sanger sequencing identified a variant carrier during screening of the family. This study showed that the c.-190G>A variant can cause classic FAP but can be missed by conventional genetic testing. Therefore, "utilizing sequencing technologies covering a larger area can help us to further explore the pathogenesis in variant-negative FAP cases" (M. Yang et al., 2020).

Peutz-Jeghers Syndrome (PJS)

Peutz-Jeghers Syndrome is another uncommon polyposis syndrome that occurs one in 8,300 to one in 20,000 births (Giardiello & Trimbath, 2006). This condition is characterized by two clinical signs: pigmented mucocutaneous macules (melanin spots) and multiple hamartomatous gastrointestinal polyps. Those affected are at higher risk for both gastrointestinal and extra-intestinal cancers. Pathogenic mutations in the *STK11* gene is most strongly associated with PJS; although not every genetic mutation associated with PJS has been identified (Chung & Delgado, 2024).

Over 95% of PJS patients present with mucocutaneous macules, which are typically found on the lips or around the lips, palms, soles of the feet, or on the buccal mucosa. However, these macules tend to be most prevalent in the first two years and typically fade after puberty. Most patients will also present with hamartomatous polyps, typically developing in the first decade of life. These polyps do not have any particularly distinguishing features and may be indicative of several other syndromes, such as Cowden syndrome (Chung, 2023).

Jia et al. (2018) analyzed clinical features of 46 patients with Peutz-Jeghers syndrome (PJS). The authors identified "black spots, abdominal pain, hematochezia, and anemia" as the main clinical features. Histologically, "20 patients were classified as hamartomatous polyps, 18 as adenomatous polyps, 14 as inflammatory polyps, and 10 as zigzag polyps". Eleven patients underwent gene sequencing with a panel of 20

genes, and five were found to have gene mutations. Three of these patients were found to have mutations in the *STK11* gene (Jia et al., 2018).

In a study by Wu et al. (2020), direct sequencing using the QIAamp DNA Blood Mini Kit and multiplex ligation-dependent probe amplification (MLPA) tests were used to detect germline *STK11* mutations in 38 patients clinically diagnosed with Peutz-Jeghers syndrome and their healthy relatives. RNA sequencing was performed in polyps of PJS patient and control groups to evaluate the difference of *STK11* expression. A clinical PJS diagnosis was made when an individual had two of the following: two or more histologically confirmed Peutz-Jeghers-type hamartomatous polyps, mucocutaneous hyperpigmentation of the mouth, lips, nose, eyes, genitalia, or fingers, and family history of PJS. Germline mutation screening of the *STK11* gene detected a pathogenic variant in all probands with a 100% mutation detection rate. "Twenty variants were nucleotide substitutions or indels that were detected by Sanger sequencing (seven were missense variants, and 13 variants were truncating). All mutations fell within the coding region spanning exon one and exon eight, and no mutation in exon nine was identified in any of these PJS individuals" (Wu et al., 2020). While missense mutations did not influence *STK11* expression, truncated mutations resulted in lower *STK11* expression which may cause greater damage to the gene product and a more severe PJS phenotype. In this study, the 13 patients with a truncated *STK11* variant did have earlier onset for PJS symptoms, including intestinal obstruction and first operation events, than those with missense mutations. This indicates that patients with truncated variant need earlier management to prevent complications. In addition, this study identified a fetus with a *STK11* pathogenic variant through non-invasive prenatal testing (NIPT). The parents chose to give birth to this fetus, and melanin spots appeared on the lips at approximately one year old and have gradually increased. This indicates that there are broad application prospects for prenatal testing and preimplantation genetic diagnosis. Due to the significance of genetic testing in this study, the author states that "it is important to detect *STK11* gene mutations to make early diagnoses and treatments to reduce the occurrence of GI complications and malignancies" (Wu et al., 2020).

Juvenile Polyposis Syndrome (JPS)

Juvenile Polyposis Syndrome is another condition thought to confer additional risk for colorectal and gastric cancer. JPS is caused by variants in the *BMPR1A* or *SMAD4* genes, but no genetic variant is found in 20-30% of the cases. These genes code for a protein that play a role in the TGFβ signal transduction system. In patients with *SMAD4* gene variant, severe polyposis in the stomach or duodenum is highly likely (NHS, 2020). Similar to syndromes discussed above, this condition is characterized by numerous polyps in the GI tract. More than half of affected JPS patients will present with rectal

bleeding and will be symptomatic by 20 years old. Differentiating JPS from other hamartomatous syndromes can be difficult, but patients meeting the clinical diagnosis criteria for JPS will often undergo genetic testing for the *BMPR1A* and *SMAD4* genes (Chung & Delgado, 2024).

Gonzalez et al. (2017) evaluated the clinicopathological features of 22 patients with "abundant gastric juvenile-type or hyperplastic-like polyps". There were 14 patients that were diagnosed with JPS an average of 40 years. Out of the 22 cases, 18 cases showed "complete or near-complete carpeting of the gastric mucosa by innumerable polyps", and *SMAD4* immunohistochemical staining revealed "patchy loss" in polyps in 19 of 20 tested cases. Furthermore, five of six patients tested harbored a *SMAD4* mutation (Gonzalez et al., 2017).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network

The NCCN recommends *APC* or *MUTYH* gene testing for individuals with a personal history of ≥20 adenomas, individuals with a known deleterious familial mutation, and individuals with multifocal or bilateral congenital hypertrophy of retinal pigment epithelium (CHRPE). The NCCN recommends that testing be considered in individuals with a personal or family history of CHRPE, osteomas, supernumerary teeth, desmoid tumor, hepatoblastoma, brain cancer (typically medulloblastoma), or cribriform variant of papillary thyroid cancer (Gupta et al., 2017; NCCN, 2023). If an *APC* variant is found, high-quality colonoscopy every 12 months, beginning at 10 to 15 years of age, is recommended. Colonoscopy is preferred over flexible sigmoidoscopy due to the possibility of missing right-sided polyps when limiting to sigmoidoscopy. However, based on patient and family preference or clinical judgment, sigmoidoscopy may also be considered. (NCCN, 2023).

