  - Multifocal or extensive oral mucosal papillomatosis
  - Multiple cutaneous facial papules (often verrucuous)

Minor Testing Criteria:[ss]

- Autism spectrum disorder
- Colon cancer
- ≥3 Esophageal glycogenic acanthoses
- Lipomas
- Intellectual disability (ie, IQ ≤75)
- Papillary or follicular variant of papillary thyroid cancer
- Thyroid structural lesions (e.g., adenoma nodule[s], goiter)
- Renal cell carcinoma
- Single GI hamartoma or ganglioneuroma
- Testicular lipomatosis
- Vascular anomalies (including multiple intracranial developmental venous anomalies)" (NCCN, 2024)

The relevant superscripts are captured below.

[pp]Multiple polyp types are often seen in patients with PHTS, and less commonly may include adenomas, hyperplastic polyps, and other histologies.

[rr]The literature available on mucocutaneous lesions is not adequate to accurately specify the number or extent of mucocutaneous lesions required to be a major criterion for CS/PHTS. Clinical judgment should be used.

[ss]evidence exists in the literature to include fibrocystic disease of the breast, fibromas, and uterine fibroids as diagnostic criteria" (NCCN, 2024)

The NCCN also notes that "Other cancers associated with PTEN but not in the testing criteria include: colorectal, kidney cancer, and melanoma."

In their section outlining the "REVISED CLINICAL DIAGNOSTIC CRITERIA FOR PTEN HAMARTOMA TUMOR SYNDROME," the NCCN recommends the following:

"Operational diagnosis in an individual (either of the following):

1. Three or more major criteria, but one must include macrocephaly, Lhermitte-Duclos disease, or GI hamartomas; or
2. Two major and three minor criteria.

Operational diagnosis in a family where one individual meets revised PTEN hamartoma tumor syndrome clinical diagnostic criteria or has a *PTEN* P/LP variant:

1. Any two major criteria with or without minor criteria; or
2. One major and two minor criteria; or
3. Three minor criteria" (NCCN, 2024).

ClinGen PTEN Expert Panel

This expert panel was convened by the ClinGen Hereditary Cancer Clinical Domain Working Group to develop PTEN-specific genetic variant interpretations. A total of 42 variants were included in the following categories: benign/likely benign (BEN/LBEN), pathogenic/likely pathogenic (PATH/LPATH), uncertain significance (VUS), and conflicting (CONF) ClinVar assertions.

The following variants were considered BEN/LBEN: 9C>G, 903G>A, 1026C>A, 1311T>C, 18A>G, 75G>A, 132C>T, 360A>G, 1104T>G, 79+35C>T, 165-13_165-10delGTTT, 254-39G>T, 801+23G>A, and 1026+32T>G.

The following variants were considered PATH/LPATH: 50_51delAA, 511C>T, 892C>T, 964A>T, 987_990delTAAA, 80-1G>C, 165-1G>A, 493-2A>G, 801+1delG, 802-2A>T, 1026+1G, 103A>G, 389G>A, 407G>A, 517C>T, and 737C>T.

The following variants were considered VUS or CONF: 1170C>T, 209+3A>T, 235G>A, 304_306dupAAA, 1052_1054delTAG, 1171C>T, 764G>A, 44G>A, 78C>T, 209+4_209+7delAGTA, 521A>G (Mester et al., 2018).

American College of Medical Genetics (ACMG)

In 2013, the ACMG published guidelines for identifying the etiology of autism spectrum disorders (ASDs). These guidelines state that "*PTEN* testing [should] be reserved for patients with ASDs with a head circumference above the 98th percentile" (Schaefer & Mendelsohn, 2013). The authors then suggest that of all ASD-related genetic evaluations, about 5% of testing will be due to *PTEN* mutations.

National Organization for Rare Disorders (NORD)

The NORD asserts that "The primary findings in PHTS include increased risk for certain types of cancer, benign tumors and tumor-like malformations (hamartomas) and neurodevelopmental disorders. The symptoms of PHTS vary greatly from person to person and can develop at any age." However, some noteworthy sign and symptoms that indicate PTEN genetic testing are captured below.

- "A small percentage of adults develop a rare tumor known as a cerebellar dysplastic gangliocytoma (Lhermitte-Duclos disease). Symptoms of Lhermitte-Duclos disease include increased intracranial pressure, impaired ability to coordinate voluntary movements (ataxia) and seizures. It is rare when a person with adult-onset Lhermitte-Duclos does not have an underlying PTEN variant, and observing this tumor type is an automatic indicator for PTEN genetic testing."
- "Macrocephaly (large head size) is found in 94% of measured patients with PHTS and can be a helpful screening tool to identify patients for PTEN genetic testing. In most patients, large head size is caused by overgrowth of brain tissue. The head shape may also be longer than average relative to width in some individuals (dolicocephaly)."

The authors go further to state that "Sotos syndrome is a rare genetic disorder characterized by excessive growth that occurs prior to and after birth (prenatally and postnatally)….The overlap of neurodevelopmental disabilities and macrocephaly in both PHTS and Sotos syndrome indicates the need for genetic testing to avoid misdiagnosis" (NORD, 2023). Genetic counseling is also suggested.

The authors report that "A diagnosis of PHTS may be suspected based upon a thorough clinical evaluation, a detailed patient history and the presence of characteristic findings. Recently, a variant risk calculator has been developed which can estimate the risk for adults to have a PTEN variant based on their personal history characteristics; this tool is available online at https://www.lerner.ccf.org/gmi/ccscore/. The diagnosis can only be confirmed when a variant of the PTEN gene is identified (NORD, 2023).

The current suggested screening regimens by age include:

"**Children (under age 18)**

- Yearly thyroid ultrasound starting at 7 years of age
- Yearly skin check with physical examination
- Consider neurodevelopmental evaluation

Adults

- Monthly breast self-examination starting at age 18 years
- Yearly thyroid ultrasound and dermatologic evaluation
- Females: breast screening (at minimum mammogram) yearly beginning at age 35; MRI may also be incorporated
- Females: consider endometrial cancer screening starting at age 35 years. Personalized management including endometrial biopsy every 1-2 years and transvaginal ultrasound as needed (postmenopausal)
- Colonoscopy beginning at age 35 (unless symptomatic or close relative with colon cancer before age 40 years); colonoscopy frequency every 5 years; more frequently if symptomatic or polyps are found
- Biannual (every other year) renal imaging (CT or MRI preferred) beginning at age 40

For patients with a family history of a particular cancer type, screening may be considered 5-10 years prior to the youngest diagnosis in the family. For example, a patient whose mother developed breast cancer at 30 may begin breast surveillance at age 25-30" (NORD, 2023).

American College of Gastroenterology (ACG)

In 2015, the ACG published guidelines on genetic testing and management of hereditary gastrointestinal cancer syndromes. These guidelines clearly state that the "Genetic evaluation of a patient with possible CS should include testing for *PTEN* mutations… CS is caused by mutations in the *PTEN* gene. Once a disease-causing mutation is identified in a patient with CS or related conditions, other family members should undergo mutation-specific testing to determine whether the disease is present or absent so that appropriate surveillance can be undertaken" (Syngal et al., 2015). Further, the ACG also notes that "Surveillance in affected or at-risk CS patients should include screening for colon, stomach, small bowel, thyroid, breast, uterine, kidney, and skin (melanoma) cancers (conditional recommendation, low quality of evidence)" (Syngal et al., 2015).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-

database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81321	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome) gene analysis; full sequence analysis
81322	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome) gene analysis; known familial variant
81323	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome) gene analysis; duplication/deletion variant
0235U	PTEN (phosphatase and tensin homolog) (eg, Cowden syndrome, PTEN hamartoma tumor syndrome), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® PTEN Analysis Lab/Manufacturer: Variantyx Inc

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing for Rett Syndrome

Policy Number: AHS – M2088 – Genetic Testing for Rett Syndrome	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Rett syndrome (RTT) is a rare X-linked neurodevelopmental disorder that occurs almost exclusively in females and is usually caused by mutations in the methyl CpG binding protein 2 (*MECP2*) gene (Amir et al., 1999). It is characterized by normal early growth and development, followed by regressions in development, walking, language, and purposeful use of the hands, along with slowed brain and head growth, distinctive hand movements, seizures, and intellectual disability (Colvin et al., 2004; Hagberg et al., 1983; Leonard et al., 2017; Naidu et al., 1986; Neul et al., 2010; Rett, 1966).

Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS – M2176	Testing for Developmental Delay

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For a child with developmental delay/intellectual disability **and** signs/symptoms of Rett syndrome (RTT), but for whom there is uncertainty in the clinical diagnosis, genetic testing of *MECP2*, *CDKL5*, and/or *FOXG1* to confirm a diagnosis of RTT **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For all other situations not described above (e.g., prenatal screening, testing of family members), genetic testing for RTT **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
AAN	American Academy of Neurology
AAP	American Academy of Pediatrics
ACMG	American College of Medical Genetics
ASD	Autism spectrum disorder
BDNF	Brain-derived neurotrophic factor
CDKL5	Cyclin-dependent kinase-like 5
CMS	Centers for Medicare and Medicaid
CNS	Child Neurology Society
CPS	Canadian Pediatric Society
CTNNB1	*Catenin beta 1*
DNA	Deoxyribonucleic acid
FDA	Food and Drug Administration
FOXG1	*Forkhead box g1*
GABA	Gamma-aminobutyric acid
GDD	Global developmental delay
LDT	Laboratory developed test
MDS	*Methyl CPG binding protein* duplication syndrome
MECP	*Methyl CPG binding protein*
miRNA	Micro ribonucleic acid
MLPA	Multiplex ligation-dependent probe amplification
NGS	Next generation sequencing
qPCR	Quantitative polymerase chain reaction
REST	Rett evaluation of symptoms and treatments
RNA	Ribonucleic acid
RTT	Rett Syndrome
SCN1A	*Sodium voltage-gated channel alpha subunit 1*

WDR45	*WD repeat domain 45*
XLID	X-linked intellectual disability

V. Scientific Background

Rett syndrome (RTT) is a severe neurodevelopmental disorder which affects approximately 1:10,000 live female births in the United States annually (Hagberg, 1985; NORD, 2023). It is a prominent cause of severe intellectual disability in women, accounting for up to 10% of cases inherited genetically (Armstrong, 1997). Originally thought to be lethal in males (Amir et al., 1999; Chahil et al., 2018; Franco & Ballabio, 2006), RTT has been identified in up to 1.3% of male patients with mental retardation (Villard, 2007) and can be associated with a more severe phenotype (Zhang et al., 2017). These males have either an extra X-chromosome (Klinefelter syndrome) or somatic mosaicism of the *MECP2* variant. Reichow et al. (2015) claim to have published the first review of male RTT data in 2015, and they only identified a total of 57 published cases.

Rett syndrome can be inherited as an X-linked dominant disorder; however, more than 99% of cases result from a de novo pathogenic mutation in the *methyl CpG binding protein 2* (*MECP2*) gene (Amir et al., 1999; Christodoulou & Ho, 1993), a transcriptional regulator located on the X chromosome. More than 200 mutations in *MECP2* have been associated with RTT (Suter et al., 2014). Analysis of parental origin of the mutated *MECP2* gene in sporadic cases of RTT showed that 94.4% of mutations were from paternal origin, 90.6% of which were point mutations; further, 5.6% of mutations were from maternal origin (Zhang et al., 2012). This may explain the high occurrence of RTT in females. MECP2 is a multifunctional protein which interprets DNA methylation and regulates chromatin architecture, gene transcription, and RNA splicing (Sun et al., 2018). The complex upstream and downstream pathways of *MECP2* involve microRNAs and neurotrophic factors, such as GABA and BDNF (Kang et al., 2014). Transcriptome level analysis in tissues derived from RTT patients report dysregulations in dendritic connectivity and synapse maturation, mitochondrial dysfunction, and glial cell activity (Shovlin & Tropea, 2018). Researchers have identified two individuals with an RTT diagnosis who lacked a mutation in the *MECP2* gene but had a mutation in other genes previously unassociated with RTT: *CTNNB1* and *WDR45* (Percy et al., 2018).

The *MECP2* gene is critical for neuronal maturation (Fukuda et al., 2005; Smrt et al., 2007), and its deficiency results in impaired dendritic morphogenesis and reduced dendritic spine numbers (Chapleau et al., 2009; Kishi & Macklis, 2010). This results in dysfunctional synaptic transmission and neural network activity (Sun et al., 2018), affecting successive stages of brain development, including prenatal neurogenesis, postnatal development of synaptic connections and function, experience-dependent

synaptic plasticity, and maintenance of adult neural function, including sensory integration (Feldman et al., 2016).

The clinical picture of RTT is characterized by a broad clinical spectrum of signs and symptoms (Pini et al., 2016) and a distinctive course of apparent normal development for the first six to 18 months of life, followed by characteristic developmental stagnation and loss of acquired skills, including loss of intellectual functioning, loss of acquired fine and gross motor skills and communication (Colvin et al., 2004; Dolce et al., 2013; Hagberg et al., 1983; Leonard et al., 2017; Naidu et al., 1986; Neul et al., 2010; Rett, 1966). Purposeful use of the hands is often replaced by repetitive stereotypical hand movements (Dy et al., 2017; Elian & de, 1996; Goldman & Temudo, 2012). Other clinical observations include deceleration of head growth, seizures, disturbed breathing patterns, scoliosis, growth retardation, and gait apraxia (Cianfaglione et al., 2015).

Despite a period of apparently normal early development, the profound neurological regressions characteristic of RTT have been found to result from *MECP2*-related defects in the establishment and refinement of early neural circuits and, later, cortical plasticity (Feldman et al., 2016). Subtle signs, such as hypotonia, jerkiness in limb movement, and limited social interaction can be present during early infancy (Ip et al., 2018).

The severity and rate of progression of this disease can vary with several recognized atypical variants. The milder forms (Zappella) present with less severe regression and milder expression of the clinical characteristics of RTT. In the most severe forms, there is no normal development period (Neul et al., 2010). Both genetic and clinical variants of RTT are associated with distinct electrophysiological profiles reflecting how genetic dysregulation of synapse formation results in differences in neuronal network architecture (Sun et al., 2018) and varying clinical phenotypes (Keogh et al., 2018). The pattern of X-chromosome inactivation can also influence the severity of the clinical disease (Archer et al., 2007; Weaving et al., 2003).

Mutations in the upstream cyclin-dependent kinase-like five (*CDKL5*) gene cause an early seizure (Hanefield) variant of the RTT phenotype (Bahi-Buisson et al., 2008), and mutations in the forkhead box G1 (*FOXG1*) gene have been found in the congenital variant (Rolando) (Ariani et al., 2008). Two cases of females with pathogenic de novo mutations in *SCN1A*, which usually leads to Dravet syndrome, but fulfill the diagnostic criteria for classic RTT have also been reported (Henriksen et al., 2018). In males, *MECP2* duplication phenotypically presents with infantile hypotonia, recurrent respiratory infections, and severe mental retardation (Villard, 2007).

Fu et al. (2020) published a set of "consensus guidelines" with input from several clinical sites, Rett Syndrome-focused centers, two patient advocacy groups, and Rett

Syndrome clinical specialists. Although this guideline focuses on "management" of Rett Syndrome, the guideline does comment on the genetics of Rett Syndrome. The guideline remarks that "nearly" all individuals with Rett Syndrome (RTT) have a loss-of-function mutation on the *MECP2* and that these mutations are "almost always" *de novo* (and thereby not expected to recur in families). Two other genes (*CDKL5* and *FOXG1*) are named as possible causes of RTT. The guideline does not note any specific treatments based on type of mutation, though two other genes (*CDKL5* and *FOXG1*) are named as possible causes of RTT. However, the guideline states that "Alterations in *MECP2*, *CDKL5* and *FOXG1* should be considered in all individuals, male and female, with developmental delays and intellectual disability" (Fu et al., 2020). This consensus guideline also notes there is hope for disease-modifying therapy as reversing symptoms in mice has occurred in a clinical research context (Fu et al., 2020).

Banerjee et al. (2019) published a paper titled "Towards a Better Diagnosis and Treatment of Rett Syndrome: A Model" summarizing the developments in the diagnosis and treatment of Rett syndrome over the past 50 years. They note that the first gene therapy trial for *MECP2* "was modelled after the successful (i.e., improved survival and motor functions) single dose intravenous adeno-associated virus serotype 9 delivery of complementary DNA." Even with promising gene therapy techniques, the authors note that the field has challenges. "The Rett syndrome field is experiencing the same challenges as other neurodevelopmental disorders pursuing neurobiologically based treatments: inadequate outcomes and measures of response." The authors also comment on the complexity of the *MECP2* mutation's role in the syndrome, "*MECP2* mutations is supportive, but not confirmatory because of the limited genotype-phenotype correlations in Rett syndrome" (Banerjee et al., 2019).

Confirmation of the genetic diagnosis can improve the medical management of the patient. It can also end the diagnostic odyssey, provide a general idea of prognosis for the patient, and/or provide closure to the family (Mroch et al., 2012). Complex neurodevelopmental disorders need multi-disciplinary treatment approaches for optimal care. The clinical effectiveness of treatments is limited in patients with rare genetic syndromes and multisystem morbidity such as RTT; single drug strategies may not be sufficient, due to the multiple overlapping physiological systems affected (Singh & Santosh, 2018).

Functional performance for self-care, upper extremity function, and mobility in RTT patients may relate to the type of mutation. Knowledge of these relationships is useful for developing appropriate rehabilitation strategies and prognosis (Pidcock et al., 2016).

Of the clinical criteria for RTT, loss of hand skills was the most significant clinical predictor of a positive genetic test for mutations of a *MECP* gene in females. Gait abnormalities and stereotypic hand movements were also strong predictors of a positive genetic test for mutations of *MECP*. Language delay is the least specific of the major criteria (Knight et al., 2016). A reliable and single multidimensional questionnaire, the Rett Evaluation of Symptoms and Treatments (REST) Questionnaire, is being developed to combine physiological aspects of the disease obtained using wearable sensor technology, along with genetic and psychosocial data to stratify patients and streamline the care pathway (Santosh et al., 2017).

Clinical Utility and Validity

Lallar et al. (2018) used Sanger sequencing to diagnose suspected RTT cases. Participants were divided into two groups: Group one was comprised of females with symptoms of classical and atypical RTT, and Group two was comprised of females with other "Rett like features" that did not fit into the first category. *MECP2* mutations were identified in 74% of females in Group one and in zero percent of females in Group two; females in Group one with classical RTT had a mutation detection rate of 93% (Lallar et al., 2018). This shows that Sanger sequencing is efficient in detecting RTT in patients with the classical form of the disease.

Sheinerman et al. (2019) used brain-enriched microRNAs (miRNAs) to identify miRNA biomarkers of RTT; for this study, 30 patients with RTT were matched with 30 healthy controls of similar age (Sheinerman et al., 2019). Results showed that miRNAs identified RTT patients with 85-100% sensitivity when compared to controls; further, the researchers determined that "the dynamics in levels of miRNAs appear to be associated with disease development (involvement of liver, muscle and lipid metabolism in the pathology)" (Sheinerman et al., 2019). These results suggest that circulating miRNAs could be used to measure RTT disease progression or individual response to treatment.