If a patient has a personal or family history of a known pathogenic variant of a colorectal polyposis or cancer gene, further evaluation is warranted. When there is no known familial or personal mutation, the NCCN recommends determining the patient or familial history of the following clinical signs:

- ten or more adenomatous polyps
- two or more hamartomatous polyps or
- five or more serrated polyps proximal to the rectum

If any of these features are identified, the NCCN recommends a detailed risk assessment/genetic evaluation for possible polyposis syndromes. The NCCN also recommends within the algorithm concerning risk assessment/genetic evaluation for

possible polyposis syndromes that for individuals for more than 10 adenomas to test for FAP, AFAP, MAP, and rare genetic causes of multiple adenomatous polyps. Within this latter group, the genes associated "include, but are not limited to monoallelic pathogenic variants in GREM1, POLE, POLD1, and AXIN2, and biallelic pathogenic variants in NTHL1 and MSH3."

The NCCN also notes the following: "When colonic polyposis is present only in the proband and/or in siblings, consider recessive inheritance or *de novo APC* gene mutations. For example MAP follows a recessive pattern of inheritance, so *MUTYH* testing should be considered if a recessive pattern is apparent in the pedigree…*MUTYH* testing is not indicated based solely on a personal history of a desmoid tumor, hepatoblastoma, or cribriform-morular variant of papillary thyroid cancer…" (NCCN, 2023).

The NCCN also makes this note for siblings of a patient with MAP: they are recommended to have site-specific testing for the familial pathogenic/likely pathogenic mutations. "Full sequencing of *MUTYH* may be considered in an unaffected parent when the other parent has MAP. If the unaffected parent is not tested, then comprehensive testing of *MUTYH* should be considered in the children. If the unaffected parent is found to have one *MUTYH* pathogenic variant, then testing the children for the familial *MUTYH* [pathogenic/likely pathogenic] variants is clinically indicated. Testing of children of *MUTYH* heterozygotes should be offered if the other parent is also a heterozygote or could still be offered if the other parent is not a heterozygote and management would change, if they have an first-degree relative affected with CRC, or to inform reproductive risks since their future children could be at risk for MAP" (NCCN, 2023).

The NCCN notes that a classical diagnosis of FAP is suspected when there are "at least 100 cumulative adenomas in the large bowel" present at a young age; however, genetic testing with multi-gene panel is recommended to differentiate between FAP, AFAP, MAP polyposis due to a mutation in a rare gene for which testing is available, and colonic polyposis of unknown etiology (NCCN, 2023).

NCCN lists clinical scenarios for which multigene testing "may be considered", such as adenomatous polyposis, a patient with personal or family history meeting criteria for more than one hereditary cancer syndrome, a colonic polyposis with uncertain histology, second-line testing with inconclusive first-line testing, if family cancer history does not meet established testing guidelines, or if an individual with limited or unknown family history is concerned about cancer predisposition. However, the NCCN also recommends against multi-gene testing in the following scenarios: if the mutation is known and there is no other reason for multi-gene testing or if genetic testing is

performed as first-line testing with a family history that is strongly suggestive of a known hereditary syndrome. In these situations, the NCCN states that a syndrome-specific panel may be considered instead. Overall, the NCCN states that multi-gene panels that include tumor and family-based criteria associated with Lynch Syndrome is recommended. Panel testing may be an option if the personal and family histories are "strongly suggestive" of an inherited condition. The panel states that "at a minimum, a germline multigene panel should include the following genes associated with CRC risk: *APC, MUTYH, MLH1, MSH2, MSH6, PMS2, EPCAM, BMPR1A, SMAD4, PTEN, STK11* and *TP53*." The NCCN also recommends genetic counseling before and after genetic testing is done (NCCN, 2023).

The NCCN recommends genetic testing for juvenile polyposis syndrome patients, noting that 50% of cases occur due to pathogenic *SMAD4* or *BMPR1A* mutations. In families with a known BMPR1A pathogenic variant, "genetic testing should be performed by age 12-15 when surveillance would begin (or sooner if symptoms warrant evaluation)." If there is a known familial mutation of *SMAD4*, genetic testing should be performed within the first 6 months of life. The NCCN also remarks that the majority of Peutz-Jeghers Syndrome cases occur due to pathogenic variants in the *STK11/LKB1* gene (NCCN, 2023).

The NCCN recommendations follow the American Society Clinical Oncology (ASCO), which issued an updated statement regarding genetic testing in 2015. ASCO states that informed consent, as well as the possibility of discovery of unexpected and harmful mutations, should be communicated carefully to the patient. ASCO states that genetic counseling is imperative both before and after genetic testing, as many genes have uncertain clinical utility and a specialist may help provide informed clinical decision-making (NCCN, 2023; Robson et al., 2015).

The NCCN also notes several genes that may decide treatment. For patients with pathogenic variants in *GREM1, POLD1, POLE, AXIN2, NTHL1*, and *MSH3*, they recommend beginning a colonoscopy no later than 25-30 years old and performing one every one to two years if negative. If polyps are found, endoscopic evaluation of the rectum every six to twelve months is recommended, depending on polyp burden. However, the NCCN does note that recommendations for these genes are still "evolving" at this time and that caution is needed when determining surveillance regimes.

Some general considerations and best practices for genetic testing from the NCCN included the following:

"Patients who have received an allogeneic bone marrow transplant should not have molecular genetic testing via blood or saliva samples due to unreliable test results

from contamination by donor DNA in such cases, DNA of the individual being tested should be extracted from a fibroblast culture from a skin punch biopsy. If this is not possible, buccal cells may be considered as an alternative source of DNA."

"In children < 18y, genetic testing is generally not recommended unless results would impact medical management, such as initiation of early colonoscopy surveillance. Clear exceptions include when FAP, JPS, PJS, or constitutional MMR deficiency (CMMRD) syndrome are suspected or known to be present in a family, in which case testing prior to age 18 is recommended to guide medical management" (NCCN, 2023).

American College of Gastroenterology

The ACG recommends that "individuals who have a personal history of >10 cumulative colorectal adenomas, a family history of one of the adenomatous polyposis syndromes, or a history of adenomas and FAP-type extracolonic manifestations (duodenal/ampullary adenomas, desmoid tumors (abdominal>peripheral), papillary thyroid cancer, congenital hypertrophy of the retinal pigment epithelium ((CHRPE), epidermal cysts, osteomas) should undergo assessment for the adenomatous polyposis syndromes. Genetic testing of patients with suspected adenomatous polyposis syndromes should include *APC* and *MUTYH* gene mutation analysis" (Syngal et al., 2015). The ACG recommends screening for CRC in patients with or at risk for "classic AP syndromes" by annual colonoscopy or flexible sigmoidoscopy starting at puberty. The ACG also recommends surveillance by colonoscopy in families with AFAP or MAP (Syngal et al., 2015).

The ACG further states that failure to identify a mutation does not rule out the diagnosis of adenomatous polyposis. Testing for any possible underlying genes should be considered if clinical suspicion is high. Failure to find a mutation means that all close relatives must still be screened, but finding a mutation confirms the diagnosis and allows relatives to be tested accurately. Once an affected patient has been genotyped, all at-risk relatives can be screened properly (Syngal et al., 2015).

The ACG also notes that "Individuals with perioral or buccal pigmentation and/or two or more histologically characteristic GI hamartomatous polyp(s) or a family history of PJS should be evaluated for PJS." Further, they state that genetic evaluation of a patient with "possible" PJS should include testing for *STK11* mutations. Regarding JPS, ACG recommends that "Individuals with five or more juvenile polyps in the colorectum or any juvenile polyps in other parts of the GI tract should undergo evaluation for JPS." A genetic evaluation of a patient with "possible" JPS should include testing for *SMAD4* and *BMPR1A* mutations (Syngal et al., 2015).

American College of Medical Genetics and Genomics

The ACMG recommends testing for FAP in individuals with "100 ≤ polyps with autosomal dominant inheritance, and for at-risk family members of individuals with known familial mutations". The ACMG also recommends testing for FAP in individuals with conditions such as congenital hypertrophy of retinal pigment epithelium or osteomas. It also recommended that "FAP testing be performed using full sequencing of the *APC* gene. If no mutation is detected, then testing for large gene rearrangements should be performed" (Hegde et al., 2014). The ACMG notes that mutations are detected in 80% of patients with FAP with DNA sequencing detecting 87% of smaller mutations, such as deletions or point mutations. The remaining mutations are larger mutations, such as gross duplications, which can be detected by RT-PCR or MLPA. ACMG recommends considering testing for AFAP in individuals with <100 adenomas. They note that individuals with 100 or more polyps at 35-40 years or older may be found to have AFAP. According to ACMG, frequent right-sided distribution of polyps is usually noted in these individuals and adenomas and cancers at an age older than that for classic FAP and other GI manifestations are found (Hegde et al., 2014).

The ACMG recommends *MUTYH* gene testing for individuals with colorectal cancer diagnosed at less than 40, the presence of 10 or more adenomatous polyps without *APC* gene mutation, and a family history of colon cancer with an autosomal recessive inheritance including colon cancers with or without polyps (Hegde et al., 2014). ACMG indicates that *MUTYH* testing should begin with testing for the two common mutations p.Y165C and p.G382D, and if none or one mutation is identified, then full sequencing of the *MUTYH* gene should be considered. The ACMG notes that 80% of mutations in Caucasian and North European populations are of these two variants but sequencing of the entire gene may detect up to 99% of mutations. The ACMG also recommends that testing of the *MUTYH* gene should also be offered to at-risk family members. Sanger sequencing and NGS are both recommended methods for sequencing. Finally, if heterozygosity for only one common mutation is detected, or no mutation is detected at all, then sequencing of the entire *MUTYH* gene may be considered (Hegde et al., 2014).

ACMG and the National Society of Genetic Counselors

The ACMG and NSGC recommend that referral for genetic counseling should be considered for "any individual with a personal history of or first-degree relative with a total of ≥10 adenomatous colon polyps with or without a colorectal or other FAP-associated cancer, a cribriform morular variant of papillary thyroid cancer; a desmoid tumor; or hepatoblastoma diagnosed before age five".

The guidelines also list clinical symptoms that should warrant assessment for cancer predisposition for JPS and PJS. For JPS, they note the following symptoms:

- "three to five cumulative histologically proven juvenile polyps in the same person"
- "Multiple juvenile polyps throughout the GI tract in the same person"
- "Any number of juvenile polyps with a family history positive of JPS"

For PJS:

- "≥ two cumulative histologically proven PJ polyps in the same person"
- "≥ one PJ polyp and mucocutaneous hyperpigmentation in the same person"
- "Any number of PJ polyps and a positive family history of PJS" (Hampel et al., 2015).

European Society for Medical Oncology (ESMO)

The ESMO published a 2019 update for hereditary gastrointestinal cancers, including some polyposis syndromes. These recommendations are as follows:

- For FAP, "Patients with multiple colorectal adenomas (>10) should be considered for panel germline genetic testing that includes *APC, MUTYH, POLE, POLD1* and *NTHL1* genes. *APC* analysis should include large rearrangements"
- "Biallelic *MUTYH* mutations should be suspected in cases of AFAP or FAP with a recessive pattern of inheritance, diagnosis before the age of 50 years, and multiple colonic polyps"
- "A multigene single analysis of *APC, MUTYH* (all exons), *POLE, POLD1* and *NTHL1* is recommended"
- "For *POLE*- and *POLD1*-mutation-positive PPAP and *NTHL1*-mutation-positive adenomatous polyposis, colonoscopic surveillance should follow MAP recommendations" (Stjepanovic et al., 2019).

The ESMO recommends germline testing of *APC* and *MUTYH* for patients with 10 or more colorectal adenomas. Full germline testing should include DNA sequencing and large rearrangement analysis.

Testing for *MUTYH* may start with the two most common mutations (Y179C, G396D), followed by analysis of the entire gene in heterozygotes. Founder mutations present in certain ethnic groups should also be considered. If a mutation is detected, testing may also be offered to at-risk family members (Balmaña et al., 2013).