In at least 95% of Rett syndrome cases, the cause is a de novo mutation in the child; *MECP2* variants are rarely inherited from a carrier mother with a germline mutation in *MECP2*, in whom favorable skewing of X-chromosome inactivation results in minimal to no clinical findings. When the mother is a known carrier, inheritance follows an X-linked dominant pattern with a 50% risk to her offspring of inheriting the *MECP2* variant (Christodoulou & Ho, 1993).

A mutation in *MECP2* does not necessarily equate to a clinical diagnosis of RTT. *MECP2* mutations have also been reported in other clinical phenotypes, including individuals with an Angelman-like picture, nonsyndromic X-linked intellectual disability, autism, in males as PPM-X syndrome (an X-linked genetic disorder characterized by

psychotic disorders, parkinsonism, and intellectual disability), and most commonly as neonatal encephalopathy (Liyanage & Rastegar, 2014; Suter et al., 2014; Williamson & Christodoulou, 2006).

Recent expert opinion in the United Kingdom concluded that genetic testing for all children with unexplained global developmental delay (GDD) should be first-line if an exogenous cause is not already established. All patients, irrespective of severity of GDD, should have investigations for treatable conditions. The yield for treatable conditions is higher than previously thought and that investigations for these conditions should be considered as first-line. Additional second-line investigations can be led by history, examination, and developmental trajectories (Mithyantha et al., 2017).

Vidal et al. (2017) have utilized next generation sequencing (NGS) in a total of 1577 patients with RTT-like clinical diagnoses or patients with potential RTT genetic mutations as determined previously by Sanger Sequencing. Of the 1577 patients with RTT-like clinical diagnoses, the NGS method was able to confirm the RTT diagnosis in 477 patients (about 30%). Further, "Positive results were found in 30% by Sanger sequencing, 23% with a custom panel, 24% with a commercial panel and 32% with whole exome sequencing," suggesting that NGS is a competitive diagnostic RTT tool compared to the aforementioned methods (Vidal et al., 2017).

Vidal et al. (2019) used multiplex ligation-dependent probe amplification (MLPA) in the *MECP2* gene of 21 RTT patients to identify deletions of varying sizes; these researchers identified both total and partial deletions of the *MECP2* gene in each patient, with identified partial deletions ranging from 1,235 bp to 85 kb. Breakpoints were delineated by DNA-qPCR; the results have allowed the researchers to "propose a genotype–phenotype correlation" which will assist in appropriate genetic counseling (Vidal et al., 2019).

Seventy-two classical Rett syndrome (RTT) female patients were included in a cohort study by Khajuria et al. (2020) to analyze exons two-four of *MECP2* gene by Sanger sequencing for sequence variations followed by deletion/duplication analysis using Multiplex Ligation-dependent Probe Amplification (MLPA). Patients were defined as classical when they showed signs of partial or complete loss of acquired purposeful hand skills, partial or complete loss of acquired spoken language, gait abnormalities, impaired or absence of ability to walk, and stereotypic hand movements. Through Sanger Sequencing, *MECP2* sequence variations were identified in 90.3% of patients. With further evaluation using MLPA, large deletions of *MECP2* were identified in 9.7% of the patients, which were negative on DNA sequencing. MLPA analysis increased the detection rate of *MECP2* sequence variants identified in patients from 90.3% to 98.6%.

The authors emphasize that "MLPA analysis of *MECP2* is crucial and needs to be performed in classical RTT patients. Large deletions can be missed using DNA sequencing and reaffirms the view that large *MECP2* deletions are an important cause of classical RTT" (Khajuria et al., 2020). Xiol et al. (2021) performed a clinical review of technological advances in RTT genetics. The authors review summarizes that our understanding of Rett syndrome has evolved "towards a spectrum of overlapping phenotypes with great genetic heterogeneity." The authors note that advances in genetic diagnosis have been impacted by the rise in next generation sequencing (NGS) and whole genome sequencing. Of note are the "90 causative genes" and "significantly overlapping phenotypes" involved in RTT spectrum disorders. To achieve an accurate and quick diagnosis of Rett syndrome, the authors strongly recommend simultaneous multiple gene testing and thorough phenotypic characterization.

Bassuk (2021) published a paper concerning methyl-CpG-binding protein 2 (*MECP2*) and its encoding of an epigenetic reader, MeCP2. The author notes that loss of function of the epigenetic reader may be a factor in RTT, but also that "locus duplications also cause a severe neurodevelopmental disorder, *MECP2* duplication syndrome (MDS)." This suggests that MeCP2 (the protein) could be what is called a "Goldilocks protein," that is, one that requires an activity level that is precise. Using the re-expression of the MeCP2 protein in mouse models, the author presents a case for the development of therapeutic interventions in people and the restoration of the desirable phenotypes. However, gene therapy must be approached with caution, as restoring function to the protein still carries the risk of "MDS overexpression phenotypes" (Bassuk, 2021).

Zade et al. (2024) studied the characteristics of RTT in Ireland. Twenty-five families completed questionnaires about the demographics, genetics, family history, clinical features, and regression. "The results show that Irish individuals with RTT have comparable presentation with respect to individuals in other countries." Importantly, "one of the main findings of this study is the limited genetic information available to individuals to support the clinical diagnosis of RTT." The authors emphasize that the study "highlights the importance of having a swift access to genetic testing to sharpen the characterization of the phenotype and increase the visibility of Irish individuals in the international RTT community" (Zade et al., 2024).

VI. Guidelines and Recommendations

American Academy of Pediatrics (AAP)

A 2014 policy statement from the AAP recommends *MECP2* mutation analysis for females with microcephaly or deceleration of head growth and other features of Rett

syndrome, or who present with stereotypical hand-wringing movements and developmental regression. *MECP2* gene mutations are extremely rare in males but may be considered in boys who present with clinical features of Rett syndrome or severe developmental regression (Moeschler & Shevell, 2014).

Complete *MECP2* deletion, duplication, and sequencing study is also recommended for females with intellectual disability or global developmental delay for whom the chromosomal microarray, specific metabolic testing, and fragile X genetic testing did not produce a diagnosis (Moeschler & Shevell, 2014).

The above guideline was reaffirmed in 2019 (AAP, 2019).

The AAP also published a guideline focusing on children with autism spectrum disorder (ASD). In it, they note that other disorders may meet certain criteria for ASD. However, the AAP notes that these disorders should prompt the "appropriate targeted testing" (or referral to a specialist). The AAP lists an example of Rett Syndrome, stating that "for example, a girl with significant developmental delays, deceleration in head growth velocity, and characteristic midline hand movements should prompt genetic testing for a mutation or deletion or duplication of *MECP2*, the gene implicated in Rett syndrome." In Supplemental Table 13, they list the following findings as representative of Rett Syndrome: "Deceleration of head growth velocity, acquired microcephaly, loss of purposeful hand use, prominent hand stereotypies (especially hand wringing or clasping), apraxia, hyperventilation or breath-holding, seizures" (Hyman et al., 2020).

Canadian Pediatric Society (CPS)

The CPS supports the guidelines mentioned above by the AAP. The CPS stated that "According to the AAP. . . *MECP2* molecular analysis should be ordered when characteristic symptomatology is present (i.e., initially normal development followed by loss of speech and purposeful hand use, stereotypical hand movement, gait abnormalities) or for moderately-to-severely affected girls" (Belanger & Caron, 2018).

RettSearch

The AAP has not provided recommendations on when to use *CDKL5* or *FOXG1* testing. RettSearch members, representing the majority of the international clinical RTT specialists, "participated in an iterative process to come to a consensus on a revised and simplified clinical diagnostic criteria for [RTT]" (Neul et al., 2010). This group provided clarifications for diagnosis of classic or typical RTT and atypical RTT and

provided guidelines for molecular evaluation of specific variant forms of RTT. The authors define RTT as a clinical diagnosis based on distinct clinical criteria, independent of molecular findings. Presence of a *MECP2* mutation is not sufficient for the diagnosis of RTT. Neul et al. (2010) proposed three distinct criteria for diagnosis of variant forms of RTT: preserved speech variant (Zapella variant), early seizure variant (Hanefeld variant) and congenital variant (Rolando variant); identifying the molecular genetics of each variant was also recommended. In the Zapella variant, the molecular analysis for *MECP2* was recommended. In Hanefeld and Rolando variants, recommended mutations for analysis were in the *CDKL5* and *FOXG1* genes, respectively. Further, it was stated that patients found negative for *MECP2* mutations and who have a strong clinical diagnosis of RTT should be considered for further screening for the *CDKL5* gene if early onset seizures or *FOXG1* gene congenital features (e.g., severe postnatal microcephaly) are present (Neul et al., 2010).

American College of Medical Genetics (ACMG)

In 2013, the ACMG revised its evidence-based guidelines for clinical genetics evaluation of autism spectrum disorders. Testing for *MECP2* mutations is recommended as part of the diagnostic workup of females who present with an autistic phenotype. Routine *MECP2* testing in males with autistic spectrum disorders is not recommended. However, when features of *MECP2* duplications (e.g., drooling, recurrent respiratory infections, hypotonic facies) are present, *MECP2* duplication testing in boys with autism and such features may be considered (Schaefer & Mendelsohn, 2013).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for

Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81302	MECP2 (methyl CpG binding protein 2) (eg, Rett syndrome) gene analysis; full sequence analysis
81303	MECP2 (methyl CpG binding protein 2) (eg, Rett syndrome) gene analysis; known familial variant
81304	MECP2 (methyl CpG binding protein 2) (eg, Rett syndrome) gene analysis; duplication/deletion variants
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)
0234U	MECP2 (methyl CpG binding protein 2) (eg, Rett syndrome), full gene analysis, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® MECP2 Analysis Lab/Manufacturer: Variantyx Inc

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genetic Testing of CADASIL Syndrome

Policy Number: AHS – M2069 – Genetic Testing of CADASIL Syndrome	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a genetic small vessel disease in which mutations in *notch receptor 3* (*NOTCH3*), located on chromosome 19 (Joutel et al., 1996), result in a clinical syndrome of adult-onset migraines (frequently with aura), progressive strokes, and cognitive decline in adults leading to severe functional impairment by the seventh decade of life (Opherk et al., 2004; Zhu & Nahas, 2016).

II. Related Policies

Policy Number	Policy Title
AHS-M2145	General Genetic Testing, Germline Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have received genetic counseling and who have received a clinical diagnosis of cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) or for whom a definitive diagnosis cannot be made without genetic testing, genetic testing of *NOTCH3* to confirm the diagnosis of CADASIL **MEETS COVERAGE CRITERIA**.

2) For asymptomatic individuals who have a first- or second-degree relative (see Note 1) diagnosed with CADASIL syndrome, the following genetic testing **MEETS COVERAGE CRITERIA**:

Genetic Testing of Mitochondrial Disorders

Policy Number: AHS – M2085 – Genetic Testing of Mitochondrial Disorders	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Mitochondrial disease refers to a heterogeneous group of disorders caused by dysfunctional mitochondria; the organelles responsible for oxidative phosphorylation within the cell. Mitochondrial diseases are classified according to the primary genetic defect, including those affecting respiratory chain proteins or ancillary proteins, mitochondrial RNA translation defects, inner membrane lipid defects, mutations causing depletion of mitochondrial DNA, or mutations to mitochondrial dynamics. Tissues with high energy demands, such as brain, heart, and skeletal muscle, are most affected by mitochondrial diseases (O'Ferrall, 2024). As a result, mitochondrial encephalopathy and cardiomyopathy are the most prominent manifestations (Meyers et al., 2013). Some examples of mitochondrial disorders include mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), myoclonic epilepsy and ragged-red-fibers (MERRF), chronic progressive external ophthalmoplegia (CPEO), Kearns-Sayre syndrome (KSS), and maternally inherited Leigh syndrome (MILS) (Hatakeyama & Goto, 2016).

When pursuing genetic testing for mitochondrial disorders, genetic counseling is strongly recommended.

II. Related Policies

Policy Number	Policy Title

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) As an alternative to muscle biopsy for individuals with clinical signs and symptoms consistent with a specific mitochondrial disorder, but for whom a definitive diagnosis cannot be made without genetic testing, genetic testing to confirm the diagnosis of a mitochondrial disorder **MEETS COVERAGE CRITERIA**.

2) For individuals who are strongly suspected of having a mitochondrial disorder but who do not have symptomology associated with a specific mitochondrial condition, genomic sequencing and large deletion detection of the entire mitochondrial genome, with heteroplasmy detection, **MEETS COVERAGE CRITERIA**.

3) For individuals who are strongly suspected of having a mitochondrial disorder but who do not have symptomology associated with a specific mitochondrial condition, genetic testing for nuclear encoded mitochondrial genes (in conjunction with or after testing for variants in the mitochondrial genome) **MEETS COVERAGE CRITERIA.**

4) For the diagnosis of mitochondrial DNA (mtDNA) depletion syndromes, quantification of mtDNA in tissue **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) The combination of mitochondrial genome testing with nuclear genome testing with whole genome sequencing (e.g., Genomic Unity ® Whole Genome Analysis), **DOES NOT MEET COVERAGE CRITERIA**.

6) For all other situations not discussed above, genetic testing for mitochondrial disorders **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ACGS	Association for Clinical Genomic Science
BGS	Bigenomic sequencing
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CM	Cardiomyopathy
CMS	Centers for Medicare and Medicaid

COX10	*Cytochrome c oxidase*
CPEO	Chronic progressive external ophthalmoplegia
DNA	Deoxyribonucleic acid
dThd	Crystalline nucleoside of thymine
EAN	European Academy of Neurology
ES	Exome sequencing
FDA	Food and Drug Administration
GLUL	*Glutamine synthetase*
KSS	Kearns-Sayre syndrome
LDTs	Laboratory-developed tests
LHON	Leber hereditary optic neuropathy
LR-PCR	Long range polymerase chain reaction
MD	Mitochondrial disease
MELAS	Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes
MERRF	Myoclonic epilepsy and ragged-red-fibers
MILS	Maternally inherited Leigh syndrome
MNGIE	Mitochondrial neurogastrointestinal encephalomyopathy
MPS	Massively parallel sequencing
MRPS23	*Mitochondrial ribosomal protein S23*
mtDNA	Mitochondrial deoxyribose nucleic acid
MT-RNR1	*Mitochondrially encoded 12S ribosomal RNA*
NADH	Nicotinamide adenine dinucleotide
NAMDC	North American Mitochondrial Disease Consortium
NARP	Neuropathy, ataxia, and retinitis pigmentosa
nDNA	Nuclear deoxyribose nucleic acid
NGS	Next-generation sequencing
nWES	Nuclear whole-exome sequencing
ONT	Oxford Nanopore Technologies
PEO	Progressive external ophthalmoplegia
PGT	Preimplantation genetic testing
PMD	Primary mitochondrial disease
PNPLA4	*Patatin like phospholipase domain containing 4*
POLG	*Polymerase gamma*
POLG1	*Deoxyribose nucleic acid polymerase subunit gamma*
Q10	Coenzyme Q10 (also known as ubiquinone)
QRSL1	*Glutaminyl-trna synthase (glutamine-hydrolyzing)-like 1*
RMND1	*Required for meiotic nuclear division protein 1*
RNA	Ribonucleic acid

TP	Thymidine phosphorylase
VUS	Variant of uncertain significance
WES	Whole-exome sequencing
WGS	Whole-genome sequencing

V. Scientific Background

Mitochondrial diseases are generally inherited and present with an elaborate genetic makeup (Lightowlers et al., 2015). Several different types of mitochondrial diseases and resulting ailments exist which include "mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS), myoclonic epilepsy and ragged-red-fibers (MERRF), chronic progressive external ophthalmoplegia (CPEO), Kearns-Sayre syndrome (KSS), neuropathy, ataxia, and retinitis pigmentosa (NARP), maternally inherited Leigh syndrome (MILS), and Leber hereditary optic neuropathy (LHON)" (Hatakeyama & Goto, 2016). These diseases can be caused by mutations in either nuclear DNA (nDNA) or mitochondrial DNA (mtDNA); many different mitochondrial disease mutations have been identified, but clinical symptoms are extremely variable and may even differ between patients carrying the same mtDNA mutation (Hatakeyama & Goto, 2016). Symptoms present in several areas of the body, including the central nervous system, cardiovascular system, gastrointestinal system, endocrine system, and neuromuscular system (Hatakeyama & Goto, 2016). Clinical differences depend on age of onset, affected organ or tissue, and disease progression. Phenotypic variability and severity can create challenges when diagnosing affected patients (O'Ferrall, 2024).

Pathogenic variants in more than 300 genes have been associated with mitochondria-related disorders (Thompson et al., 2019). For example, infantile onset of mitochondrial diseases with multiple mitochondrial respiratory chain defects results from mutation(s) in the Required for Meiotic Nuclear Division protein 1 (*RMND1*) gene (Ng et al., 2016). Further, a pathogenic variant in the ubiquinone biosynthesis protein (*COQ4)* gene has been affiliated with mitochondrial disease development (Lightowlers et al., 2015; Ling et al., 2019). Patients with mutations in the NADH dehydrogenase mitochondrial (*MT-ND1* and *NDUF)* genes share phenotypic and genotypic correlations in Leigh syndrome (Sofou et al., 2018). The individual symptoms are nonspecific, and symptom patterns can overlap considerably. As a result, a patient often cannot be easily classified into one particular syndrome (Chinnery, 2014).

Previously, the prevalence of mitochondrial diseases was considered low. With the advent of advanced genetic analysis tools, numerous studies now report a higher incidence of mitochondrial-associated mutations. A meta-analysis of the prevalence of

the three primary mtDNA mutations that cause LHON in Europe shows a prevalence of approximately 1:45,000 (Mascialino et al., 2012). A longitudinal study in Sweden reports an incidence of mitochondrial encephalomyopathies, in general, at 1:11,000, and an incidence of infantile mitochondrial myopathy with cytochrome C oxidase deficiency at 1:51,000. The authors conclude that "mitochondrial encephalomyopathies are relatively common neurometabolic disorders in childhood" (Darin et al., 2001). A 2015 study in the United Kingdom reports that "the total prevalence of adult mitochondrial disease, including pathogenic mutations of both the mitochondrial and nuclear genomes (≈1 in 4,300), is among the commonest adult forms of inherited neurological disorders" (Gorman et al., 2015). An Australian study estimates a "minimum birth prevalence of 13.1/100 000 or 1/7634 for respiratory chain disorders with onset at any age" (Skladal et al., 2003).

Barca et al. (2020) evaluated the phenotypic and molecular characteristic of 666 participants in the North American Mitochondrial Disease Consortium (NAMDC) aiming to better understand mitochondrial diseases in North America. Multisystemic disorder was the most common diagnosis (113 participants), compared to classical mitochondrial syndrome. Leigh syndrome (97 participants) and MELAS (71 participants) were the most frequent classical syndromes. Pathogenic variants in mtDNA, with the most common variants being *POLG1* and *PDHA1*, were more common than pathogenic gene variants (Barca et al., 2020).

The figure below (taken from O'Brien et al. (2014)) gives examples of classical phenotype mitochondrial diseases along with the clinical features and molecular genetics associated with each disorder.