American Society of Colon and Rectal Surgeons (ASCRS)

The ASCRS has released guidelines on inherited polyposis syndromes. A polyposis diagnosis should be considered "in patients with over 20 adenomas, patients with history of desmoid tumor, extracolonic manifestations, or family members of individuals with known FAP, AFAP, or MAP". Germline testing of the *APC* gene is recommended for these individuals. The ASCRS lists 20 as the cutoff as the risk of finding a genetic mutation rises above 10% at this mark. Genetic counseling is recommended prior to genetic testing. The ASCRS recommends patients with clinical polyposis but without an identified mutation to be treated according to their phenotype. However, this was noted to be a weak recommendation based on low quality evidence (Herzig et al., 2017).

European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) Polyposis Working Group

This Working Group released guidelines on both Juvenile Polyposis Syndrome (JPS) and Peutz-Jeghers Syndrome (PJS).

For JPS, the Working Group recommends routine predictive testing for at-risk children at 12-15 years of age. If a child has rectal bleeding before this age, a colonoscopy should be performed, and if polyps are found, that child should undergo genetic testing.

Pediatric patients with a *SMAD4* mutation should be evaluated for Hereditary Hemorrhagic Telangiectasia (HHT), including screening for cerebral and pulmonary arteriovenous malformations.

"Children with *BMPR1A* mutation and early onset polyposis and/or a severe phenotype and/or extraintestinal manifestations should be evaluated for PTEN mutation".

"If a specific gene mutation has been detected in a child, then genetic testing should be offered to all first-degree family members. If no specific gene mutation was detected, then first-degree relatives should be referred for screening colonoscopy at the age of 12 to 15 years" (Cohen et al., 2019).

Regarding PJS, the ESPGHAN recommends offering predictive genetic testing for an asymptomatic at-risk child as early as 3 years of age. Symptomatic at-risk children should have genetic testing performed earlier.

However, the ESPGHAN notes that "No clear genotype-phenotype correlation has been demonstrated in PJS. Furthermore there have been no clear clinical differences found between cases with and without detectable germline *STK11* mutations" (Latchford et al., 2019).

American Society for Gastrointestinal Endoscopy (ASGE)

The ASGE released recommendations for the role of genetic testing in the management of patients with FAP syndromes. As family history may not be present due to germline mutations of the *APC* gene, ASGE recommends genetic testing to make a confirmatory FAP diagnosis before moving forward with morbid surgery or invasive endoscopic screening. Genetic testing is also recommended when a patient presents with ten or more cumulative adenomatous polyps on a single colonoscopy, if a patient presents with ten or more adenomas and a history of CRC, or if a patient has twenty or more adenomatous polyps in a lifetime. In addition, genetic counseling is recommended for all patients with or suspected to have FAP syndromes and first-degree relatives (J. Yang et al., 2020).

The *APC* gene testing is recommended in children at the age of 10-12 years. If AFAP or MAP is suspected, patients should undergo genetic testing at the age of 18-20 years. Younger children, aged six months to five years, can undergo confirmatory *APC* gene testing if parents agree to screen for hepatoblastoma with alpha-fetoprotein test and liver function test every six months. Otherwise, testing is deferred until 10-12 years old. Children without *APC* gene abnormalities should follow average-risk screening guidelines (J. Yang et al., 2020).

Finally, the guideline comments that "Once an individual is found to be affected with MAP, his or her relatives should also be screened for mutations in *MUTYH*…Similar to FAP, genetic testing for mutations in *MUTYH* should be considered in those with (1) 20 or more colorectal adenomas over multiple colonoscopies, (2) a known family history of MAP, (3) 10 or more adenomas found on a single colonoscopy, or (4) criteria for serrated polyposis syndrome with at least some adenomas noted on examination". The guideline further notes "serrated polyposis syndrome" is defined by the WHO as one of the following conditions: "(1) at least 5 serrated polyps proximal to the sigmoid colon with two or more >10 mm in size, (2) any number of serrated polyps proximal to the sigmoid colon in an individual who has a first-degree relative with serrated polyposis syndrome, or (3) >20 serrated polyps of any size distributed throughout the colon." The guideline does remark that genetic testing for *MUTYH* in children should be postponed until adulthood due to the later onset of the condition.

American Gastroenterological Association (AGA)

The AGA released recommendations on genetic testing for young adult-onset colorectal cancer. AGA recommends genetic testing to all young adult CRC patients based on the patient's family history of hereditary CRC, other cancer syndromes, and the presence of polyps. AGA also recommends germline testing for those who do not fit clinical criteria for one hereditary syndrome or have no family history of cancer. AGA

encourages early integration of genetic counselors as increased genetic testing could lead to the chances of finding genetic variants of unknown significance or a pathogenic variant that does not have clear management guidelines (Boardman et al., 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On January 18, 2019, the FDA approved the *MUTYH*-Associated Polyposis (MAP) testing by 23andMe, Inc (FDA, 2024).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81201	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; full gene sequence
81202	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; known familial variants
81203	APC (adenomatous polyposis coli) (eg, familial adenomatosis polyposis [FAP], attenuated FAP) gene analysis; duplication/deletion variants
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)

81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)
81479	Unlisted molecular pathology procedure

Genetic Testing for PTEN Hamartoma Tumor Syndrome

Policy Number: AHS – M2087 – Genetic Testing for PTEN Hamartoma Tumor Syndrome	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Phosphatase and tensin homolog (PTEN) hamartoma tumor syndromes (PHTS) are primarily characterized by hamartomatous tumors (disorganized growths of native cells in native tissues) caused by *PTEN* germline mutations. PHTS includes Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome (BRRS), *PTEN*-related Proteus syndrome (PS), and Proteus-like syndrome (PLS)(C. Eng, 2016; Stanich & Roberts, 2023).

Genetic counseling is strongly recommended for individuals pursuing genetic testing for PHTS.