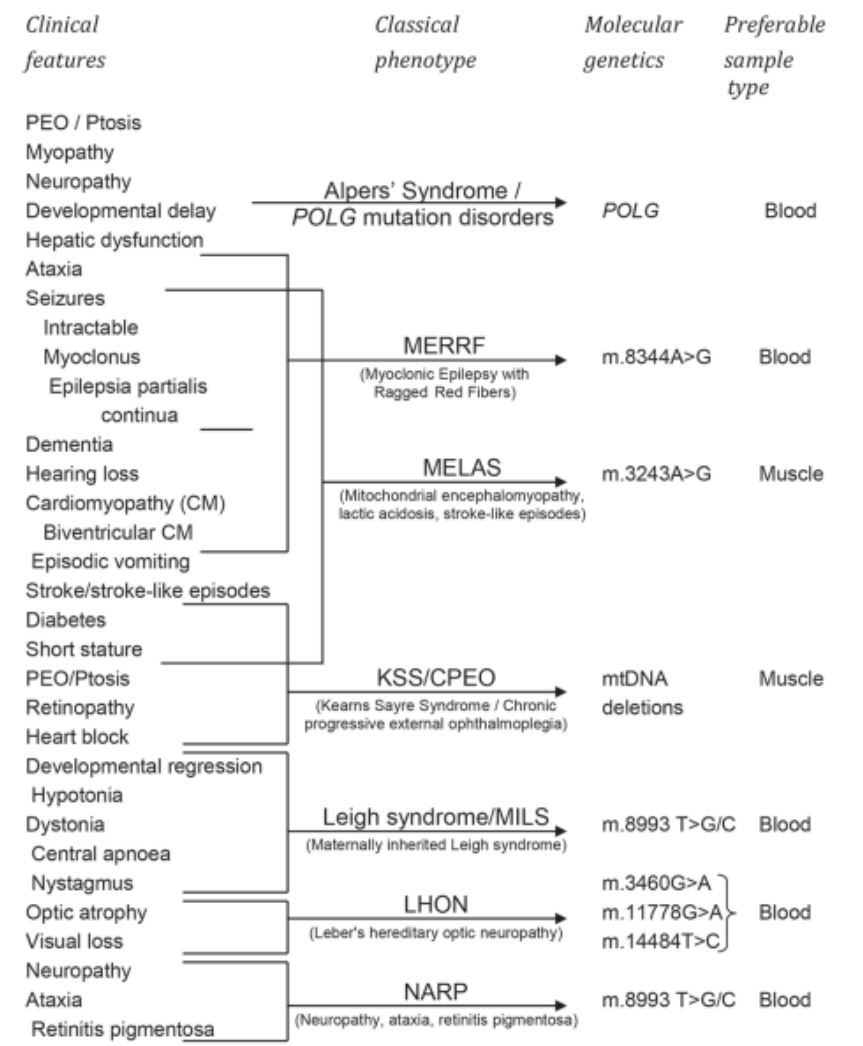

Figure 1. Algorithm for mitochondrial mutation analysis. Key clinical features, although not specific for each disease, can be used to select pertinent genetic tests and hence improve the efficiency of the analysis process.

The evaluation and diagnostic approach for a mitochondrial disorder varies according to age, clinical phenotype, and presumed inheritance pattern. Biochemical testing is indicated for patients who do not have a clear clinical picture of one specific disorder. Measurement of serum lactic acid is often used as a screening test, but the test is neither sensitive nor specific for mitochondrial disorders (Schon et al., 2012). "Identifying causative mutations underlying mitochondrial dysfunction is the ultimate gold standard for the diagnosis. Two mitochondrial diseases (MNGIE and coenzyme Q10 deficiency) are particularly important to identify because of potential treatments" (O'Ferrall, 2024).

Proprietary Testing

Vairantyx provides two separate tests, Exome Plus Analysis and Whole Genome Analysis. While the manufacturer offers two tests, the descriptions of what these two tests are reporting on is nearly identical and, currently, it is unclear as to the difference between them.

Genomic Unity ® Exome Plus Analysis

This test provides a full, phenotypically driven analysis of all relevant genes and variant types. This analysis includes genome-wide sequence analysis, genome-wide structural variant analysis, mitochondrial genome analysis with heteroplasmy (≥ five percent), mitochondrial genome large deletions analysis, short tandem repeat (STR) analysis (AFF2, *AR, ARX, ATN1, ATXN1, ATXN2, ATXN3, ATXN7, ATXN8OS, ATXN10, C9ORF72, CACNA1A, CNBP, CSTB,- DIP2B, DMPK, FGF14, FMR1, FOXL2, FXN, GIPC1, GLS, HTT, JPH3, LRP12, NOP56, NOTCH2NLC, PABPN1, PHOX2B, PPP2R2B, RFC1, TBP, TCF4, VWA1, ZFHX3, ZIC2*). This test has a performance rate of >99.9% sensitivity, >99.9% specificity, 99.8% positive predictive value, and a 96% clinical sensitivity for structural variants (Variantyx, 2024a).

Genomic Unity ® Whole Genome Analysis

Whole Genome Analysis can be ordered as a first-line test or when previous testing was non-diagnostic. This type of analysis includes genome-wide sequence analysis, genome-wide structural variant analysis, mitochondrial genome sequence analysis with heteroplasmy (≥ five percent) and large deletion analysis, STR analysis for adult-onset movement disorder with or without cognitive involvement (*AFF2, AR, ARX, ATN1, ATXN1, ATXN2, ATXN3, ATXN7, ATXN8OS, ATXN10, C9ORF72, CACNA1A, CNBP, CSTB, DIP2B, DMPK, FGF14, FMR1, FOXL2, FXN, GIPC1, GLS, HTT, JPH3, LRP12, NOP56, NOTCH2NLC, PABPN1, PHOX2B, PPP2R2B, RFC1, SOX3, TBP, TCF4, VWA1, ZFHX3, ZIC2*). This test has a performance rate of >99.9% sensitivity, >99.9% specificity, >99.8% positive predictive value, and a 96% clinical sensitivity for structural variants (Variantyx, 2024b).

Clinical Utility and Validity

Clinical utility is high for confirming the diagnosis of mitochondrial disorders in people who have clinical features consistent with a specific mitochondrial disease. In these patients, a positive result on genetic testing can avoid a muscle biopsy and eliminate the need for further clinical workup (Dimmock & Lawlor, 2017). Additionally, genetic testing may impact reproductive decision making when a defined mitochondrial disease is present in the family that is severe enough to cause impairment and/or

disability. If genetic testing is used in this situation, there will be a decreased risk of a mitochondrial disorder in the offspring. Such testing includes whole-exome sequencing, whole-genome sequencing, and whole mitochondrial sequencing.

The most common first-line diagnostic test for a mitochondrial disease is massively parallel sequencing (MPS), also known as Next-Generation Sequencing (NGS); other accepted methods included targeted panels, whole-exome sequencing (WES) and whole-genome sequencing (WGS) (Horvath & Chinnery, 2019). Broad-based exome sequencing has been considered the first-line diagnostic tool for primary mitochondrial disease (PMD) (McCormick et al., 2018), and other researchers have used WES in tandem with rapid mitochondrial genome (mtDNA) sequencing for diagnoses (Akesson et al., 2019).

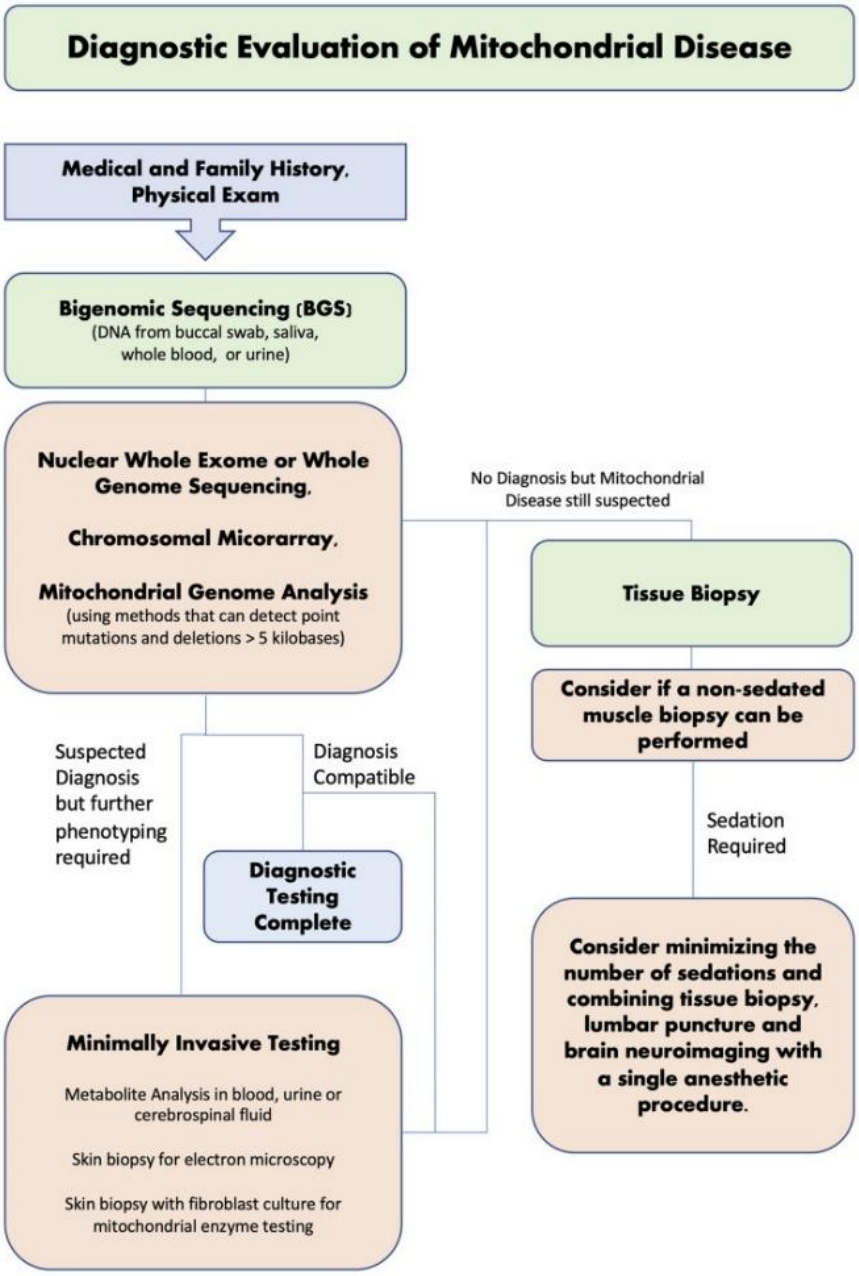
Whole-exome sequencing is likely to increase the detection rate but will also increase the rate of identifying a variant of uncertain significance (VUS). In one study from the U.K., 53 patients who had biochemical evidence of a mitochondrial disorder but were negative on genetic testing of the primary mitochondrial disorder mutations, underwent whole exome sequencing. Probable pathogenic mutations causative of a mitochondrial disorder was identified in 28 patients (53%), and an additional four patients had variants that were possibly pathogenic (Taylor et al., 2014). "False negative rates vary by genomic region; therefore, genomic testing may not be as accurate as targeted single gene testing or multigene molecular genetic testing panels. Most laboratories confirm positive results using a second, well-established method" (Chinnery, 2014).

Expanded panels are defined as panels that include more genes than are associated with any specific disorder. When these panels are used in individuals with nonspecific signs and symptoms that are not consistent with a "classic" presentation of a mitochondrial disorder, the probability of finding a pathogenic mutation is considerably less. Conversely, the likelihood of a false-positive result and the number of VUS may be substantially increased (O'Brien et al., 2014). Table 1, below, lists examples of commercially available expanded genetic panels for mitochondrial disorders.

Table 1. Examples of Commercially Available Expanded Genetic Panels for Mitochondrial Disorders

Laboratory	Lab Test or Panel	Number of Genes Included on Panel

Gene Dx® (Gaithersburg, MD)	MitoXpanded Panel (GeneDX, 2023b)	~1800
	Combined Mito Genome Plus Mito Focused Nuclear Gene Panel (GeneDX, 2023a)	202
ARUP® (Salt Lake City, UT)	Mitochondrial Disorders Panel (ARUP, 2023)	>150
Baylor® Genetics (Houston, TX)	Mitome200 Nuclear Panel (Baylor, 2023)	164
Medical Neurogenetics® (Atlanta, GA)	Mitochondrial Genome Sequencing & Deletion Analysis (Medical Neurogenetics, 2022)	>300



Wood et al. (2019) compared the mtDNA sequencing results of the long-read sequencing technology Oxford Nanopore Technologies (ONT) MinION to the Illumina MiSeq, a NGS platform. A total of 12 patients participated in this study (three healthy controls and nine with known mtDNA deletion disorders). Both of these NGS methods were more efficient than LR-PCR and/or Southern Blotting; further, MinION proved to be just as accurate as the Illumina MiSeq in this study, successfully identifying all mtDNA deletions (Wood et al., 2019). This tool may assist in making the mitochondrial disease diagnostic process more efficient and cost effective in the future.

Wagner et al. (2019) researched the effectiveness of exome sequencing (ES) for mitochondrial disease diagnostics; data was used from 2111 clinical cases. The researchers stated that "ES identified known pathogenic mtDNA point mutations in 38 individuals, increasing the diagnostic yield by nearly two percent. Analysis of mtDNA variants by ES had a high recall rate (96.2 ± 5.6%) and excellent precision (99.5 ± 2.2%) when compared to the gold standard of targeted mtDNA next generation sequencing" (Wagner et al., 2019). These results suggest that ES should be considered as a diagnostic tool for both nDNA and mtDNA testing.

Legati et al. (2016) suggest a two-tiered approach to genetic testing where targeted NGS is used first in cases of suspected mitochondrial disorders followed by WES in patients who have inconclusive results. "Importantly, WES on selected cases has unraveled the presence of pathogenic mutations in genes encoding non-mitochondrial proteins (e.g. the transcription factor E4F1), an observation that further expands the intricate genetics of mitochondrial disease and suggests a new area of investigation in mitochondrial medicine" (Legati et al., 2016).

Pronicka et al. (2016) suggest that WES is a better diagnostic tool than NGS. A total of 113 pediatric Polish patients participated in this study; variants were identified in both nDNA and mtDNA (Pronicka et al., 2016). WES was able to identify "likely causative mutations" in 67 patients, with 50.5% of all detected genetic changes novel variants; further, "In 47 patients, changes in 31 MD-related genes (*ACAD9, ADCK3, AIFM1, CLPB, COX10, DLD, EARS2, FBXL4, MTATP6, MTFMT, MTND1, MTND3, MTND5, NAXE, NDUFS6, NDUFS7, NDUFV1, OPA1, PARS2, PC, PDHA1, POLG, RARS2, RRM2B, SCO2, SERAC1, SLC19A3, SLC25A12, TAZ, TMEM126B, VARS2*) were identified" (Pronicka et al., 2016).

In a study by Kerr et al. (2020), 390 patients were recruited and tested for mitochondrial disease (MD) through traditional diagnostic pathways (metabolite analysis, tissue neuropathology and respiratory chain enzyme activity) and new diagnostic approaches (next-generation sequencing (NGS) and nuclear whole-exome sequencing (nWES)). Testing through traditional diagnostic methods resulted in a mitochondrial diagnosis in 115 out of 390 patients (29.50%). In comparison, 116 out of 390 patients were recruited for NGS, which identified 36 patients (31%) with a mitochondrial diagnosis. To confirm diagnosis, patients were further tested through nWES, which provided a secondary diagnosis in "two cases who already had a pathogenic variant in mtDNA, and a revised diagnosis (*GLUL*) in one case that had abnormal pathology but no pathogenic mtDNA variant" (Kerr et al., 2020). nWES also identified a mitochondrial diagnosis in one patient who tested negative from NGS. The author offers a diagnostic evaluation strategy, as shown in the figure below, and recommends that "a non-invasive, bigenomic sequencing (BGS) approach (using both a nWES and optimized mtDNA analysis to include large deletions) should be the first step in investigating for mitochondrial diseases. There may still be a role for tissue biopsy in unsolved cases or when the diagnosis is still not clear after NGS studies" (Kerr et al., 2020).

Another study clearly demonstrates the heterogeneity of genetic mutations causing mitochondrial disorders. Of the 142 patients with childhood-onset mitochondrial disorders, researchers "identified 37 novel mutations in known mitochondrial disease genes and three mitochondria-related genes (*MRPS23*, *QRSL1*, and *PNPLA4*) as novel causative genes" (Kohda et al., 2016). These researchers utilized whole mtDNA and exome and chromosomal aberration analysis approaches to "enhance the ability to identify pathogenic gene mutations in patients" (Kohda et al., 2016).

A study by Fang et al. (2017) recruited 141 children with suspected mitochondrial disorders and used NGS to identify genetic characteristics. Forty children were gene

confirmed with a known mitochondrial disease; 62.5% of those cases were due to a mtDNA mutation and 37.5% due to a nDNA mutation. This study found the most prevalent disorders to be Leigh syndrome and MELAS (Fang et al., 2017).

Spath et al. (2021) studied parallel preimplantation genetic testing (PGT) for mtDNA disease and aneuploidy on four patients at risk of transmitting mtDNA disease. Aneuploidy is the condition of having an abnormal number of chromosomes. "Half of the embryos tested were shown to be aneuploid (16/33)." Notably, not all the participants had the same mtDNA mutations. Patients A and D had a m.8993T>G mutation; mutations were detected in embryo biopsies from Patient A but not Patient B. Patient C had a m.10191T.G mutation, no mutations were detected in embryo biopsies from Patient C. Patient D had a m3243A>G mutation, mutations were detected in embryo biopsies from Patient D. Patients A and D displayed somatic heteroplasmy for mtDNA mutations, "heteroplasmic women had a higher incidence of affected embryos than those with undetectable somatic mutant mtDNA but were still able to produce mutation-free embryos." The authors concluded that "strategies providing a combination of PGT for mtDNA disease and aneuploidy may be advantageous compared with approaches that consider only mtDNA" (Spath et al., 2021).

Wu et al. (2021) evaluated the cost-efficiency and cost-benefit of genomic sequencing for children presenting clinical indications of mitochondrial diseases compared to the conventional diagnosis pathway in Australia. The authors used a decision tree model approach and a discrete-event simulation approach on data from 78 pediatric-onset patients. The conventional diagnosis pathway refers to a diagnostic workup including metabolic, imaging, and histopathological investigations, and genetic testing. Genomic sequencing was less costly and more effective than conventional care. The authors concluded that "genomic sequencing is cost-saving relative to traditional investigative approaches, while enabling more diagnoses to be made in a timely manner, offering substantial personal benefits to children and their families" (Wu et al., 2021).

Farahvash et al. (2021) did a case study on two siblings with mitochondrial neurogastrointestinal encephalopathy disease (MNGIE). The two patients experienced gastrointestinal and cachexia symptoms for years and underwent numerous exploratory tests and surgeries which did not improve their condition. Eventually, the patients were diagnosed with MNGIE following genetic testing for the TYMP gene. The authors concluded that "MNGIE diagnosis is important to establish to avoid unnecessary invasive testing for gastrointestinal, ophthalmological, and neurological symptoms and to ensure patients receive appropriate nutritional and genetic counselling" (Farahvash et al., 2021).

VI. Guidelines and Recommendations

Mitochondrial Medicine Society

The Mitochondrial Medicine Society published the following consensus recommendations on genetic testing for mitochondrial disorders (Parikh et al., 2015):

1. "Massively parallel sequencing/NGS of the mtDNA genome is the preferred methodology when testing mtDNA and should be performed in cases of suspected mitochondrial disease instead of testing for a limited number of pathogenic point mutations.
2. Patients with a strong likelihood of mitochondrial disease because of a mtDNA mutation and negative testing in blood, should have mtDNA assessed in another tissue to avoid the possibility of missing tissue-specific mutations or low levels of heteroplasmy in blood; tissue-based testing also helps assess the risk of other organ involvement and heterogeneity in family members and to guide genetic counseling.
3. Heteroplasmy analysis in urine can selectively be more informative and accurate than testing in blood alone, especially in cases of MELAS due to the common m. 3243A>G mutation.
4. mtDNA deletion and duplication testing should be performed in cases of suspected mitochondrial disease via NGS of the mtDNA genome, especially in all patients undergoing a diagnostic tissue biopsy.
    a. If a single small deletion is identified using polymerase chain reaction–based analysis, then one should be cautious in associating these findings with a primary mitochondrial disorder.
    b. When multiple mtDNA deletions are noted, sequencing of nuclear genes involved in mtDNA biosynthesis is recommended.
5. When a tissue specimen is obtained for mitochondrial studies, mtDNA content (copy number) testing via real-time quantitative polymerase chain reaction should strongly be considered for mtDNA depletion analysis because mtDNA depletion may not be detected in blood.
    a. mtDNA proliferation is a nonspecific compensatory finding that can be seen in primary mitochondrial disease, secondary mitochondrial dysfunction, myopathy, hypotonia, and as a by-product of regular, intense exercise.
6. When considering nuclear gene testing in patients with likely primary mitochondrial disease, NGS methodologies providing complete coverage of known mitochondrial disease genes is preferred. Single-gene testing should usually be avoided because mutations in different genes can produce the same

phenotype. If no known mutation is identified via known NGS gene panels, then whole exome sequencing should be considered."

The Mitochondrial Medicine Society also commented on the set of mtDNA depletion syndromes, which are "characterized by a significant reduction in mtDNA copy number in affected tissues". They note that diagnosis of these conditions "requires quantification of mtDNA content, typically in affected tissue, with identification of a significant decrease below the mean of normal age, gender, and tissue-specific control when normalized to nDNA tissue content". Since NGS of the mtDNA genome does not identify mtDNA content, a separate quantitative real-time polymerase chain reaction must be used (Parikh et al., 2015).

The Mitochondrial Medicine Society in 2017 released their guidelines regarding patient care standards. Within this set of guidelines, they state, "Pregnancy in mitochondrial disease also elicits the concern of transmission of a genetic disorder. Appropriate preconception genetic counseling and discussion of options of prenatal testing are needed. A fetus affected by mitochondrial disease may also be at higher risk for prenatal morbidity. Finally, premature ovarian failure is a feature of several mitochondrial disorders and affected women should be referred for assisted reproductive technologies if they wish to have children" (Parikh et al., 2017).

Association for Clinical Genomic Science (ACGS)

The ACGS published guidelines for the genetic testing strategies for diagnostic and familial testing, variant interpretation and reporting, and prenatal diagnosis and reproductive options. The guidelines report the minimal level of testing recommended for the most common diagnostic referrals, listed below, noting possible further testing with nuclear DNA testing and whole mtDNA sequencing for all phenotypes.

- Phenotype: ataxia, possible diagnosis of late-childhood or adult-onset peripheral neuropathy, pigmentary retinopathy (NARP) or mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). Minimum level of testing for: m.8993T>G p.(Leu156Arg), m.8993T>C p.(Leu156Pro)(MT-ATP6), m.3243A>G (MT-TL1).
- Phenotype: cardiomyopathy, familial hypertrophic cardiomyopathy with maternal inheritance. Minimum level of testing for: m.4300A>G (MT-TI), m.3243A>G (MT-TL1).
- Phenotype: diabetes mellitus and sensorineural hearing loss. Minimum level of testing for: m.3243A>G (MT-TL1), m.3243A>G (MT-TL1).
- Phenotype: encephalopathy/seizures with lactic acidosis, possible diagnosis of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) or infantile onset subacute relapsing encephalopathy,

cerebellar and brain stem signs (MILS). Minimum level of testing for: m.3243A>G, (MT-TL1), m.8993T>G p.(Leu156Arg), m.8993T>C p.(Leu156Pro), (MT-ATP6).

- Phenotype: non-syndromic sensorineural hearing loss, particularly if onset following aminoglycoside exposure. Minimum level of testing for m.1555A>G (MT-RNR1).
- Phenotype: Kearns-Sayre syndrome onset, below the age of 20 years, PEO and pigmentary retinopathy with one of either cardiac conduction block, cerebrospinal fluid protein concentration greater than 100 mg/dL, or cerebellar ataxia. Minimum level of testing for: large-scale mtDNA rearrangements (single and multiple deletions), m.3243A>G (MT-TL1).
- Phenotype: Leber hereditary optic neuropathy, optic atrophy, childhood or midlife (adult-onset) acute or subacute painless bilateral central vision loss. Minimum level of testing for: m.3460G>A p.(Ala52Thr) (MT-ND1), m.11778G>A p.(Arg340His) (MT-ND4), m.14484T>C p.(Met64Val) (MT-ND6).
- Phenotype: mtDNA depletion syndrome, neonatal or infantile hepatocerebral, myopathic, encephalomyopathic or neurogastrointestinal presentations; may also include growth failure, lactic acidosis, and hypoglycemia. Minimum level of testing for: mtDNA copy number analysis.
- Phenotype: myoclonic epilepsy, myoclonus, seizures; cerebellar ataxia; myopathy. Minimum level of testing for: m.8344A>G (MT-TK), m.3243A>G (MT-TL1).
- Phenotype: Pearson syndrome, sideroblastic anemia of childhood; Pancytopenia; Exocrine pancreatic failure. Minimum level of testing for: large-scale mtDNA rearrangements.
- Phenotype: progressive external ophthalmoplegia (PEO), ptosis, typically adult-onset ptosis, paralysis of the extraocular muscles (ophthalmoplegia), oropharyngeal weakness, and variably severe proximal limb weakness. Minimum level of testing for: large-scale mtDNA rearrangements (single and multiple deletions, m.3243A>G (MT-TL1).
- Phenotype: stroke-like episodes, typically before age 40 years. Minimum level of testing for: m.3243A>G (MT-TL1) (Mavraki et al., 2020).

European Academy of Neurology (EAN)

Regarding genetic testing for mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS), the EAN recommends "Urgent genetic testing for MELAS should be considered in patients presenting with suspected SLE [stroke-like episode]. Search for the m.3243A>G variant (in urine where possible) and, if m.3243A>G variant is negative, POLG sequencing is required. Muscle biopsy should be considered after excluding m.3243A>G and POLG variants." The EAN also notes that valproic acid is "contraindicated, mainly in patients with POLG variants" (Mancuso et al., 2020).

MNGIE International Network

The MNGIE [Mitochondrial neurogastrointestinal encephalomyopathy] International Network recommended *TYMP* sequencing to confirm a MNGIE diagnosis. If a variant of unknown significance or a wild-type variant is found, the Network recommends biochemical testing of thymidine (dThd) and deoxyuridine levels to determine thymidine phosphorylase (TP) activity. The Network also remarks on several treatment options (both short- and long-term), which focus on restoring the biochemical balance of the patient (Hirano et al., 2020).

United Kingdom Best Practice Guidelines

In 2024, a group of clinical scientists part of the "United Kingdom National Health Service Highly Specialised Services for Rare Mitochondrial Disorders" group revised and updated their 2008 guidelines for genetic testing for mitochondrial disease (Mavraki et al., 2023).

In a proband with suspected mitochondrial disease, the group recommends that "first-line targeted testing of blood DNA can be appropriate for routine referrals (where there is not an urgent clinical need to obtain a diagnosis), for clinical presentations which are highly suggestive of a particular variant or gene (e.g., MELAS, MERRF, LHON, Pearson syndrome, POLG-related disorders), and/or where resources are limited. In patients where no pathogenic variant is detected in blood, additional clinical information and samples (e.g., urine) or a muscle biopsy for biochemical and histopathological investigations may be suggested." The group also notes that "alternatively, comprehensive NGS-based testing can be adopted for sensitive and efficient first-line genetic testing. This approach can be followed for all referral indications but is particularly appropriate for more complex phenotypes and/or for urgent referrals" (Mavraki et al., 2023).

The group notes that "specific single gene testing remains a valuable simple and rapid first-line test when the associated disorder is common, for treatable disorders with a characteristic phenotype, when there are common founder variants(s), and/or if biochemical evidence points to a defect in the particular gene" (Mavraki et al., 2023).

For family testing, the group recommends that "following a genetic diagnosis of mitochondrial disease, it is recommended that the proband (and their family) are referred to clinical genetics or a specialist mitochondrial service for appropriate genetic counselling and family follow-up." The group notes that testing of asymptomatic children below the age of 16 with a family history of mtDNA-related mitochondrial disease is challenging, and recommends that "laboratories discuss referrals for genetic testing of asymptomatic children with specialised clinicians or clinical geneticists wherever possible prior to testing" (Mavraki et al., 2023).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)

CPT	Code Description
81440	Nuclear encoded mitochondrial genes (eg, neurologic or myopathic phenotypes), genomic sequence panel, must include analysis of at least 100 genes, including BCS1L, C10orf2, COQ2, COX10, DGUOK, MPV17, OPA1, PDSS2, POLG, POLG2, RRM2B, SCO1, SCO2, SLC25A4, SUCLA2, SUCLG1, TAZ, TK2, and TYMP
81460	Whole mitochondrial genome (eg, Leigh syndrome, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes [MELAS], myoclonic epilepsy with ragged-red fibers [MERFF], neuropathy, ataxia, and retinitis pigmentosa [NARP], Leber hereditary optic neuropathy [LHON]), genomic sequence, must include sequence analysis of entire mitochondrial genome with heteroplasmy detection
81465	Whole mitochondrial genome large deletion analysis panel (eg, Kearns-Sayre syndrome, chronic progressive external ophthalmoplegia), including heteroplasmy detection, if performed
81479	Unlisted molecular pathology procedure
0212U	Rare diseases (constitutional/heritable disorders), whole genome and mitochondrial DNA sequence analysis, including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variants, proband Proprietary test: Genomic Unity® Whole Genome Analysis – Proband Lab/Manufacturer: Variantyx Inc
0213U	Rare diseases (constitutional/heritable disorders), whole genome and mitochondrial DNA sequence analysis, including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variants, each comparator genome (eg, parent, sibling) Proprietary test: Genomic Unity® Whole Genome Analysis – Comparator- Lab/Manufacturer: Variantyx Inc
0214U	Rare diseases (constitutional/heritable disorders), whole exome and mitochondrial DNA sequence analysis, including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variants, proband Proprietary test: Genomic Unity® Exome Plus Analysis – Proband Lab/Manufacturer: Variantyx Inc
0215U	Rare diseases (constitutional/heritable disorders), whole exome and mitochondrial DNA sequence analysis, including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and

CPT	Code Description
	categorization of genetic variants, each comparator exome (eg, parent, sibling) Proprietary test: Genomic Unity® Exome Plus Analysis – Comparator Lab/Manufacturer: Variantyx Inc
0417U	Rare diseases (constitutional/heritable disorders), whole mitochondrial genome sequence with heteroplasmy detection and deletion analysis, nuclear-encoded mitochondrial gene analysis of 335 nuclear genes, including sequence changes, deletions, insertions, and copy number variants analysis, blood or saliva, identification and categorization of mitochondrial disorder–associated genetic variants Proprietary test: Genomic Unity® Comprehensive Mitochondrial Disorders Analysis Lab/Manufacturer: Variantyx Inc

a) Testing restricted to the known familial *NOTCH3* likely pathogenic or pathogenic variant.

b) Comprehensive *NOTCH3* sequencing only if the specific familial likely pathogenic or pathogenic variant is unknown.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For all other situations not discussed above, genetic testing for CADASIL syndrome **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: First-degree relatives include parents, full siblings, and children of the individual. Second-degree relatives include grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings of the individual.

IV. Table of Terminology

Term	Definition
AD	Alzheimer disease
AHA	American Heart Association
ASA	American Stroke Association
CADASIL	Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid Services
cSVD	Cerebral small-vessel disease
CT	Computed tomography
EAN	European Academy of Neurology
EFNS	European Federation of Neurological Studies
EGFr	Epidermal growth factor-like repeat
EMR	Electronic medical records
FDA	Food and Drug Administration
GOM	Granular osmiophilic material
HTRA1	Serine protease
LDT	Laboratory-developed test
MCI	Mild cognitive impairment
MRI	Magnetic resonance imaging

NGS	Next-generation sequencing
NORD	National Organization for Rare Disorders
NOTCH3	*Notch receptor 3*
PV	Pathogenic variant
SVD	Small vessel disease
SVaD	Subcortical vascular dementia
T2	Transverse relaxation time
TIA	Transient ischemic attack
USPSTF	United States Preventive Services Task Force
VCI-SVD	Vascular cognitive impairment secondary to small vessel disease
VSMCs	Vascular smooth muscle cells
WES	Whole-exome sequencing
WMHs	White matter hyperintensities

V. Scientific Background

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is the most common hereditary small vessel disease and is characterized by granular osmiophilic material deposits surrounding blood vessels, a prominent thickening of the vessel wall by extracellular matrix accumulation, and a progressive loss of vascular smooth muscle cells (VSMCs) (Fernandez-Susavila et al., 2018; Ferrante et al., 2019; Monet-Lepretre et al., 2013). Small vessel diseases such as this are an important cause of stroke and vascular cognitive decline in adults (Chabriat et al., 2009). VSMC dysfunction may be caused by mutations in the *NOTCH3* gene, leading to irregularities in VSMC proliferation, cell cycle affliction, senescence, and cellular apoptosis (Dziewulska et al., 2018).

Individual symptoms, onset, and disease severity span a wide spectrum (Wang, 2018). Thus, descriptions of hereditary multi-infarct dementia, chronic familial vascular encephalopathy, and familial subcortical dementia, originally thought to be separate disorders, represent early reports of this condition (Dichgans, 2024). CADASIL usually presents with one or more of the following: dementia, psychiatric disturbances, migraine, and recurrent strokes (Chabriat et al., 2009; Dichgans et al., 1998; M.Wang, 2018). Rarer symptoms include lumbago, humpback, and Parkinson syndrome (Lim et al., 2019). Migraine with aura occurs in 55% of CADASIL cases and is often the initial manifestation of the disease (Di Donato et al., 2017). Subcortical ischemic attacks begin at a mean age of 47 years and present as lacunar syndromes (Adib-Samii et al., 2010; Dichgans et al., 1998). Accumulation of lacunae, which impact executive performance and function independence, strongly correlate to clinical severity (Ling et al., 2017). Cognitive impairment associated with CADASIL is progressive; a profile of frontal lobe dysfunction, declarative memory impairment suggestive of a retrieval deficit, and

relatively preserved language is often evident with this disease (Harris & Filley, 2001). A concurrent stepwise deterioration due to recurrent strokes is also common (Rutten & Lesnik Oberstein, 2016). Mood disturbances are reported in approximately 30% of individuals (Adib-Samii et al., 2010; Dichgans et al., 1998). Further, apathy, which may be independent of depression, is reported in 40% of individuals (Reyes et al., 2009).

Genetic linking of the disorder to chromosome 19 was first recognized in 1993, and the identification of the *NOTCH3* gene from the CADASIL mapped region was later discovered in 1996 (Ping & Zhao, 2018). While CADASIL was originally diagnosed via neuroimaging techniques, such as magnetic resonance imaging (MRI), the identification of the distinctive missense mutations in *NOTCH3* has allowed genetic testing to debut as the current gold standard for CADASIL diagnostics (Rutten & Lesnik Oberstein, 2016). However, MRI testing for the detection of cerebral white matter changes in the brain is still used to assist in CADASIL diagnoses; most often, MRI imaging is used as a diagnostic measure before symptoms present (Ferrante et al., 2019).

Missense mutations in the *NOTCH3* gene typically lead to the gain or loss of a cysteine, therefore resulting in an unpaired number of cysteine residues in one of 34 highly conserved epidermal growth factor-like repeat (EGFr) domains (Joutel et al., 1996; Papakonstantinou et al., 2019; Rutten et al., 2014). This leads to an increased multimerization tendency of mutant NOTCH3 (Duering et al., 2011), toxic accumulation of the protein and extracellular matrix in disulfide cross-linked detergent-insoluble aggregates (Monet-Lepretre et al., 2013), altered neurovascular coupling (Huneau et al., 2018), and ultimately reduced cerebral blood flow, recurrent stroke, and vascular dementia (Rutten et al., 2016). However, certain *NOTCH3* mutations do not present with a cysteine change; this type of non-cysteine mutation can cause a great loss of structure in the NOTCH3 protein (Papakonstantinou et al., 2019).

More than 200 *NOTCH3* mutations have been reported since its original discovery in the development of CADASIL syndrome in 1996; some of these mutations result in a phenotypic change while some present as a silent mutation. A few prevalent *NOTCH3* variants include the 34 identified in EGFr. EGFr 1–6 pathogenic variants are more common in the CADASIL population than EGFr 7–34 pathogenic variants; unfortunately, patients with EGFr 1–6 variants tend to present with more severe symptoms and phenotypes (Papakonstantinou et al., 2019; Rutten et al., 2018). These severe symptoms include stroke onset an average of 12 years earlier and overall lower survival rates (Papakonstantinou et al., 2019).

The prevalence of the disease has been estimated to be at 0.8 to five per 100,000 individuals (Moreton et al., 2014; Narayan et al., 2012; Razvi et al., 2005). However,

many suspect that these numbers are underestimates. A more recent investigation of the frequency of the characteristic missense CADASIL mutations in a public database found a total prevalence of 3.4/1000 (Rutten et al., 2016).

Currently, no efficient treatment options to cure or prevent CADASIL syndrome are available (Hack et al., 2019; NORD, 2019); however, recent studies have shown proof of concept for a novel application of exon skipping and are a first step towards the development of a rational therapeutic approach to treat up to 94% of CADASIL-causing mutations (Rutten et al., 2016). Further, neurofilament light chains have now been identified as a promising CADASIL biomarker and can be detected in the serum of affected patients (Ferrante et al., 2019).

Analytical Validity

There are no established diagnostic criteria for CADASIL. The phenotype is highly variable, and although imaging may be suggestive, no characteristic is pathognomonic; genetic testing remains the gold standard for diagnosis (Rutten & Lesnik Oberstein, 2016; Wang, 2018). As a heterozygous pathogenic variant in the NOTCH3 protein coding gene is well established as a main reason for CADASIL development, a CADASIL diagnosis is generally delivered based on molecular genetic testing or electron microscopy and immunohistochemistry results. Molecular genetic testing approaches may include both gene-targeted testing and in-depth genomic testing, such as exome sequencing and genome sequencing (Hack et al., 2019; Papakonstantinou et al., 2019).

Immunohistochemistry combined with electron microscopy of skin biopsy can be useful when molecular testing is not definitive (Rutten & Lesnik Oberstein, 2016). Immunohistochemistry assay of a skin biopsy sample for the accumulation of NOTCH3 protein in the walls of small blood vessels (Joutel et al., 2001) has an estimated sensitivity and specificity at 85-90% and 95-100%, respectively (Lesnik Oberstein et al., 2003). Detection of granular osmiophilic material deposits (GOM) containing the ectodomain of the *NOTCH3* gene by electron microscopy (del Rio-Espinola et al., 2009; Muqtadar & Testai, 2012) had a sensitivity of 45% and a specificity of 100% (Brulin et al., 2002; Malandrini et al., 2007; Markus et al., 2002).