II. Related Policies

Policy Number	Policy Title
AHS-M2003	Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate Cancers
AHS-M2108	Molecular Markers in Fine Needle Aspirates Of The Thyroid

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

All major and minor criteria are defined in Note 1

1) For asymptomatic individuals who are in a family with a known pathogenic *PTEN* mutation, the following testing **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial mutation.
   b) Comprehensive *PTEN* gene sequencing when the specific *PTEN* mutation is unknown.

2) For individuals suspected of having Cowden Syndrome (CS)/PTEN hamartoma tumor syndrome (PHTS), genetic testing for a *PTEN* mutation **MEETS COVERAGE CRITERIA** when at least one of the following clinical signs is present:
   a) Three or more major criteria (one must be macrocephaly, Lhermitte-Duclos disease, or gastrointestinal hamartomas).
   b) Two major and three minor criteria.

3) For individuals not meeting the clinical diagnostic criteria above, genetic testing for a *PTEN* mutation **MEETS COVERAGE CRITERIA** when the individual has a personal history of any one of the following:
   a) Adult Lhermitte-Duclos disease (cerebellar tumors).
   b) Autism spectrum disorder and macrocephaly.
   c) Two or more biopsy-proven trichilemmomas.
   d) Two or more major criteria (one must be macrocephaly).
   e) Three major criteria without macrocephaly.
   f) Two major and two or more minor criteria (for individuals without macrocephaly).
   g) One major and three or more minor criteria.
   h) Four or more minor criteria.

4) For individuals with a personal history of Bannayan-Riley-Ruvalcaba syndrome (BRRS), genetic testing for a *PTEN* mutation **MEETS COVERAGE CRITERIA**.

5) For at-risk individuals with a relative who has been clinically but not genetically diagnosed with CS/PHTS or BRRS, genetic testing for a *PTEN* mutation **MEETS COVERAGE CRITERIA** when at least **one** of the following conditions are met:
   a) The at-risk individual has any one major criterion.
   b) The at-risk individuals has two minor criteria.

6) For individuals with a *PTEN* pathogenic/likely pathogenic variant detected by tumor profiling on any tumor type in the absence of germline analysis, genetic testing for a *PTEN* mutation **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

7) For all other situations not described above, genetic testing for a PTEN mutation **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: The NCCN provides the following major and minor testing criteria for Cowden Syndrome/PTEN Hamartoma Tumor Syndrome (Category 2A recommendation: based on lower-level evidence, there is uniform NCCN consensus that the intervention is appropriate):

Major Testing Criteria

- Breast cancer
- Endometrial cancer
- Follicular thyroid cancer
- Multiple GI hamartomas or ganglioneuromas
- Macrocephaly (megalocephaly) (ie, ≥97%, 58 cm in adult female, 60 cm in adult male)
- Macular pigmentation of glans penis
- Mucocutaneous lesions (any of the following):
  - One biopsy-proven trichilemmoma
  - Multiple palmoplantar keratoses
  - Multifocal or extensive oral mucosal papillomatosis
  - Multiple cutaneous facial papules (often verrucuous)

Minor Testing Criteria

- Autism spectrum disorder
- Colon cancer
- ≥3 Esophageal glycogenic acanthoses
- Lipomas
- Intellectual disability (i.e., IQ ≤75)
- Papillary or follicular variant of papillary thyroid cancer
- Thyroid structural lesions (e.g., adenoma, nodule[s], goiter)

- Renal cell carcinoma
- Single GI hamartoma or ganglioneuroma
- Testicular lipomatosis
- Vascular anomalies (including multiple intracranial developmental venous anomalies)

IV. Table of Terminology

Term	Definition
ACG	American College of Gastroenterology
aCGH	Array comparative genomic hybridization
ACMG	American College of Medical Genetics and Genomics
AKT	Protein Kinase B
ALK	*Anaplastic lymphoma kinase gene*
ASDs	Autism spectrum disorders
BEN	Benign
BP	Base pair
BRCA1	*Breast cancer type 1 gene*
BRCA2	*Breast cancer type 2 gene*
BRRS	Bannayan-Riley-Ruvalcaba Syndrome
CC	Cleveland Clinic
CC15	Cleveland Clinic Score of 15
CGH	Comparative genomic hybridization
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
CONF	Conflicting
CS	Cowden Syndrome
DNA	Deoxyribonucleic acid
DTC	Differentiated thyroid carcinoma
ERCC2	*ERCC excision repair 2 gene*
FDA	Food and Drug Administration
FTC	Follicular thyroid carcinoma
GI	Gastrointestinal
HRAS	*HRas proto-oncogene*
IQ	Intelligence quotient
LBEN	Likely benign
LDD	Lhermitte-Duclos Disease
LDTs	Laboratory-developed tests
LPATH	Likely pathogenic
MLPA	Multiplex ligation-dependent probe amplification

mTOR	Mechanistic Target of Rapamycin
MUTYH	*mutY DNA glycosylase*
NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
NORD	National Organization for Rare Disorders
PATH	Pathogenic
PCR	Polymerase chain reaction
PHTS	PTEN Hamartoma Tumor Syndromes
PI3K	Phosphatidylinositol 3-Kinase
PLS	Proteus-Like Syndrome
PS	Proteus Syndrome
PTEN	*Phosphatase and tensin homolog*
qPCR	Quantitative polymerase chain Reaction
RET	*Ret proto-oncogene*
RNA	Ribonucleic acid
SOLAMEN	Segmental Overgrowth, Lipomatosis, Arteriovenous Malformation, and
TSC2	*Tuberous sclerosis complex 2 gene*
VUS	Variant of uncertain significance

V. Scientific Background

Tumor suppressor genes serve several purposes within the body; these genes are able to regulate cell division, restore DNA errors, and tell cells when to die (a process known as apoptosis). Communication of these processes occurs via various cell signaling pathways. In particular, the tumor suppressor gene known as phosphatase and tensin homolog (*PTEN*) is an important phosphatase regulator of the phosphatidylinositol 3-kinase (PI3K)/AKT signaling pathway and the mechanistic target of rapamycin (mTOR) signaling pathway (Sansal & Sellers, 2004; Stanich & Roberts, 2023). The PI3K/AKT and mTOR signaling pathways are critical for cell proliferation, cell cycle progression, and apoptosis.