Magnetic resonance imaging (MRI) is useful to demonstrate radiologic features of CADASIL, including recent lunar infarctions and white matter hyperintensities. Computed tomography (CT) scans are less sensitive than MRI in this regard (Dichgans, 2024). MRI may also provide prognostic information. Brain lesions in CADASIL patients tend to precede symptoms by 10 to 15 years; however, a normal MRI in the fourth decade of life should not automatically rule out CADASIL syndrome even though most patients exhibit an abnormal MRI by age 35 (Samoes et al., 2016). White matter hyperintensities on MRI can be visualized in those aged 21 years and older, and lesion

volume correlates with the level of disability and three-year clinical course of CADASIL (Jouvent et al., 2016). Isolated T2 hyperintensities involving the temporal poles can differentiate CADASIL from chronic microvascular ischemia due to hypertension with a sensitivity and specificity of 95% and 80%, respectively (O'Sullivan et al., 2001). Cerebral microbleeds visible on T2 weighted MRI images detected in 36% of patients with CADASIL were independently associated with an increased risk of incident ischemic stroke and may be a marker for a subgroup of patients with CADASIL who have a more severe or advanced form of the disease (Puy et al., 2017).

Guo et al. (2021) studied the role of *NOTCH3* gene mutations and variants in Alzheimer Disease (AD) and subcortical vascular dementia (SVaD). CADASIL is a common etiology of SVaD. A total of 667 AD patients, 96 SVaD patients, and 365 healthy control participants, all recruited from the Southern Han Chinese population, were included in the study. The authors performed targeted capture sequencing on *NOTCH3* and adjacent intron regions. "Five known pathogenic variants (p.R182C, p.C201S, p.R544C, p.R607C, and p.R1006C) and two novel likely pathogenic variants (p.C201F and p.C1061F) were detected in 16 SVaD patients."

No pathogenic variants were found in AD patients. The authors concluded that the "findings broaden the mutational spectrum of NOTCH3 and validate the pathogenic role of *NOTCH3* mutations in SVaD, but do not support the notion that *NOTCH3* variation influences the risk of AD" (Guo et al., 2021).

Cho et al. (2021) performed an analysis on whole-exome sequencing data from 200,632 participants in the UK Biobank. The authors note that CADASIL is considered rare, but there is a higher frequency of cysteine-altering *NOTCH3* variants which could increase risk of apparently sporadic lacunar stroke. The authors compared frequency of stroke, vascular dementia, clinical features of CADASIL, and MRI white matter hyperintensity volume between carriers and non-carriers of 67 cysteine-altering *NOTCH3* variants. "*NOTCH3* variant carriers had increased risk of stroke (OR: 2.33, $p=0.0004$) and vascular dementia (OR: 5.00, $p=0.007$), and increased white matter hyperintensity volume (standardised difference: 0.52, $p<0.001$) and white matter ultrastructural damage on diffusion MRI (standardised difference: 0.72, $p<0.001$)." The authors concluded that "cysteine-changing *NOTCH3* variants are more common in the general population than expected from CADASIL prevalence and are risk factors for apparently 'sporadic' stroke and vascular dementia" (Cho et al., 2021).

Gravesteijn et al. (2021) studied the effect of *NOTCH3* variant position on NOTCH3 protein aggregation load. Vascular NOTCH3 aggregation was measured in skin biopsies and brain tissue from CADASIL patients. "CADASIL patients with an EGFr 7-34 variant have significantly less vascular NOTCH3 aggregation than patients with an EGFr

1-6 variant." The authors concluded that *NOTCH3* variant position may be a factor that underlies differences in CADASIL disease severity (Gravesteijn et al., 2021).

Clinical Utility and Validity

One study has reported that the sequence analysis of *NOTCH3* is 95-100% sensitive and 100% specific to establish the diagnosis of CADASIL (Dotti et al., 2005; Peters et al., 2005; Tikka et al., 2009; Yin et al., 2015). A preliminary scale was proposed to screen for patients who should undergo *NOTCH3* gene analysis with a sensitivity of 96.7% and a specificity of 74.2% (Pescini et al., 2012). Another study of Russian patients with clinically suspected CADASIL concluded that careful assessment of genealogical, clinical, and neuroimaging data in patients with lacunar stroke can help select patients with a high probability of finding mutations on genetic screening (Abramycheva et al., 2015). In the absence of clinical features suggestive of CADASIL, screening of patients with lacunar stroke, leukoarosis, and migraine have low yield (de Vries et al., 2009; Dong et al., 2003).

As individual symptoms and disease severity span a wide spectrum, it must be noted that symptom onset alone cannot warrant a CADASIL syndrome diagnosis. Researchers previously screened 123 patients who exhibited two common CADASIL symptoms: lacunar stroke and transient ischemic attack. These participants were genetically tested for CADASIL; it was determined that only 12.5% had a *NOTCH3* mutation, showing that common CADASIL symptoms are shared with many other disorders (Bersano et al., 2018). This highlights the importance of genetic testing as a diagnostic measure. Further, three features were found to be significantly associated with a CADASIL diagnosis: "A family history of stroke, the presence of dementia and external capsule lesions on MRI" (Bersano et al., 2018).

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) was first diagnosed by visualizing granular osmiophilic material (GOM) in the tunica media of small arteries through light microscopy. Although GOM deposit is the pathological hallmark of CADASIL, *NOTCH3* genetic sequencing is the confirmative diagnostic tool. While most genetic tests use Sanger sequencing methods to target specific *NOTCH3* exons, next-generation sequencing (NGS) and whole exome sequencing (WES) have proven to deliver greater efficacy. One study has reported that NGS and WES have increased sensitivity to detect low frequency variants of *NOTCH3* mutations compared to Sanger sequencing. Through Sanger sequencing, 10.8% of tests were able to identify *NOTCH3* mutations compared to 15.8% of tests identifying mutations through next-generation sequencing. With NGS, the results were in concordance with Sanger sequencing, but it extended the capacity to detect mutations and previously unreported variants. As

diagnostic sequencing techniques continue to advance, NGS and WES may play an important role in identifying other genes involved with CADASIL (Dunn et al., 2020).

Rutten et al. (2018) analyzed the effect of *NOTCH3* pathogenic variant (PV) location on CADASIL disease variability. The authors correlated PV position with brain MRI lesion load, age of first stoke, and survival on 664 European CADASIL patients. "CADASIL patients with an EGFr 1–6 pathogenic variant have a 12-year earlier onset of stroke than those with an EGFr 7–34 pathogenic variant, lower survival, and higher white matter hyperintensity volumes." The authors concluded that *NOTCH3* PV location is "the most important determinant of CADASIL disease severity"(Rutten et al., 2018).

Mukai et al. (2020) correlated genotypes and phenotypes of 179 Japanese CADASIL probands. The authors identified 68 mutations, "p.Cys388Arg, p.Cys435Phe, p.Gly481Cys, p.Cys743Tyr, and p.Cys1009Phe were novel ones." The authors then analyzed genotype-phenotype correlations on the three most common mutations. "p.Arg141Cys showed typical CADASIL phenotypes, whereas p.Arg75Pro showed mild and atypical phenotypes, a low frequency of stroke/TIA [transient ischemic attack], high frequency of hypertension, and low frequency of temporal pole lesions. p.Arg182Cys showed various initial symptoms other than stroke/TIA." The authors also studied mutation location and the age of stroke/TIA onset, and found that mutations of EGFr 1-6 (excluding p.Arg75Pro) were significantly correlated with a younger age of stroke/TIA onset than mutations in EGFr 7-43. The authors concluded that the data clarified genotype-phenotype correlations and the effect of mutation location on the age of stroke/TIA onset in Japanese CADASIL probands (Mukai et al., 2020).

Hack et al. (2020) performed a cross-sectional study using 118 participants with a *NOTCH3* cysteine altering variant and 184 age- and sex-matched control participants. Clinical, neuroimaging, and whole-exome data was compared. There was no difference in dementia, mild cognitive impairment, migraine with aura, or depression prevalence. Participants with a *NOTCH3* cysteine altering variant had a higher had a higher risk of stroke, white matter hyperintensity, and lacunas after age 65. The authors note that the classic mid-adult onset CADASIL phenotype was not reported, suggesting "*NOTCH3* variants do not only cause the rate and more severe hereditary CADASIL but are much more commonly associated with a milder [cerebral small vessel disease] SVD phenotype, specifically when these variants are located in EGFr 7 to 35" (Hack et al., 2020).

Liu et al. (2021) tracked clinical and MRI data of three patients from a family in China over seven years. Genetic tests confirmed CADASIL diagnosis on all three participants, including a novel mutation of p.C533S on exon 10 of *NOTCH3*. The same heterozygous mutations were detected across family members. The authors conclude that there is

"distinct heterogeneity of CADASIL patients in the same family with the same mutation" (Liu et al., 2021).

Chen et al. (2021) assessed the diagnostic utility of using NGS and MRI data for the diagnosis of adult onset leukodystrophy. The authors used a panel of 200 neurodegeneration-related genes and an MRI brain-based diagnostic algorithm from 45 patients with young-onset cognitive impairment with leukodystrophy. All the patients with an established genetic diagnosis had MRI brain patterns consistent with their diagnosis. A total of 51.4% of patients with MRI changes consistent with vascular cognitive impairment secondary to small vessel disease (VCI-SVD) had pathogenic variants (89.5% of which were pathogenic *NOTCH3* and 11.5% of which were *HTRA1* variants). The authors concluded that the results "demonstrated a high diagnostic utility incorporating a targeted neurodegeneration gene panel and MRI-based diagnostic algorithms in young-onset cognitive impairment patients with leukodystrophy" (Chen et al., 2021).

Anisetti et al. (2023) gathered the electronic medical records (EMR) of adult patients with confirmed CADASIL disease to analyze the use of a recently proposed grading system. A grade of zero (asymptomatic), Grade One (migraine only), Grade Two (stroke, TIA, or MCI), Grade Three (gait assistance or dementia) or Grade four (bedbound or end-stage) was given to each patient. The inter-rater reliability of grading was also assessed with an 81.8% agreement on ratings. Results showed that those patients who received a lower grade on the CADASIL scale were younger (49.5 vs. 61.9 years) and were less likely to have hypertension and/or diabetes mellitus. Higher ratings were correlated with increased vascular risk factors. The authors concluded that a CADASIL grading system based on symptoms was a reliable categorization of patients to assess higher vascular risk factor burden (Anisetti et al., 2023).

Boston et al. (2024) completed a systematic review on the most common *NOTCH3* mutations that cause CADASIL and CADASIL-like cerebral small vessel disease. The authors were aiming to investigate the association between phenotypes and genotypes across the most common *NOTCH3* mutations in CADASIL patients. "The six most common NOTCH3 missense mutations globally were the p.R75P, p.R133C, p.R141C, p.R169C, p.R182C, and p.R544C, of which p.R133C was described to occur most often." p.R75P, p.R141C, p.R182C and p.R544C genotypes were "highly congruent" with white matter hyperintensities on MRI. P.R141C genotype was associated with decreased disease severity. Although there were some associations, overall, "statistical analysis showed there were no overall differences between the phenotypic characteristics of the two common mutations, p.R141C and p.R544C" (Boston et al., 2024)

Predictive Testing of At-Risk Family Members

For an asymptomatic individual, knowledge of mutation status will generally not lead to any management changes that can prevent or delay the onset of the disorder. Avoiding tobacco use may be a factor that delays onset of disease, but this is a general recommendation that is not altered by genetic testing. Goldman (2015) has suggested that asymptomatic family members follow the guidelines for presymptomatic testing for Huntington disease (HDSA, 2016).

Genetic testing for CADASIL may assist decision making in areas such as employment choices and reproductive decision making. However, the impact of these decisions on health outcomes is uncertain. Further, the testing of asymptomatic at-risk individuals with nonspecific or equivocal symptoms is not useful in predicting age of onset, severity, type of symptoms, or rate of progression in asymptomatic individuals (Rutten & Lesnik Oberstein, 2016). Initial data from Reyes et al. (2012) show that predictive testing is rarely requested and has a high dropout rate.

Di Donato et al. (2017) state that the MRI of an unaffected family member could have a similar impact to a genetic test because MRIs are able to accurately predict CADASIL disease development before symptoms present. Therefore, the potential implications of MRI testing should be shared before this type of testing is completed.

Akrich et al. (2024) studied the population at risk of CADASIL who had not completed diagnostic procedures, aiming to understand the hesitation. The study included a questionnaire survey with 40 questions about why people choose to undergo or not undergo a genetic test, and what lead to that decision. The questionnaire was sent to 883 people, and 359 replied. Of the 359 replies, 197 were from *NOTCH3*-mutation carriers, 81 were from close relatives, and 81 were from individuals at risk of CADASIL. "Results suggest that, far from being a simple, unequivocal path, the decision-making process leading to the choice of diagnosis is initially slowed down by the need to distance oneself from the disease so that it doesn't take over one's life, and then evolves under the influence of a complex tangle between advancing age, the presence of early symptoms, and the personal relationship with uncertainty" (Akrich et al., 2024).

VI. Guidelines and Recommendations

American Heart Association (AHA) and American Stroke Association (ASA)

The American Heart Association and American Stroke Association provide suggestions on when rare genetic causes could be suspected. They suggest that the diagnosis could be made based on testing for mutations in the *NOTCH3* gene (Kleindorfer et al., 2021; Powers et al., 2019; Smith et al., 2017).

In 2023, the AHA released a scientific statement about the management of inherited central nervous system small vessel diseases, specifically CADASIL. The AHA recommends: "Consider gene testing in patients with small vessel stroke before 55 y of age with a paucity of vascular risk factors (eg, normotensive, nondiabetic, nonsmoker) or positive family history of CADASIL." The AHA also notes that "one should distinguish diagnostic testing in individuals who have clinical manifestations of disease from predictive or presymptomatic testing. In general, children, unless emancipated minors, should not undergo predictive testing because this robs them of the choice of knowing or not knowing their status. The penetrance of *NOTCH3* variants is incomplete and highly variable. Testing and finding mutations in *NOTCH3* can lead to pessimistic prognostication and bias of detecting asymptomatic brain lesions with MRI. This can have life-changing, negative psychological consequences" (Meschia et al., 2023).

European Federation of Neurological Societies (EFNS)

The European Federation of Neurological Societies guideline on the molecular diagnosis of channelopathies, epilepsies, migraine, stroke, and dementias notes that most *NOTCH3* mutations occur within exons three and four and suggests direct sequencing of these two exons if clinical suspicion is high (Burgunder et al., 2010).

United States Preventive Services Task Force (USPSTF)

As of September 19, 2023, the USPSTF has not published guidelines for the genetic testing of CADASIL patients.

European Academy of Neurology (EAN)

The European Academy of Neurology (EAN) released guidelines for monogenic cerebral small-vessel disease (cSVD), including diagnosis and management of CADASIL. EAN suggests that the first line diagnosis for CADASIL should be genetic testing, but diagnosis can also be established by skin biopsy with electron microscopy revealing granular osmiophilic material (GOM). Most *NOTCH3* variants causing CADASIL are due to a loss or gain of a cysteine in the EGFR repeats. Some non-cysteine changing variants have been reported, but most of these non-cysteine changing variants do not lead to a diseased state. If genetic testing reveals a non-cysteine changing variant, electron microscopy to visualize GOM is a useful tool to confirm CADASIL diagnosis. If the *NOTCH3* variant is of unknown significance, CADASIL diagnosis can be established with skin biopsy via electron microscopy or immunohistochemistry of the NOTCH3 extracellular domain. The guideline recommends "considering" a CADASIL diagnosis in any patient with "unexplained symmetrical periventricular WMHs [white matter hyperintensities] and a positive family history of migraine with aura, stroke, mood disorders or dementia." The guideline also

notes that CADASIL cannot be ruled out in the presence of "common cerebrovascular risk factors and extensive WMHs" or in "the absence of a medical or family history of migraine with aura." The guideline remarks that "although most patients have a family history, if the clinical and imaging phenotype is consistent with CADASIL the diagnosis should be considered" (Mancuso et al., 2020).

Overall, the EAN remarks that "CADASIL can only be definitively confirmed by genetic testing, revealing a *NOTCH3* mutation altering the number of cysteines in one of the 34 EGFr domains of the NOTCH3 protein" (Mancuso et al., 2020).

National Organization for Rare Diseases (NORD)

The National Organization for Rare Diseases released diagnosis guidelines on the disease. "CADASIL is based on symptoms, family history, and brain MRI lesions compatible with the disease. The CADASIL diagnosis can only be confirmed by DNA testing of blood samples for characteristic mutations in the *NOTCH3* gene or by identifying granular osmiophilic material (GOM) inclusions on a skin biopsy" (Orjuela, 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description

81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Genomic Testing for Hematopoietic Neoplasms

Policy Number: AHS – M2182 – Genomic Testing for Hematopoietic Neoplasms	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Hematologic cancers impact the normal production and function of blood cells. These cancers often begin in bone marrow, where stem cells develop into white blood cells, red blood cells, or platelets. Hematologic cancers such as myeloid and lymphoid neoplasms occur when there is an uncontrolled growth of abnormal cells which overtake the development of normal blood cells. An overabundance of abnormal cells interferes with the regular functions of normal cells (ACCC, 2022). Myeloid neoplasms occur when there is a proliferation of myeloid cells that have originated from a primitive stem cell (NCBI, 2023b). In contrast, lymphoid neoplasms are composed of a lymphocytic cell population which is usually malignant (clonal) by molecular genetic and/or immunophenotypic analysis (NCBI, 2023a).

For guidance on flow cytometry in hematopoietic neoplasms, please refer to AHS-F2019-Flow Cytometry. For guidance on minimal/measurable residual disease (MRD) in hematopoietic neoplasms, please refer to AHS-M2175-Minimal Residual Disease.

II. Related Policies

Policy Number	Policy Title
AHS-F2019	Flow Cytometry
AHS-M2101	Mutation Analysis in Myeloproliferative Neoplasms
AHS-M2175	Minimal Residual Disease

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For the initial diagnosis and profiling of hematopoietic neoplasms, the following testing **MEETS COVERAGE CRITERIA**:
   a) Bone marrow cytogenetics **and/or** fluorescent in situ hybridization (FISH) of bone marrow samples.
   b) Multigene panel testing.

2) For the differential diagnosis of chronic myeloid leukemia (CML) or acute lymphoblastic leukemia (ALL) or for optimal risk stratification and treatment planning for individuals diagnosed with B-cell ALL (B-ALL), one time qualitative or quantitative RT-PCR testing on blood or bone marrow for identification of the *BCR-ABL1* fusion gene transcript type, including determination of transcript size (e.g., p190 vs. p210), **MEETS COVERAGE CRITERIA.**

3) For individuals diagnosed with acute lymphoblastic leukemia (ALL) or pediatric ALL (PEDALL) who are under surveillance, the following tests **MEET COVERAGE CRITERIA** once every 3 to 6 months for at least 5 years:
   a) Bone marrow cytogenetics.
   b) Bone marrow FISH.
   c) Multigene panel testing.

4) For all individuals with Philadelphia chromosome positive ALL (Ph+ ALL), *BCR-ABL1* transcript-specific quantification **MEETS COVERAGE CRITERIA** at the following frequency:
   a) Once per month for individuals who have detectable levels of *BCR-ABL1* transcript.
   b) Once every three months for individuals who have undetectable levels of *BCR-ABL1* transcript.

5) For individuals diagnosed with acute myeloid leukemia (AML) who had cytogenetic abnormalities at diagnosis, cytogenetic or FISH testing **MEETS COVERAGE CRITERIA** at the following time points:
   a) Fourteen to twenty-one days after the start of therapy to document hypoplasia.

i) When hypoplasia is documented, repeat analysis seven to fourteen days later to clarify persistence of leukemia.

ii) When hypoplasia is not documented, repeat analysis at the time of hematologic recovery to document remission.

b) By 42 days post-treatment with either standard-dose or high-dose cytarabine induction for poor-risk AML, regardless of the degree of hematologic recovery.

6) For individuals with AML who have experienced relapsed/refractory disease after the completion of post-remission therapy, multigene panel testing **MEETS COVERAGE CRITERIA**.

7) For optimal risk stratification and treatment planning for individuals diagnosed with chronic lymphocytic leukemia (CLL) or small lymphocytic leukemia (SLL), one time testing with any of the following tests (when not already performed during initial diagnosis) **MEETS COVERAGE CRITERIA:**

a) FISH to detect +12; del(11q); del(13q); del(17p).

b) *TP53* mutation testing.

c) CpG-stimulated metaphase karyotype for complex karyotype.

d) Immunoglobulin heavy chain variable region gene (IGHV) mutation testing.

8) For individuals diagnosed with chronic myeloid leukemia (CML), quantitative reverse transcription polymerase chain reaction (qPCR) testing for the *BCR-ABL1* fusion gene transcript **MEETS COVERAGE CRITERIA** at the following frequency:

a) To establish baseline levels at diagnosis.

b) For individuals undergoing TKI therapy:

i) Every 3 months after initiation of therapy until major molecular response (MMR) (*BCR-ABL1* (IS) < 1% (>0.1%-1%)) has been achieved.

ii) Every 3 months for 2 years and every 3-6 months thereafter.

iii) If there is a 1-log increase in *BCR-ABL1* transcript levels with MMR, repeat in 1-3 months.

9) For individuals diagnosed with CML who are pursuing or who are actively undergoing TKI therapy, bone marrow cytogenetics **MEETS COVERAGE CRITERIA** at the following time points:

a) To establish cytogenetic changes.

b) When there is a failure to reach response milestones.

c) When there is any sign of loss of hematologic response.

d) When there is any sign of loss of complete cytogenetic response (CCyR) or its molecular response correlate, defined as an increase in *BCR-ABL1* transcript to >1%.

10) Evaluation of BCR-ABL kinase domain point mutations in patients with CML **MEETS COVERAGE CRITERIA** at the following time points:

a) When the individual has chronic phase CML.

b) When there is failure to reach response milestones.

c) When there is any sign of loss of hematologic response.

d) When there is any sign of loss of CCyR or its molecular response correlate, defined as an increase in *BCR-ABL1* transcript to 1%.

e) When there is a 1-log increase in *BCR-ABL1* transcript levels and a loss of MMR.

f) When the disease progresses to accelerated or blast phase.

11) For individuals with CML who are undergoing treatment discontinuation with TKI therapy and who remain in MMR after discontinuation of therapy, qPCR on blood or bone marrow for the *BCR-ABL1* fusion gene transcription **MEETS COVERAGE CRITERA** at the following frequency:

a) Every month for the first 6 months following discontinuation.

b) Once every two months in months 7-12 following discontinuation.

c) Once every three months beginning 12 months following discontinuation of therapy, as long as the individual remains in MMR.

12) For individuals with CML, the use of FISH to monitor response to TKI therapy **DOES NOT MEET COVERAGE CRITERIA**.

13) Simultaneous testing of both bone marrow and blood for monitoring purposes **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

14) For the diagnosis or prognosis of individuals with confirmed acute leukemia, global/gene specific methylation, microRNA (miRNA) expression, **or** gene expression analysis **DOES NOT MEET COVERAGE CRITERIA**.

15) For diagnosis or prognosis of myeloid or lymphoid neoplasms, all other testing not addressed above **DOES NOT MEET COVERAGE CRITERIA.**

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ABL1	*Abelson murine leukemia viral oncogene homolog 1*
AML	Acute myeloid leukemia
ANKRD26	*Ankyrin repeat domain containing 26*
APL	Acute promyelocytic leukemia
ASCO	American Society of Clinical Oncology
ASH	American Society of Hematology
ASXL1	*ASXL transcriptional regulator 1*
ASXL2	*ASXL transcriptional regulator 2*
BAALC	Brain and acute leukemia cytoplasmic
BCR-ABL1	*BCR activator of RhoGEF and GTPase- ABL proto-oncogene 1, non-receptor tyrosine kinase*
BCSH	British Committee for Standards in Haematology
c-KIT	Commonly used alias for *KIT proto-oncogene, receptor tyrosine kinase*
CAP	College of American Pathologists
CBF	Core-binding factor
CALR	*Calreticulin*
CBFA2	*CBFA2/RUNX1 partner transcriptional co-repressor 2*
CEBPA	*CCAAT/enhancer binding protein alpha*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CLL	Chronic lymphocytic leukemia
CMS	Centers for Medicare and Medicaid
CML	Chronic myeloid leukemia
CN	Normal karyotypes
CT	Computed tomography
CR	Complete hematologic remission
DDX41	*DEAD-box helicase 41*
DNA	Deoxyribonucleic acid
DNMT3A	*Deoxyribonucleic acid methyltransferase 3A*

ELN	European LeukemiaNet
EMSO	European Society For Medical Oncology
ERG	ETS transcription factor ERG
EVI1	Ecotropic virus integration site 1 protein homolog
EZH2	*Enhancer of zeste 2 polycomb repressive complex 2 subunit*
FDA	Food and Drug Administration
FDG-PET	Fluorodeoxyglucose positron emission tomography
FISH	Fluorescence in situ hybridization
FLT3	*FMS-like tyrosine kinase 3*
GATA2	GATA binding protein 2
IDH1	*Isocitrate dehydrogenase 1*
IDH2	*Isocitrate dehydrogenase 2*
IGHV	Immunoglobulin heavy chain variable region gene
ITD	Internal tandem duplications
iwCLL	International Workshop on Chronic Lymphocytic Leukemia
JAK2	*Janus kinase 2*
KIT	*KIT proto-oncogene, receptor tyrosine kinase*
KRAS	*KRAS proto-oncogene, GTPase*
LTD	Laboratory-developed test
MBNL1	*Muscleblind like splicing regulator 1*
MECOM	MDS1 and EVI1 complex locus
MEIS1	Muscleblind like splicing regulator 1
miRNA	Micro ribonucleic acid
Mkneg	Non-chromosomal karyotype
MLL-PTD	*Mll -Partial Tandem Duplication*
MPL	*MPL proto-oncogene, thrombopoietin receptor*
MRD	Minimal residual disease
MYH11	*Myosin heavy chain 11*
NCCN	National Comprehensive Cancer Network
NGS	Next generation sequencing
NPM1	*Nucleophosmin 1*
*NPM1*mut	*NPM1* mutations
NRAS	*NRAS proto-oncogene, GTPase*
PCR	Polymerase chain reaction
PMF	Polyamine modulated factor 1
PML-RAR	*Promyelocytic leukemia-retinoic acid receptor*
RNA	Ribonucleic acid
RT-PCR	Reverse transcription- polymerase chain reaction
RUNX1	*RUNX family transcription factor 1*

RUNX1T1	*RUNX1 partner transcriptional co-repressor 1*
SPI1	Spi-1 proto-oncogene
SF3B1	*Splicing factor 3b subunit 1*
SRSF2	*Serine and arginine rich splicing factor 2*
SLL	Small lymphocytic leukemia
TET2	*Tet methylcytosine dioxygenase 2*
TKD	*Tyrosine kinase domain*
TP53	*Tumor protein 53*
WHO	World Health Organization
WT1	*Wilms' tumor 1*

V. Scientific Background

Acute Lymphoblastic Leukemia (ALL)

Acute lymphocytic leukemia occurs when a bone marrow cell develops a mutation in its genetic material. ALL can be of B-cell precursor (BCP) lineage (BCP-ALL) or, less commonly, T-cell precursor lineage (T-ALL). However, "Both comprise multiple subtypes commonly defined by structural chromosomal alterations that are initiating lesions, with secondary somatic (tumor-acquired) DNA copy number alterations and sequence mutations that contribute to leukemogenesis. Chromosomal alterations include aneuploidy and chromosomal rearrangements that result in oncogene deregulation or expression of chimeric fusion genes. The prevalence of these alterations varies according to age and identification is important for diagnosis, risk classification, and, for some lesions, targeted therapy. Common genomic features of *BCR-ABL1*–like ALL are alterations of B-lymphoid transcription factor genes (particularly *IKZF1* deletions) and genetic alterations deregulating cytokine receptor and tyrosine kinase signaling. These include rearrangements and mutation of *CRLF2* (approximately 50%), rearrangements of *ABL*-class tyrosine kinase genes (12%), rearrangements of *JAK2* (7%) and the erythropoietin receptor gene (*EPOR*; three to ten percent), mutations activating JAK-STAT signaling (11%) and Ras signaling (*NRAS*, *KRAS*, *PTPN11*, and *NF1*; six percent), and less common kinase alterations (*FLT3*, *NTRK3*, *BLNK, TYK2*, and *PTK2B*)" (Iacobucci & Mullighan, 2017).

Acute myeloid leukemia (AML)

Acute myeloid leukemia is the most common acute leukemia in adults (80%), with a median age at diagnosis of 65 years. An AML diagnosis in adults is generally associated with a poor prognosis. This disease is much less common in children younger than ten years of age, as less than ten percent of acute leukemias are

diagnosed as AML in this age group (Schiffer & Gurbuxani, 2024; Siegel et al., 2017; Yamamoto & Goodman, 2008).

A clinical presentation of AML includes symptoms related to complications of pancytopenia, including weakness and fatigability, infections of variable severity, and hemorrhagic findings (Schiffer & Gurbuxani, 2024). Analysis of gene sequencing of AML cases generally reveal more than ten significant gene mutations; many of which are thought to participate in leukemogenesis (CGARN, 2013). The most common gene mutations are as follows: *FLT3* (28%), *NPM1* (27%), *DNMT3A* (26%), *IDH1* or *IDH2* (20%), *NRAS* or *KRAS* (12%), *RUNX1* (10%), *TET2* (8%), *TP53* (8%), *CEBPA* (6%), and *WT1* (6%). Mutations impacting signal activation are frequent (60% of cases); the most common of which are mutations in *FLT3* (Stock & Thirman, 2022).

The second most common mutation in AML (27%) is of nucleophosmin (NPM1), a ubiquitously expressed phosphoprotein that normally shuttles between the nucleus and cytoplasm (Falini et al., 2005; Stock & Thirman, 2022). *NPM1* mutations are associated with improved outcomes although the mechanism is not known. Concurrent mutations (such as an *FTL3* mutation) may influence prognosis, but generally *NPM1* patients without concurrent mutations have better prognoses (Schiffer & Uy, 2024).

The *CCAAT/enhancer binding protein alpha* (*CEBPA*) gene mutation is also common in AML. *CEBPA* encodes a transcription factor necessary for myeloid differentiation. This mutation is one of the two mutations associated with familial leukemia and consists of about ten percent of AML cases. Familial AML with a *CEBPA* mutation has a phenotype similar to those of "sporadic AML with biallelic *CEBPA* mutations," but most of the current data revolves around the assessment of *CEBPA* double mutations. *CEBPA* single mutations and hypermethylated *CEBPA* requires further study (Schiffer & Uy, 2024).

Isocitrate dehydrogenase (IDH) 1 and 2 mutations comprise approximately 15% of AML cases. These mutations are mutually exclusive with *Tet Methylcytosine Dioxygenase 2* (*TET2*) and *Wilms' tumor 1* (*WT1*) mutations but are commonly seen with *NPM1* and *DNA methyltransferase 3A* (*DNMT3A*) mutations. Data on the prognoses of these mutations is varied (Schiffer & Uy, 2024).

The *KIT* mutations also comprise about six percent of AML cases. *KIT* encodes the receptor for a stem cell factor, and prognoses are varied (Castells & Akin, 2021; Schiffer & Uy, 2024). Some researchers suggest that of all *KIT* mutations, the D816 mutation is the most unfavorable prognostic factor in AML patients (Yui et al., 2017).

Approximately eight percent of AML cases consist of *WT1* gene mutations. *WT1* encodes a transcriptional regulator for genes involved in maturation and growth.

Again, the prognosis of this mutation is mixed (Schiffer & Uy, 2024), although some researchers strongly support the theory that *WT1* mutations are associated with poor AML prognoses (Hou et al., 2010). The *WT1* mutation status of AML patients may also change during disease progression. New research has suggested that after allogenic stem cell transplantation, AML relapse could be due to a gain in *WT1* gene alterations and a "high mutation load" (Vosberg et al., 2018).

The *ASXL Transcriptional Regulator 1 (ASXL1)* and *ASXL Transcriptional Regulator 2* (*ASXL2)* may also be mutated in AML cases. *ASXL1* has an unclear function, but it is speculated to be related to histone post-translational modifications. The frequency of *ASXL1* is varied, as estimates range from six percent to 30%. Furthermore, *ASXL1* mutations are mutually exclusive with *NPM1* mutations, and *ASXL2* mutations are associated with *RUNX1* mutations (also known as *AML1* or *CBFA2*) (Schiffer & Uy, 2024).

The *DNMT3A* gene amounts to 20%-22% of AML cases. This gene plays a role in epigenetic modifications for development and differentiation. Mutations in this gene affect hematopoietic stem cell differentiation. Prognoses of this gene mutation have been mixed (Schiffer & Uy, 2024).

Tumor protein 53 (*TP53*) and RAS and may also be present in AML cases and may be accompanied by other genetic abnormalities. RAS regulates cell signal transduction, and its mutation leads to a constitutionally active growth stimulus whereas *TP53* encodes a transcriptional activator of growth inhibitory genes (Frucht & Lucas, 2023; Rai & Stilgenbauer, 2023).

Gene expression profiling and microRNA expression profiling may also contribute to assessment and management of AML. Gene expression profiling has been used to differentiate between risk groups based on cytogenetic evaluation whereas microRNA profiling evaluates the regulation of gene expression. However, neither technique is used regularly in clinical practice as these techniques have yet to be widely validated (Schiffer & Uy, 2024).

Chronic Lymphoblastic Leukemia (CLL)

In Western countries, CLL is the most common form of leukemia; in the United States, it accounts for 25 to 30 percent of all leukemias (Rai et al., 2024). CLL and SLL (small lymphocytic leukemia) are mature B cell neoplasms characterized by a progressive accumulation of monoclonal B lymphocytes. It should be noted that "CLL is considered to be identical (ie, one disease with different manifestations) to the non-Hodgkin

lymphoma SLL. The malignant cells seen in CLL and SLL have identical pathologic and immunophenotypic features. The term CLL is used when the disease manifests primarily in the blood, whereas the term SLL is used when involvement is primarily nodal" (Rai et al., 2024). It is also worth mentioning that "In less than 10 percent of patients, CLL/SLL presents primarily in the lymph nodes as a non-Hodgkin lymphoma (ie, SLL)" and that "this presentation accounts for less than 5 percent of all non-Hodgkin lymphomas" (Rai et al., 2024).

The CLL exomes carry approximately "5–20 somatically acquired mutated genes per individual case, much fewer than many other solid cancers. Importantly, the somatically acquired mutation status of sequence variants in genes, like other studies of genomic changes in cancer, necessitates confirmation of the absence of these candidate mutations in paired non-tumorous DNA (T-cell–, buccal cell– or skin-derived DNA). Mutations in *TP53* are of major clinical relevance, are often associated with del17p and gain in frequency over time. *TP53* mutated and associated del17p states substantially lower response rates, remission duration, and survival in CLL. Mutations in *NOTCH1* and *SF3B1* are recurrent, often associated with progressive CLL" (Amin & Malek, 2016).

Chronic myeloid leukemia (CML)

The first human malignancy in which a specific chromosomal defect, known as the minute or Philadelphia (Ph) chromosome, could be linked to pathogenetic events of leukemogenesis (Nowell & Hungerford, 1960). The Ph chromosome translocation (t(9;22)(q34;q11.2)) fuses the breakpoint cluster region protein (*BCR*) gene from chromosome 22 with the Abelson murine leukemia viral oncogene homolog 1 (*ABL1*) proto-oncogene from chromosome nine in a head-to-tail manner to form the transcriptionally active *BCR-ABL* fusion gene (Schrijver & Zehnder, 2022). The fusion of *BCR* at the 5' side in *ABL* alters the tightly regulated function of the Src homology 3 (SH3) domain, disabling control over the tyrosine kinase enzyme. The resulting chimeric BCR-ABL protein has constitutively elevated tyrosine phosphokinase activity (Kurzrock et al., 2003) that activates a number of downstream signaling molecules, including PI3K, AKT, JNK, RAS and STAT5 (Ren, 2005). This then disrupts cellular signal transduction pathways, leading to issues in the regulation of both apoptosis and cell proliferation (Warmuth et al., 1999), ultimately leading to factor-independent and leukemogenic cell growth (Van Etten, 2023).

Detection of the Ph chromosome is the hallmark of CML and is found in up to 95 percent of patients (Leoni & Biondi, 2015). In approximately five percent of CML cases, the Ph chromosome cannot be detected, and *BCR-ABL1* formation is attributed to microscopically undetectable translocations or variant complex translocations involving

a third chromosome (Schrijver & Zehnder, 2022). Independent of which other chromosomes are involved in variant translocations, the generation of the *BCR-ABL* fusion gene is the "fundamental cause of Ph-positive leukemias" (Van Etten, 2023), as the 210-KDa fusion protein BCR-ABL is essential for initiation, maintenance, and progression of CML (Ren, 2005). Testing for BCR-ABL1 detects both the Ph chromosome and fusion gene or its transcripts. The BCR-ABL1 transcript is the RNA copy made by the cell.

The FMS-like tyrosine kinase 3 (FLT3) is a transmembrane tyrosine kinase receptor that stimulates cell proliferation upon activation. Both internal tandem duplications (ITDs) of different lengths and point mutations in the activating loop of the kinase domain result in ligand-independent activation of the FLT3 receptor and a proliferative signal. A *FLT3-ITD* mutation has been shown to have a poor prognosis in contrast to *FTL3* point mutations in the activation loop of the kinase domain. Higher ratios of mutated alleles compared to wild-type alleles confer worse prognoses (Schiffer & Uy, 2024).

The *BCR-ABL1*, refers to the fusion gene resulting from a reciprocal translocation that joins the *ABL1* gene from chromosome 9 to the *BCR* gene on chromosome 22 and is necessary for the development of chronic myeloid leukemia (Tachibana et al., 2022) (Van Etten, 2023). This reciprocal translocation also generates a shortened derivative chromosome 22, known as the Philadelphia (Ph) chromosome (Schrijver & Zehnder, 2022). The Ph chromosome is a diagnostic hallmark, present in 95% of people with CML and approximately three to five percent children and 25%–40% adults with acute lymphoblastic leukemia (ALL) (Leoni & Biondi, 2015). An aggressive form of cancer resulting from the neoplastic transformation of lymphoid precursors characterized by the presence of too many lymphoblasts or lymphocytes in the bone marrow and peripheral blood (PDQ, 2023). Predominately a childhood disease, approximately 60% of cases were diagnosed in patients younger than 20 years of age (Pui, 2011).