Loss of function of the *PTEN* gene contributes to an increased risk of both benign and malignant tumors and is implicated in increased lifetime risks of breast, thyroid, uterine, renal, and other cancers; patients may also display clinical features such as cognitive changes, skin changes, macrocephaly (enlarged head) and intestinal polyposis (Ngeow & Eng, 2020). Further, loss of *PTEN* gene functionality results in a spectrum of autosomal dominant disorders known *PTEN* hamartoma tumor syndromes (PHTS); this includes Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome (BRRS), *PTEN*-related Proteus syndrome (PS), and Proteus-like syndrome (PLS) (C. Eng, 2016; Charis Eng, 2016). Autism spectrum disorders (ASDs) with macrocephaly and

adult Lhermitte-Duclos disease (LDD) have also been associated with PHTS (Pilarski, 2019; Stanich & Roberts, 2023).

A diagnosis of PHTS is established by identification of a germline pathogenic variant in *PTEN* via molecular genetic testing. A single-gene sequence analysis will detect up to 80% of CS cases, 60% of BRRS cases, 50% PLS cases, and 20% of PS cases. Deletion and duplication analysis or promoter region analysis may also detect additional cases, but further research is required. In addition to single gene analysis, gene panels or further comprehensive testing may assist with clinical management (C. Eng, 2016). All types of mutations have been reported including missense, nonsense, splice site, insertions, and deletions; therefore, *PTEN* mutation testing usually requires sequence analysis of the entire coding region and deletion/duplication analysis(C. Eng, 2016; Marsh et al., 1999). Mutations have also been reported in the *PTEN* promoter, and a test for mutations in this region of the gene has become clinically available (Stanich & Roberts, 2023). Mingo et al. (2018) recently found that the pathogenicity of frequent *PTEN* mutations targeting the N-terminus "may be related, at least in part, with the retention of *PTEN* in the nucleus. This could be important for the implementation of precision therapies for patients with alterations in the *PTEN* pathway." Germline *PTEN* mutations are found in approximately 20 to 34% of individuals who meet clinical criteria for CS or who meet criteria for genetic testing (Pilarski, 2019; Pilarski et al., 2011; Tan et al., 2011). This number seems to be highly variable as Giorgianni et al. (2013) state that approximately 80% of CS patients have a *PTEN* mutation at locus 10q23.2.

Cowden Syndrome (CS)

Cowden Syndrome is defined by multiple hamartomas with a high risk for benign and malignant tumors in the thyroid, breast, and endometrium. Besides multiple hamartomas in a variety of tissues, patients typically exhibit macrocephaly as well as characteristic dermatologic manifestations, such as trichilemmomas (benign tumors originating from hair follicles) and papillomatous papules (wart-like growths) (Garofola & Gross, 2024). For individuals with CS, the lifetime risk of developing breast cancer is as high as 85%; for thyroid cancer, which is usually follicular carcinoma, the lifetime risk is as high as 35%; finally, for endometrial cancer, the risk may reach as high as 28% (C. Eng, 2016; Charis Eng, 2016). The estimated prevalence of CS is 1 in 200,000 to 250,000, though it is likely underreported (Stanich & Roberts, 2023). Of all PHTS, only CS has been documented to confer a predisposition to cancer; however, it has been suggested that any patients with *PTEN* mutations should be assumed to have cancer risks similar to CS (Stanich & Roberts, 2023).

Bannayan-Riley-Ruvalcaba Syndrome (BRRS)

Bannayan-Riley-Ruvalcaba Syndrome is characterized by hamartomas along with macrocephaly, lipomas, and pigmented penile macules. It is also associated with high birth weight, developmental delay or deficiency, proximal muscle myopathy, joint hypermobility, high palate, and scoliosis (Stanich & Roberts, 2023). Similar mutations in the *PTEN* gene are found in both CS and BRRS, which are now considered phenotypically distinct presentations of a similar genetic abnormality (Lachlan et al., 2007; Marsh et al., 1999).

PTEN-related *Proteus Syndrome (PS)*

PTEN-related Proteus Syndrome is characterized by hamartomatous overgrowth of multiple tissues with hyperostosis (excessive bone growth), vascular malformations, dysregulation of fatty tissues, connective tissue nevi, and epidermal nevi. Phenotypic features of PS are usually present at birth and progress over an individual's lifetime (Hobert & Eng, 2009).

Proteus-like Syndrome (PLS)

Proteus-like Syndrome is undefined but typically refers to individuals with similar clinical features to PS who do not meet the diagnostic criteria (C. Eng, 2016; Charis Eng, 2016; Hobert & Eng, 2009). Overall, limited information is available on PLS. Stanich and Roberts (2023) report that PLS cases typically exhibit "a distinct type of epidermal nevus (also referred to as segmental overgrowth, lipomatosis, arteriovenous malformation, and epidermal nevus (SOLAMEN) syndrome or type 2 segmental Cowden syndrome)."

Autism Spectrum Disorders (ASDs)

Autism Spectrum Disorders are a collection of disorders presenting with common abnormalities associated with social and communication behaviors. A few studies have been published which research the relationship between *PTEN* mutations and ASDs. Schaefer and Mendelsohn (2013) completed a literature review of at least seven different studies and determined that 15 of 318 (5%) individuals with an ASD diagnosis had a pathogenic *PTEN* mutation; further, macrocephaly was present in all 15 cases.

Lhermitte-Duclos Disease (LDD)

Lhermitte-Duclos Disease is a rare disease characteristic of benign tumor development in the granule cells of the cerebellum. It has been reported that "Most LDD patients appear to have a germline loss of the *PTEN* allele and go on to lose the remaining *PTEN* allele at some point, thereby allowing abnormal growth of the granule cells" (Giorgianni et al., 2013). LDD often develops in conjunction with CS, but may also develop singularly (Stanich & Roberts, 2023).

Proprietary Testing

Ambry Genetics, GeneDx, Invitae, and Blueprint Genetics all have genetic tests for *PTEN* mutations. Invitae and Blueprint Genetics both use a next-generation sequencing (NGS) assay that performs full *PTEN* gene sequencing and deletion/duplication analysis (Ambry, 2024; Blueprint, 2024; GeneDx, 2024; Invitae, 2022). The Invitae assay "achieves >99% analytical sensitivity and specificity for single nucleotide variants, insertions, and deletions <15bp [base pair] in length, and exon-level deletions and duplications." The Blueprint Genetics NGS sequencing assay for single genes performs similarly with a >99% specificity and sensitivity for single nucleotide variants, including insertions, deletions, and indels up to 50 bp. The Invitae assay has a clinical sensitivity of 85% for CS, 70% for BRRS, 20-50% for Proteus-Like Syndrome, and 10% for PTEN-related macrocephalic autism spectrum disorder. The clinical sensitivity is not provided by Blueprint Genetics; however, clinical sensitivity is said to vary based on patient clinical presentation (Blueprint, 2024; Invitae, 2022).

GeneDx utilizes a PCR-amplified assay with capillary sequencing to confirm variants of clinical or uncertain significance. Their assay also performs deletion/duplication testing using "either exon-level CGH [comparative genomic hybridization] or MLPA [multiplex ligation-dependent probe amplification]. Confirmation of copy number changes is performed by MLPA, qPCR [quantitative polymerase chain reaction], or repeat aCGH [array CGH] analysis." GeneDx has found that "for those probands with Cowden syndrome, sequence analysis of the coding and promoter regions is expected to detect 47-80% of causative variants, while large deletions and duplications have been reported. For individuals with Bannayan-Riley-Ruvalcaba syndrome, ~60% of causative pathogenic variants will be detected by sequencing while 11% will be detected by deletion/duplication analysis" (GeneDx, 2024). Ambry Genetics also utilizes a PCR-amplified assay with NGS, as well as Sanger Sequencing for any regions "missing or with insufficient read depth coverage for reliable heterozygous variant detection." Their assay also performs gross deletion and duplication analysis, with any copy number changes detected from NGS confirmed by targeted chromosomal microarray or MLPA. Their analytical sensitivity is >99.9% for described mutations in the *PTEN* gene when present and has an identical clinical sensitivity to that described by Invitae (Ambry, 2024).

Clinical Utility and Validity

Yehia et al. (2018) conducted a four-year multicenter study; all participants had suspected BRRS or Cowden/Cowden-like (CS/CS-like) syndromes without *PTEN* mutations. Exome sequencing and targeted analysis was completed on 59 genes supported by the American College of Medical Genetics and Genomics

(ACMG), as well as on 24 additional genes known to be associated with inherited cancer syndromes. "Pathogenic or likely pathogenic cancer susceptibility gene alterations were found in seven of the 87 (8%) CS/CS-like and BRRS patients and included *MUTYH*, *RET, TSC2*, *BRCA1*, *BRCA2*, *ERCC2* and *HRAS*" (Yehia et al., 2018).

Ngeow et al. (2015) estimated the cost effectiveness of each *PTEN* mutation detected in CS-like patients using the PTEN Cleveland Clinic (CC) score. This is a risk assessment tool which helps to estimate an individual's risk of having a *PTEN* mutation. Several questions are answered through an online survey, and a total risk score between 0 and 100 is provided (CC, 2020). The authors found that the cost to detect one *PTEN* mutation was between $3720 to $4573 at a CC score of 15 (CC15). The authors also concluded that "In sensitivity analyses, CC15 is robustly the most cost-effective strategy for probands who are younger than 60 years" (Ngeow et al., 2015).

Isik et al. (2020) researched the genotype to phenotype correlation of patients with *PTEN* mutations. A total of ten molecularly confirmed PHTS patients participated in this study; these participants originated from seven different families. The authors note that "Macrocephaly was the most common clinical finding, involving all patients. This was followed by skin lesions, neurodevelopmental delay, and pathologic cranial magnetic resonance imaging findings" (Isik et al., 2020). Further, sequencing of the *PTEN* gene identified seven different *PTEN* variants; four variants were located in exon five. The authors conclude by highlighting the importance of screening for *PTEN* mutations in patients with macrocephaly, particularly due to an increased risk of cancer.

Jonker et al. (2020) conducted an extensive literature search to identify evidence to support a thyroid carcinoma surveillance program among children with PHTS. They found that children with PHTS were at an increased risk of developing differentiated thyroid carcinoma (DTC), "with 4 years being the youngest age reported at presentation and FTC [follicular thyroid carcinoma] being overrepresented." This finding supports genetic testing for *PTEN* mutations, as that could provide guidance and awareness for potential thyroid cancer development at an early age and reduce morbidity with early diagnosis. "Consensus within the study team was reached to recommend surveillance from the age of 10 years onwards, since at that age the incidence of DTC seems to reach 5%" (Jonker et al., 2020). This recommendation was also supported by Baran et al. (2021), who further retrospectively investigated patients at the Children's Hospital of Philadelphia with a PHTS diagnosis between January 2003 and June 2019. They found "the most common clinical feature at presentation was macrocephaly (85.1%), followed by impaired development (42.0%), skin/oral lesions (30.9%), and autism spectrum disorder (27.2%)," which also appears to corroborate the physical findings of Isik et al. (2020).

Cummings et al. (2022) conducted a systematic review and meta-analysis of the behavioral and psychological features associated with *PTEN* mutations and the prevalence of autism spectrum disorder characteristics. Using a random effects model, the researchers estimated a pooled prevalence of ASD at 25%, with frequent reporting of intellectual disability and developmental delay, including issues that pertained globally, to motor, and to speech and language. Less frequently were mentions of emotional difficulties ad impaired cognitive functioning. This indicates that further research using appropriate comparison groups may provide greater depth of the association with aberrations affecting *PTEN*.