Analytic Validity

There is very limited published literature on the analytic validity and clinical validity of genetic testing for *FLT3* and *NPM1* mutations in AML. However, the analytic validity of PCR in general is extremely high (Leonard, 2016). Other tools, such as flow cytometry and next generation sequencing (NGS) have also been used for AML prognostic and diagnostic purposes.

Ampasavate et al. (2019) have developed a quantitative protocol and flow cytometry-based method for monitoring an anti-FLT3 interaction. The FLT3 biomarker has been previously identified as a poor prognostic marker for AML patients. This method can rapidly identify intact FLT3 on the leukemic cell surface. "The results demonstrated good linearity ($r2 > 0.99$)"; further, "when compared with Western blotting results, FLT3

protein expression levels in leukemia patient's bone marrow samples were demonstrated in the same trend" (Ampasavate et al., 2019). The researchers state that this technique is reliable, rapid, effective and "provided a practical analysis of FLT-3 biomarker levels which is valuable for physician decision in acute leukemia treatment" (Ampasavate et al., 2019).

Alonso et al. (2019) have researched the utility of a 19-gene NGS panel for AML diagnostic purposes. This targeted NGS panel was studied in a cohort of 162 patients with AML. The authors note that "The assay yielded a median read depth >2000×, with 88% of on-target reads and a mean uniformity >93% without significant global strand bias. The method was sensitive and specific, with a valid performance at the clinical variant allele frequency cutoff of 3% for point mutations and five percent for insertions or deletions." The researchers conclude that this is a "reliable and reproducible method" for AML diagnoses (Alonso et al., 2019).

Molecular testing for the diagnosis of CML confirms typical findings in the blood and bone marrow by the demonstration of the Ph chromosome, the *BCR-ABL1* fusion gene or the BCR-ABL1 fusion mRNA. Molecular testing techniques include conventional cytogenetics, fluorescence in situ hybridization (FISH) analysis and reverse transcription polymerase chain reaction (RT-PCR) (Van Etten, 2022). Conventional cytogenetic karyotyping is no longer the diagnostic modality of choice due to its requirements for a highly skilled staff, culturing of cells, long turnaround time, and lower sensitivity (5-10%). Despite this, conventional cytogenetics are still the gold standard, and "should be performed" especially at diagnosis to detect additional clonal abnormalities (Yeung et al., 2016). FISH is more sensitive (0.1-5%) than karyotyping and can be performed on peripheral blood in addition to bone marrow and tissue. FISH can detect certain very rare translocations not usually detectable by the vast majority of commercial and laboratory-developed RT-PCR assays, but FISH is highly specific to the targeted region and may miss other chromosomal changes. Quantitative RT-PCR is the most sensitive technique currently available (0.001-0.01% sensitivity).

On July 22, 2016 the FDA approved the QuantideX qPCR BCR-ABL IS Kit as an *in vitro* nucleic acid amplification test for the quantitation of BCR-ABL1 and ABL1 transcripts in total RNA from whole blood of diagnosed t(9;22) positive Chronic Myeloid Leukemia (Tachibana et al.) patients expressing BCR-ABL1 fusion transcripts type e13a2 and/or e14a2 as a class II device with special controls (FDA, 2016). Brown et al. (2019) performed a study to describe the analytical validation of this kit. They were able to find that "the test has a limit of detection of MR molecular response] 4.7 (0.002% IS) and a linear range from MR0.3 (50%IS) to MR4.7 (0.002%IS) for both Major transcripts. Single-site and multisite precision studies demonstrated a maximum SD of 0.13 MR (30% CV within the assay range between MR0.7 and MR3.7)."

Clinical Utility and Validity

The clinical utility of testing fallows for further risk stratification, prognostication, and guide management decisions in patients with AML. Several studies have concluded that *FLT3* and *NPM1* mutation testing in cytogenetically normal AML is useful for prognosis and treatment decision making (DeZern et al., 2011; Pastore et al., 2014; Willemze et al., 2014).

Devillier et al. (2015) sought to identify biological and prognostic subgroups based on genetic mutations in AML patients. A total of 125 AML patients with myelodysplasia-related changes ("MRC") were evaluated. The authors focused on the 26 patients with *ASXL1* mutations and 28 with *TP53* mutations. The *ASXL1* mutation cohort was found to have a higher proportion of marrow dysgranulopoiesis and an overall survival (OS) rate that was below average for wild-types (14% for *ASXL1* mutants, 37% for wild-types). The *TP53* cohort was found to have a "complex karyotype" and predicted a poor outcome with unfavorable cytogenetic risk AML. Both mutations were found to be an independent factor associated with shorter OS (Devillier et al., 2015).

Bolouri et al. (2018) examined 993 children's genetic data from the Children's Oncology Group (Khoury et al.) AML trials to characterize the molecular landscape of AML. The authors found that certain somatic variants, such as *MBNL1,* were "disproportionately prevalent" in children compared to adults. However, certain variants common in adults such as *TP53*, were not found in children. Other mutations such as *NRAS* and *KRAS* were "frequent" in pediatric AML. The authors concluded that their results "highlight the need for and facilitate the development of age-tailored targeted therapies for the treatment of pediatric AML" (Bolouri et al., 2018).

Jongen-Lavrencic et al. (2018) conducted a study of 482 patients 18 to 65 years with newly diagnosed AML. Targeted next-generation sequencing (NGS) was carried out at diagnosis and after induction therapy (during complete remission). At least one mutation was detected in 430 (89.2%) patients, and mutations persisted in 51.4% of those patients during complete remission. The detection of minimal residual disease was associated with a significantly increased relapse rate than no detection. Persistent DTA mutations (mutations in *DNMT3A*, *TET2*, and *ASXL1*) were not correlated with an increased relapse rate. Overall, the authors concluded, "A comparison of sequencing with flow cytometry for the detection of residual disease showed that sequencing had significant additive prognostic value. Among patients with AML, the detection of molecular minimal residual disease during complete remission had significant independent prognostic value with respect to relapse and survival rates, but the detection of persistent mutations that are associated with clonal hematopoiesis did not have such prognostic value within a 4-year time frame" (Jongen-Lavrencic et al., 2018).

Kuwatsuka et al. (2018) evaluated the genetic background of 103 young adults and their subsequent clinical outcomes. The 103 cases included mutations in *FLT3-ITD, KIT, CEBPA, NRAS, KRAS, WT1, MLL-PTD*, and *NPM1*. Overall, *FLT3-ITD* and *NPM1* mutations were associated with a greater mortality risk. *NPM1* mutations conferred a 100% survival rate in the absence of *FLT3-ITD* mutations, but *FLT3-ITD* conferred only a 35% survival without *NPM1* mutations (Kuwatsuka et al., 2018).

Zhu et al. (2017) assessed the effect of gene mutations on the subsequent cytogenetic aberrations. A total of 560 patients were enrolled, and the authors examined the following alterations: "*CEBPA*, *NPM1, FLT3, C-KIT, NRAS, WT1, DNMT3A, MLL-PTD* and *IDH1/2*, as well as expression levels of MECOM, ERG, GATA2, WT1, BAALC, MEIS1 and SPI1." The investigators found that the expression levels of MECOM, MEIS1, and BAALC influenced cytogenetic aberration. Further, *FLT3*, *C-KIT*, and *NRAS* mutations all contained a "conversed" expression profile of MEIS1, WT1, GATA2, and BAALC expression. The investigators also noted "*FLT3, DNMT3A, NPM1* and biallelic *CEBPA* represented the mutations associated with the prognosis of AML in our group" (Zhu et al., 2017).

Papaemmanuil et al. (2016) examined the relationship between genotype and pathophysiology in AML. A total of 1540 patients with 5234 driver mutations across 76 genes were studied. The authors found three genomic subcategories in addition to the currently defined AML subgroups: mutations in genes encoding chromatin, RNA splicing regulators or both (such as *ASXL1* or *RUNX1*), *TP53* mutations, chromosomal aneuploidies or both (unusual karyotypes and *TP53*), and *IDH2* mutations. The authors noted that "patients with chromatin–spliceosome and *TP53*–aneuploidy AML had poor outcomes." The *NPM1* cohort was the largest of the sample (27%, 436 patients) and 319 of those patients also carried a DNA methylation or hydroxylmethylation gene, such as *IDH1/2* or *TET2*. The authors also noted that *NPM1-DNMT3A–NRASG12/13* had an "unexpectedly benign" prognosis, and the *NPM1* subgroup's prognoses were largely determined by the context in which the NPM1 mutation occurred (such as in *NRAS, IDH*, and so on) (Papaemmanuil et al., 2016).

Sperr et al. (2016) evaluated the effect of a genetic mutation and karyotype on the efficacy of treatment for elderly patients. A total of 192 patients over 60 years old were enrolled, and 115 of these patients achieved "complete hematologic remission (CR)." The authors stated that *NPM1* mutations (*NPM1*mut) and karyotype were the only independent predictors of survival, also noting that *NPM1*mut showed a prognostic impact on both normal (CN) and non-chromosomal (Mkneg) karyotypes. The authors concluded that "elderly patients with CN/Mkneg-*NPM1*mut or core binding factor AML can achieve long term median continuous CR when treated with intensive induction and consolidation therapy whereas most elderly patients with CN/Mkneg-NPM1wild-

type or CN/Mkpos AML may not benefit from intensive chemotherapy" (Sperr et al., 2016).

Heiblig et al. (2019) assessed the impact of *NPM1* subtypes on treatment outcomes. One hundred seventy-five patients were examined. The authors found that out of the *NPM1* AML cases, 73% (128) were "Type A" mutations (TCTG at exon 12) and 27% (47) were "Non Type-A mutations" (Type B: CATG and Type D: CGTG). The Type-A mutations were found to achieve minimal residual disease (MRD) earlier than non Type-A mutations. However, non-type A mutations achieved better rates of medial survival (Heiblig et al., 2019).

D'Adda et al. (2019) evaluated the effect of the BCR-ABL transcript on efficacy of TKIs. The *BCR*-ABL1 fusion gene may cause CML pathogenesis due to several breakpoints; the most common occur around exon 13 and 14 of the *BCR* gene and cause the formation of e13a2 and e14a2 transcripts (Greenfield et al., 2019). Out of 173 sampled patients, 67 had the e13a2 transcript, and 106 had the e14a2 version. The patients with the e14a2 version were more likely to achieve a deep molecular response to TKIs (sustained or otherwise). After 68 months, the sustained deep molecular response (sDMR) rate was 39.6% for e14a2 patients compared to 19.6% for e13a2 patients. Overall, the maximum rate of sDMR for e13a2 patients was 37%, after 60 months. Furthermore, only two patients (three percent) with the e13a2 transcript achieved treatment-free remission (TFR) whereas 25 of e14a2 patients achieved TFR (23%) (D'Adda et al., 2019).

Xu et al. (2020) have analyzed data from 220 normal karyotype AML pediatric patients. Participants were selected from the Cancer Genome Atlas database. It was found that 12.7% of these patients had *WT1* mutations, and that "the *WT1*-mutated group suffered lower rates of complete remission (CR) ($P < 0.001$ and $P < 0.001$, respectively) but higher rates of minimal residual disease (MRD) ($P = 0.003$ and $P = 0.021$, respectively) after both one and two courses of induction chemotherapy" (Xu et al., 2020). Patients with *WT1* mutations also had significantly worse event-free and overall survival rates ($P=0.007$ and $P<0.001$, respectively) (Xu et al., 2020).

Sasaki et al. (2020) studied the impact of *ASXL1, DNMT3A, JAK2, TET2*, and *TP53* mutations on survival in newly diagnosed acute myeloid leukemia (AML) patients. The 421 bone marrow aspirates were studied using NGS for these mutations with a minimum variant allele frequency (VAF) of 5%. "A total of 71 patients (17%) had *ASXL1* mutations, 104 patients (25%) had *DNMT3A* mutations, 16 patients (4%) had *JAK2* mutations, 82 patients (20%) had *TET2* mutations, and 86 patients (20%) had *TP53* mutations." The median VAF of *ASXL1* was 34.31% (range, 1.17%-58.62%), *DNMT3A* was 41.76% (range, 1.02%-91.66%), *JAK2* was 46.70% (range, 10.4%-71.7%), *TET2* was

42.78% (range, 2.26%-95.32%), and *TP53* was 45.47% (range, 1.15%-93.74%). In patients with these mutations, the median overall survival was 11 months. In patients without these mutations, the overall survival was 27 months. The authors conclude that "The VAF of *ASXL1, DNMT3A, JAK2, TET2, TP53*, and *NPM1* mutations is associated with worse prognosis in patients with newly diagnosed AML" (Sasaki et al., 2020).

Duncavage et al. (2021) investigated the clinical utility and accuracy of whole-genome sequencing (WGS) for the purpose of risk stratification in patients with acute myeloid leukemia (AML) or myelodysplastic syndromes (MDS). The results from 263 patients were compared with findings from cytogenetic analysis and targeted sequencing. When conducting the WGS, they found that all 40 recurrent translocations and 91 copy-number alterations found on cytogenetic analysis were identified on WGS. There were also new clinically reportable genomic events among 17.0% of the patient sample. The standard AML risk groups, "as defined by sequencing results instead of cytogenetic analysis, correlated with clinical outcomes." WGS was also able to classify patients with inconclusive cytogenetic analysis results into risk groups. This demonstrates that WGS could increase the diagnostic yield of AML and MDS and supplement the accuracy of cytogenetic analysis (Duncavage et al., 2021).

In a retrospective study, Yang reported the clinical significance of *BCR-ABL1* mutations in patients with Philadelphia chromosome-positive CML who underwent allogeneic hematopoietic cell transplantation. Of 315 patients in this study, point mutations were detected in 152 patients. One hundred and one of these 152 patients (66%) had T315I mutations and 51 had mutations other than T315I. The patients were followed 38 months later and overall survival at three years was worse in patients with the mutations than the non-mutation group, especially in the chronic phase of CML. Overall survival in the non-T315I group was significantly worse than that in the no-mutation group. The authors conclude that "mortality risk was significantly higher in patients with the BCR-ABL1 mutation than in patients without the mutation" (Tachibana et al., 2022).

VI. Guidelines and Recommendations

World Health Organization (WHO)

In a revision of the fourth edition on Classification of Tumors of Hematopoietic and Lymphoid Tissues, World Health Organization (WHO) incorporated new molecular genetic findings and clinical data into its classification of acute leukemias. WHO expanded on the prognostic significance of various gene mutations for each AML subtype. For example, for the AML with recurrent genetic abnormalities, inv(3) (q21.3; q26.2) does not represent a fusion gene, but rather a repositioning of a distal GATA2 enhancer leading to activation of MECOM (EVI1) expression and GATA2

haploinsufficiency. The AML with *CEBPA* mutation is defined based on biallelic mutation instead of single mutations because of prognostic significance. The provisional two categories are also added such as AML with *RUNX1* for de novo AML without preexisting cytogenetic abnormalities associated with MDS and AML with *BCR-ABL1* fusion gene. AML with *NPM1* or biallelic *CEBPA* mutations and multilineage dysplasia are now considered separately instead of being a part of AML with myelodysplasia-related changes because of a lack of prognostic significance. The complete list for acute myeloid neoplasms 2016 WHO classification is shown in Figure 1 (Arber et al., 2016).

In the absence of *JAK2, CALR,* and *MPL* mutations, the presence of another clonal marker is included as one of the major diagnostic criteria for PMF. Additional mutation in *ASXL1, EZH2, TET2, IDH1, IDH2, SRSF2* and *SF3B1* genes are noted to be of use in determining the clonal nature of the disease.

In the fifth edition of the World Health Organization Classification of Haematolymphoid Tumours: Myeloid and Histiocytic/Dendritic Neoplasms, WHO places greater emphasis in "the separation of AML with defining genetic abnormalities from AML defined by differentiation". The latter eschews the previously ambiguous categorical term AML NOS, and other notable changes include the "elimination of the 20% blast requirement for AML types with defining genetic abnormalities (with the exception of AML with BCR::ABL1 fusion and AML with CEBPA mutation)" and "the introduction of a section on AML with other defined genetic alterations, a landing spot for new and/or uncommon AML subtypes that may (or may not) become defined types in future editions of the classification" (Khoury et al., 2022). Their list of acute myeloid leukemias is presented below.

Acute myeloid leukaemia with defining genetic abnormalities
Acute promyelocytic leukaemia with *PML::RARA* fusion
Acute myeloid leukaemia with *RUNX1::RUNX1T1* fusion
Acute myeloid leukaemia with *CBFB::MYH11* fusion
Acute myeloid leukaemia with *DEK::NUP214* fusion
Acute myeloid leukaemia with *RBM15::MRTFA* fusion
Acute myeloid leukaemia with *BCR::ABL1* fusion
Acute myeloid leukaemia with *KMT2A* rearrangement
Acute myeloid leukaemia with *MECOM* rearrangement
Acute myeloid leukaemia with *NUP98* rearrangement
Acute myeloid leukaemia with *NPM1* mutation
Acute myeloid leukaemia with *CEBPA* mutation
Acute myeloid leukaemia, myelodysplasia-related
Acute myeloid leukaemia with other defined genetic alterations

Acute myeloid leukaemia, defined by differentiation
Acute myeloid leukaemia with minimal differentiation
Acute myeloid leukaemia without maturation
Acute myeloid leukaemia with maturation
Acute basophilic leukaemia
Acute myelomonocytic leukaemia
Acute monocytic leukaemia
Acute erythroid leukaemia
Acute megakaryoblastic leukaemia

(Khoury et al., 2022)

Moreover, in defining acute myeloid leukemia, *myelodysplasia-related* (AML-MR), WHO offers the following abnormalities and mutations of interest:

Cytogenetic and molecular abnormalities defining acute myeloid leukaemia, myelodysplasia-related.

Defining cytogenetic abnormalities	Defining somatic mutations
Complex karyotype (≥3 abnormalities)	*ASXL1*
5q deletion or loss of 5q due to unbalanced translocation	*BCOR*
Monosomy 7, 7q deletion, or loss of 7q due to unbalanced translocation	*EZH2*
11q deletion	*SF3B1*
12p deletion or loss of 12p due to unbalanced translocation	*SRSF2*
Monosomy 13 or 13q deletion	*STAG2*
17p deletion or loss of 17p due to unbalanced translocation	*U2AF1*
Isochromosome 17q	*ZRSR2*
idic(X)(q13)	

(Khoury et al., 2022).

The WHO published guidelines on the classification of myeloid neoplasms and acute leukemia. In the recent revision of the fourth edition on Classification of Tumors of Hematopoietic and Lymphoid issues, World Health Organization (WHO) incorporated new molecular genetic findings and clinical data into its classification of acute leukemias (Arber et al., 2016).

They state that: "With regard to chronic myeloid leukemia , BCR-ABL1^{+}, most cases of CML in chronic phase can be diagnosed from peripheral blood (Papaemmanuil et al.) findings combined with detection of t(9;22)(q34.1;q11.2) or, more specifically, *BCR-ABL1* by molecular genetic techniques. However, a bone marrow (BM) aspirate is essential to ensure sufficient material for a complete karyotype and for morphologic evaluation to confirm the phase of disease. In the era of tyrosine-kinase inhibitor (TKI) therapy, newly diagnosed patients may have a nearly normal lifespan, but regular monitoring for *BCR-ABL1* burden and for evidence of genetic evolution and development of resistance to TKI therapy is essential to detect disease progression" (Arber et al., 2016).