VI. Guidelines and Recommendations

The International Cowden Consortium Operational Criteria for the Diagnosis of Cowden Syndrome *Ver 2000*

The following recommendations were provided:

Pathognomonic criteria

Mucocutaneous lesions

- Trichilemmomas, facial
- Acral keratoses
- Papillomatous papules
- Mucosal lesions

Major criteria

- Breast carcinoma
- Thyroid carcinoma (non-medullary), especially follicular thyroid carcinoma
- Macrocephaly (megalencephaly) (say, ≥97th centile)
- Lhermitte-Duclos disease (LDD)
- Endometrial carcinoma

Minor criteria

- Other thyroid lesions (e.g., adenoma or multinodular goitre)
- Mental retardation (say, IQ
- GI hamartomas
- Fibrocystic disease of the breast
- Lipomas
- Fibromas
- Genito-urinary tumours (e.g., renal cell carcinoma, uterine fibroids) or malformation

According to the International Cowden Consortium, an operational diagnosis of Cowden Syndrome is made if the individual meets any of the following:

(1) Mucocutaneous lesions alone if:

(a) there are six or more facial papules, of which three or more must be trichilemmoma, or
(b) cutaneous facial papules and oral mucosal papillomatosis, or
(c) oral mucosal papillomatosis and acral keratoses, or
(d) palmoplantar keratoses, six or more

(2) Two major criteria but one must include macrocephaly or LDD

(3) One major and three minor criteria

(4) Four minor criteria

According to the International Cowden Consortium, an operational diagnosis of Cowden Syndrome in a family where one person is diagnostic for Cowden syndrome is made if any of the following criteria are met:

(1) The pathognomonic mucocutaneous lesion

(2) Any one major criterion with or without minor criteria

(3) Two minor criteria

Pilarski et al. (2013) published revised evidence-based criteria covering the spectrum of PTEN-related clinical disorders. The revised guidelines define the operational diagnosis of PTEN Hamartoma Tumor syndrome in an individual who meets either one of the following:

- Three or more major criteria, but one must include macrocephaly, Lhermitte-Duclos disease, or gastrointestinal hamartomas; or
- Two major and three minor criteria

The operational diagnosis in a family where one individual meets the revised PTEN Hamartoma Tumor syndrome clinical diagnostic criteria or has a PTEN mutation is as follows (Pilarski et al., 2013):

- Any two major criteria with or without minor criteria; or
- One major and two minor criteria; or
- Three minor criteria

Pilarski et al. (2013) defined the major and minor criteria as follows:

Major Criteria:

- Breast Cancer
- Endometrial cancer (epithelial)
- Thyroid Cancer (follicular)
- Gastrointestinal hamartomas (including ganglioneuromas, adenomas, hyperplastic polyps; ≥3)
- Lhermitte-Duclos disease (adult)
- Macrocephaly (megalocephaly) (i.e., ≥97th percentile, 58 cm in adult women, 60 cm in adult men)
- Macular pigmentation of glans penis
- Multiple mucocutaneous lesions (any of the following):
  - Multiple trichilemmomas (≥3, at least one biopsy proven)
  - Acral keratoses (≥3 palmoplantar keratotic pits and/or acral hyperkeratotic papules) 4 – GT63
  - Mucocutaneous neuromas (≥3)
  - Oral papillomas (particularly on tongue and gingiva), multiple (≥3) OR biopsy proven OR dermatologist diagnosed

Minor Criteria:

- Autism spectrum disorder
- Colon cancer
- ≥3 esophageal glycogenic acanthoses
- Lipomas (≥3)
- Intellectual disability (i.e., IQ ≤75)
- Renal cell carcinoma
- Testicular lipomatosis
- Thyroid cancer (papillary or follicular variant of papillary)
- Thyroid structural lesions (e.g., adenoma, multinodular goiter)
- Vascular anomalies (including multiple intracranial developmental venous anomalies)

National Comprehensive Cancer Network (NCCN)

The NCCN guidelines for Cowden Syndrome/PTEN Hamartoma Tumor syndrome recommend testing in individuals who meet any of the following criteria:

- "Individual from a family with a known *PTE*^{cc} P/LP variant
- Individual with a personal history of Bannayan-Riley-Ruvalcaba syndrome (BRRS)

- Individual meeting clinical diagnostic criteria[mm] for CS/PHTS
- Individual not meeting the clinical diagnostic criteria[mm] for CS/PHTS with a personal history of:
  - Adult Lhermitte-Duclos disease (cerebellar tumors); or
  - Autism spectrum disorder and macrocephaly; or
  - Two or more biopsy-proven trichilemmomas; or
  - Two or more major criteria (one must be macrocephaly); or
  - Three major criteria, without macrocephaly; or
  - One major and ≥3 minor criteria;[nn] or
  - ≥4 minor criteria

- individual with a relative with a clinical diagnosis of CS/PHTS or BRRS for whom testing has not been performed
  - individual must have the following:
    - Any one major criterion, OR
    - Two minor criteria
- *PTEN* P/LP variant detected by tumor genomic testing on any tumor type in the absence of germline analysis[oo]"

The relevant superscripts are captured below.

"[cc]When this gene is included as part of a multi-gene panel, an individual does not need to meet these testing criteria if testing criteria on other testing criteria pages are met.

[nn]If an individual has two or more major criteria, such as breast cancer and nonmedullary thyroid cancer, but does not have macrocephaly, one of the major criteria may be included as one of the three minor criteria to meet testing criteria.

[oo]This should prompt a careful evaluation of personal and family history of the individual to determine the yield of germline sequencing. Somatic PTEN pathogenic/likely pathogenic variants are common in many tumor types in absence of germline pathogenic/likely pathogenic variant" (NCCN, 2024).

Aforementioned major and minor testing criteria are reported below.

"Major Testing Criteria:

- Breast cancer
- Endometrial cancer
- Follicular thyroid cancer

- Multiple GI hamartomas or ganglioneuromas[pp]
- Macrocephaly (megalocephaly) (ie, ≥97%, 58 cm in adult female, 60 cm in adult male)[qq]
- Macular pigmentation of glans penis
- Mucocutaneous lesions[rr] (any of the following):
  - One biopsy-proven trichilemmoma
  - Multiple palmoplantar keratoses