They also introduced a provisional classification of ALL: B-ALL with translocations involving tyrosine kinases or cytokine receptors ("BCR-ABL1–like ALL"). They note that "This newly recognized entity is assuming increasing importance because of its association with an adverse prognosis and responses of some cases to TKI therapies; however, it has been difficult to define in the clinical setting. It was originally described separately by different groups who demonstrated a series of cases of poor-prognosis

childhood ALL with gene expression profiles similar to those seen in cases of ALL with BCR-ABL1, though different algorithms applied to the same sets of cases did not classify all cases the same way.

The cases with translocations involving tyrosine kinase genes involve many different genes including ABL1 (with partners other than BCR), as well as other kinases including ABL2, PDGFRB, NTRK3, TYK2, CSF1R, and JAK2. Over 30 different partner genes have been described. Some patients, especially those with EBF1-PDGFRB translocations, have shown remarkable responses to TKI therapy, even after failing conventional therapy" (Arber et al., 2016).

In the 5th Edition of the World Health Organization Classification of Hematolymphoid Tumors, the WHO updated their cytogenetic and molecular genetic information regarding AML. They highlight the following in their update:

- "Newly discovered recurrent cytogenetic abnormalities listed in *AML with other defined genetic abnormalities* include *RUNX1T3* (*CBFA2T3)::GLIS, KAT6A::CREBBP, FUS::ERG, MNX1::ETV6*, and *NPM1::MLF1*. Those listed in "B-LBL/L with other defined genetic abnormalities"
  include *DUX4* rearrangement, *MEF2D* rearrangement, *ZNF384* rearrangement, *NU TM1* rearrangements, *MYC* rearrangement, *PAX5alt* or *PAX5 p.P80R*. With more data accumulated, neoplasms with these new genetic abnormalities will very likely become separated subtypes in the next edition, and there will be more newly discovered genetic alterations listed here. Biallelic *TP53* alterations have been frequently found in MDNs, acute erythroid leukemia, and myeloid neoplasms post cytotoxic therapy, and they usually predict a worse prognosis"
- "Gene mutations in the MAPK pathway are commonly seen in histiocytic neoplasms. *CXCR4* mutations are detected in a significant proportion of lymphoplasmacytic lymphoma cases, mostly concurrent with *MYD88* mutations, and the presence of them is associated with resistance to ibrutinib therapy (32). The mutational profiles of extranodal MZL (EMZL) and nodal MZL differ, and there are significant genetic differences among EMZLs arising in different anatomic sites"
- "*STAT3* mutation is commonly seen in CD8+ T-LGLL and gamma/delta T-LGLL, and it is associated with neutropenia and unfavorable overall survival;
  while *STAT5b* mutation is associated with a poor prognosis only in CD8+ T-LGLL but has no prognostic impact in CD4+ T-LGLL and gamma/delta T-LGLL" (Li, 2022).

Though the WHO did not take any specific stance with these in their new version, these mutations and pathways may be worth keeping abreast of for the future.

College of American Pathologists (CAP) and American Society of Hematology (ASH)

Following recent progress in molecular genetic findings and 2016 WHO classification of acute leukemias, the College of American Pathologists (CAP) and the American Society of Hematology (ASH) have formed an expert panel to review and establish guidelines for appropriate laboratory testing. The published guideline provides twenty-seven guideline statements ranging from recommendations on what testing is appropriate for the diagnostic and prognostic evaluation of leukemias to where the testing should be performed and how results should be reported.

There, the societies recommend that "The pathologist should review recent or concurrent CBC counts and leukocyte differentials and evaluate a peripheral blood (PB) smear (*Strong recommendation*)." Moreover, they note that "In addition to performing morphologic assessment (blood and BM), the pathologist or treating clinician should obtain sufficient samples and perform conventional cytogenetic analysis (ie, karyotype), appropriate molecular genetic and/or FISH testing, and FCI. The flow cytometry panel should be sufficient to distinguish AML (including APL), including early T-ALL, B-ALL, and AL of ambiguous lineage in all patients diagnosed with AL. Molecular genetic and/or FISH testing does not, however, replace conventional cytogenetic analysis (*Strong recommendation*)" (de Haas et al., 2019).

In those patients with suspected or confirmed AL, "the pathologist may request and evaluate cytochemical studies to assist in the diagnosis and classification of AML *(Expert consensus opinion)*". Furthermore, "For patients with suspected or confirmed AL, the pathologist may use flow cytometry in the evaluation of CSF (*Recommendation)*" and that "the pathologist or treating clinician should ensure that flow cytometry analysis or molecular characterization is comprehensive enough to allow subsequent detection of MRD (*Strong recommendation*)." It is also mentioned that "For patients with AL other than those with ALL who are receiving intrathecal therapy, the treating clinician may, under certain circumstances, obtain a CSF sample when there is no clinical contraindication. The treating clinician or pathologist should ensure that a cell count is performed and that examination and enumeration of blasts on a cytocentrifuge preparation are performed and are reviewed by the pathologist *(Expert consensus opinion)*" (de Haas et al., 2019).

Many genes should be tested for patients with suspected or confirmed B-ALL. In pediatric patients, "the pathologist or treating clinician should ensure that testing for

t(12;21)(p13.2;q22.1); *ETV6-RUNX1*, t(9;22)(q34.1;q11.2); *BCR-ABL1*, *KMT2A* (*MLL*) translocation, *iAMP21*, and trisomy 4 and 10 is performed (*Strong recommendation*)", while for adult patients, they assert "the pathologist or treating clinician should ensure that testing for t(9;22)(q34.1;q11.2); *BCR-ABL1* is performed. In addition, testing for *KMT2A* (*MLL*) translocations may be performed. (*Strong recommendation* for testing for t(9;22)(q34.1;q11.2) and *BCR-ABL1*; *Recommendation* for testing for *KMT2A* (*MLL*) translocations)" (de Haas et al., 2019).

The CAP and the ASH also propound that "For patients with suspected or confirmed ALL, the pathologist or treating clinician may order appropriate mutational analysis for selected genes that influence diagnosis, prognosis, and/or therapeutic management, which include, but are not limited to, *PAX5, JAK1, JAK2,* and/or *IKZF1* for B-ALL and *NOTCH1* and/or *FBXW7* for T-ALL. Testing for overexpression of CRLF2 may also be performed for B-ALL (*Recommendation*)."

The appropriate molecular genetic testing for AML is discussed starting from 16th guideline statement.

The expert panel strongly recommends testing for *FLT3-ITD* in adult and pediatric patients with suspected or confirmed AML of any type. They also recommend testing for other mutational analysis that could include, but not limited to, *IDH1, IDH2, TET2, WT1, DNMT3A*, and/or *TP53* for prognostic and/or therapeutic purposes (Statement 16).

In the 17th guideline statement, expert panel strongly recommends testing for *KIT* mutation in adult patients with confirmed core-binding factor (CBF) AML (AML with t(8;21)(q22;q22.1); RUNX1-RUNX1T1 or inv(16)(p13.1q22) /t(16;16)(p13.1;q22); CBFB-MYH11). It is only an expert consensus opinion for testing *KIT* mutation in pediatric patients with confirmed core binding factor AML (AML with t(8;21)(q22;q22.1); RUNX1-RUNX1T1 or inv(16)(p13.1q22) /t(16;16)(p13.1;q22); CBFB-MYH11) which is not a strong recommendation (Statement 17).

The strong recommendation is also given for patients other than those with confirmed core binding factor AML, APL, or AML with myelodysplasia-related cytogenetic abnormalities that testing is needed for mutational analysis for *NPM1*, *CEBPA*, and *RUNX1* (Statement 19).

In the 20th guideline statement, expert panel is providing no recommendation on either for or against the use of global/gene specific methylation, microRNA (miRNA) expression, or gene expression analysis for diagnosis or prognosis in patients with confirmed acute leukemia.

Finally, in their last statement, expert panel strongly recommends the use of current WHO terminology for the final diagnosis and classification of acute leukemias (Arber et al., 2017).

American Society of Clinical Oncology (ASCO)

The ASCO fully endorses the 2017 CAP and ASH guideline regarding the initial diagnostic work-up of acute leukemia (de Haas et al., 2019). The ASCO supports all twenty-seven guideline statements. The statements relevant to this policy are noted in the 2017 CAP and ASH guidelines above.

National Comprehensive Cancer Network (NCCN)

Acute myeloid leukemia

For the evaluation of AML in individuals 18 years of age or older, the NCCN guidelines recommends a history and a physical, complete blood count (CBC), platelets, differential, comprehensive metabolic panel (CMP), uric acid, lactate dehydrogenase (LDH), B12 and folic acid evaluation, prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen as part of the workup. Moreover, they recommend bone marrow core biopsy and aspirate analyses (including immunophenotyping by immunohistochemistry stains plus flow cytometry) and analysis for chromosomal structural variations using cytogenetics, FISH, or whole genome sequencing.

In terms of molecular analyses, they list "(*ASXL1*, *c-KIT*, *FLT3* [ITD (internal tandem duplication) and TKD (tyrosine kinase domain)], *NPM1*, *CEBPA*, *IDH1, IDH2*, *RUNX1*, *TP53*, and other mutations" as targets. A "Comprehensive pathology report, including diagnosis of AML (acute myeloid leukemia) with recurrent cytogenetics vs. AML not otherwise specified (NOS), blast count, cellularity, morphologic dysplasia, and mutation status if available" is also mentioned, and the NCCN "Recommend additional molecular and genetic testing for heritable hematologic malignancy predisposition in a subset of patients, particularly in patients <50 years". For patients with potential hematopoietic cell transplantation (HCT) in the future, HLA typing is also noted, "(except for patients with a major contraindication to HCT) and/or early referral to transplant center" (NCCN, 2024d). The NCCN also highlights that "A variety of gene mutations are associated with specific prognoses (category 2A) and may guide medical decision-making (category 2B). Other genetic lesions may have therapeutic significance. The field of genomics in myeloid malignancies and related implications in AML are evolving rapidly. Mutations should be tested in all patients. Multiplex gene panels and targeted next-generation sequencing (NGS) analysis are recommended for the ongoing management of AML and various phases of treatment" (NCCN, 2024d).

The NCCN cautions that the "importance of obtaining adequate samples of marrow or peripheral blood at diagnosis for full karyotyping and FISH cytogenetic analysis for the most common abnormalities cannot be overemphasized. Although FISH studies for common cytogenetic abnormalities may allow for rapid screening to identify either favorable- or unfavorable-risk groups, additional tests are needed to provide a full picture of the genetic factors that contribute to risk" (NCCN, 2024d).

As a part of monitoring during therapy for individuals with AML, the NCCN recommends a bone marrow aspirate/biopsy 14 to 21 days after the "start of therapy to document hypoplasia. If hypoplasia is not documented or indeterminate, repeat biopsy within 7 days to clarify persistence of leukemia. If hypoplasia, then repeat biopsy at time of hematologic recovery to document remission. If cytogenetics were initially abnormal, include cytogenetics as part of the remission documentation." Furthermore, as a follow-up to both standard-dose cytarabine induction therapy or high-dose cytarabine induction for poor-risk AML, the NCCN recommends that all patients should have bone marrow aspirate and biopsy by day 42 post-treatment, "regardless of the degree of hematologic recovery. When performed, BM aspirate and biopsy should include cytogenetic and molecular studies, as appropriate" (NCCN, 2024d).

As a part of surveillance and therapy for individuals with relapsed/refractory disease after the completion of consolidation, the NCCN recommends comprehensive genomic profiling to determine mutation status of actionable genes.

For the evaluation or workup for blastic plasmacytoid dendritic cell neoplasm in individuals 18 years of age or older, the NCCN recommends cytogenetic analysis (karyotype and/or FISH) and molecular analysis "(most common aberrations include: most common aberrations include: *TET2*, *ASXL1*, *ZRSR2*, *SRSF2*, *TP53*, *NRAS*, *IDH2*, and *ETV6*)" (NCCN, 2024d).

Chronic Lymphocytic Leukemia (CLL) and Small Lymphocytic Leukemia (SLL)

For the diagnosis of chronic lymphocytic leukemia and small lymphocytic leukemia, the NCCN notes the following components as essential:

- "Hematopathology review of peripheral blood smear and all slides with at least one paraffin block representative of the tumor, if the diagnosis was made on a lymph node or bone marrow biopsy.
- Flow cytometry of blood is adequate for the diagnosis of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL)."

- "CLL diagnosis requires presence of monoclonal B lymphocytes ≥5 x 109 /L in peripheral blood[b]
- Clonality of B cells should be confirmed by flow cytometry"
- Adequate immunophenotyping to establish diagnosis by flow cytometry using cell surface markers:[c] kappa/lambda, CD19, CD20, CD5, CD23, CD10, CD200; if flow cytometry is used to establish diagnosis, also include cytospin for cyclin D1 or fluorescence in situ hybridization (FISH) for t(11;14); t(11q;v)."
- "SLL diagnosis requires presence of lymphadenopathy and/or splenomegaly with monoclonal B lymphocytes ≤5 x 109 /L in peripheral blood
- SLL diagnosis should be confirmed by histopathology evaluation of lymph node biopsy"

- "Biopsy is generally not required. If diagnosis is not established by flow cytometry, then proceed with lymph node biopsy. Bone marrow aspirate with biopsy can be pursued if peripheral blood and lymph node biopsy material are nondiagnostic. Fine-needle aspiration (FNA) or core needle biopsy alone is not generally suitable for the initial diagnosis of CLL/SLL. In certain circumstances, when a lymph node is not easily accessible for excisional or incisional biopsy, a combination of core needle biopsy and FNA biopsy in conjunction with appropriate ancillary techniques for the differential diagnosis (ie, immunohistochemistry [IHC], flow cytometry) may be sufficient for diagnosis."
  - "Adequate immunophenotyping to establish diagnosis by IHC[c]: CD3, CD5, CD10, CD20, CD23, cyclin D1, LEF1, SOX11[d]"
- "Absolute monoclonal B lymphocyte count[b]" (NCCN, 2024a).

In superscript b, the NCCN cautions that "Absolute monoclonal B lymphocyte count <5000/mm^3 that persists more than 3 months in the absence of palpable adenopathy or other clinical features of lymphoproliferative disorder is MBL. Cells of the same phenotype may be seen in reactive lymph nodes; therefore, diagnosis of SLL should only be made when effacement of lymph node architecture is seen. Bone marrow examination is not helpful for the diagnosis of MBL." Moreover, they note in superscript c that "Typical immunophenotype: CD5+, CD23+, CD43+/-, CD10-, CD19+, CD20 dim, sIg dim+, and cyclin D1-. Note: Some cases may be sIg bright+ or CD23- or dim; some MCL may be CD23+; cyclin D1 immunohistochemistry or FISH for t(11;14) should be considered in all cases, especially for those with an atypical immunophenotype (ie, CD23 dim or negative, CD20 bright, sIg bright). CD200 positivity may distinguish CLL from mantle cell lymphoma (MCL), which is usually CD200-" (NCCN, 2024a).

Other analyses that may be "informative for prognostic and/or therapy determination" include

- "FISH to detect: +12; del(11q); del(13q); del(17p)
- *TP53* sequencing
- CpG-stimulated metaphase karyotype for complex karyotype (CK)
- Molecular analysis to detect: Immunoglobulin heavy chain variable region gene (IGHV) mutation status
- Beta-2-microglobulin" (NCCN, 2024a).

During workup, history and physical exam including measurement of size of liver and spleen and palpable lymph nodes, performance status, B symptoms, complete blood count (CBC) with differential, comprehensive metabolic panel, and beta-2-microglobulin are essential according to the NCCN. They also note that the following tests may be "useful under certain circumstances": quantitative immunoglobulins; reticulocyte count, haptoglobin, and direct antiglobulin test (Coombs) ; chest/abdominal/pelvic CT with contrast of diagnostic quality, if clinically indicated; uric acid; lactate dehydrogenase (LDH); unilateral bone marrow aspirate and biopsy (may be informative for the diagnosis of immune-mediated or disease-related cytopenias); hepatitis B and C testing if treatment is contemplated; pregnancy testing in patients of childbearing age if systemic therapy or RT is planned; discussion of fertility preservation; and FDG-PET/CT scan to direct nodal biopsy, if histologic transformation is suspected (NCCN, 2024a).

Chronic Myeloid Leukemia

The NCCN's recommendations for CML include the following table:

Monitoring Response to TKI Therapy and Mutational Analysis	
Test	**Recommendation**
Bone marrow cytogenetics[1]	At diagnosis Response milestones not reached Any signs of loss of hematologic response Any sign of loss of CCyR or its molecular response correlate (MR2.0: BCR::ABL1 [IS] ≤1%) - defined as an increase in *BCR::ABL1* transcript to >1%
qPCR using IS [International Scale]	At diagnosis Every 3 months after initiating treatment. After *BCR::ABL1* (IS) ≤1%[2] (MR2.0)[2] has been achieved, every 3 months for 2 years and every 3-6 months thereafter

	If there is 1-log increase in *BCR::ABL1* transcript levels with MMR, qPCR should be repeated in 1-3 months
***BCR::ABL* kinase domain mutation analysis**	CP-CML Response milestones not reached ○ Any sign of loss of hematologic response ○ Any sign of loss of CCyR or its molecular response correlate (MR2.0: BCR::ABL1 [IS] ≤1%) – defined as an increase in *BCR::ABL1* transcript to >1% ○ 1-log increase in *BCR::ABL1* transcript levels and loss of MMR Disease progression to AP-CML or BP-CML
[1]FISH has been inadequately studied for monitoring response to treatment. [2]CCyR correlates with *BCR-ABL1* (IS) ≤1% (MR2.0). [3]Consider myeloid mutation panel to identify *BCR::ABL1*–independent resistance mutations in patients with no *BCR::ABL1* kinase domain mutations	

The NCCN (2023) also states that for the diagnosis and workup of CML-1:

- "Initial evaluation should consist of a history and physical exam, including palpation of spleen, complete blood count (CBC) with differential, chemistry profile, and hepatitis B panel. Bone marrow aspirate and biopsy for morphologic and cytogenetic evaluation and quantitative reverse transcriptase polymerase chain reaction (RT-PCR) to establish the presence of quantifiable *BCR::ABL1* mRNA transcripts at baseline are recommended to confirm the diagnosis of CML.
- Bone marrow cytogenetics with a minimum of 20 metaphases is useful to detect additional chromosomal abnormalities (ACAs) in Ph-positive cells, also known as clonal cytogenetic evolution (discussed below).9-13 If bone marrow evaluation is not feasible, fluorescence in situ hybridization (FISH) on the bone marrow or a peripheral blood specimen with dual probes for BCR and ABL1 genes can be used to confirm the diagnosis of CML."
- "Quantitative RT-PCR (qPCR) should be done at initial workup to establish the presence of quantifiable BCR::ABL1 mRNA transcripts."
- "Qualitative RT-PCR for detecting atypical BCR::ABL1 transcripts should be considered if there is discordance between FISH and qPCR results." (NCCN, 2023).

The NCCN provides the following early treatment response milestones for those with CML:

EARLY TREATMENT RESPONSE MILESTONES
CRITERIA FOR RESPONSE AND RELAPSE

BCR::ABL1 (IS)	3 months	6 months	12 months[m]
>10%[n]	YELLOW	RED	
>1%–10%	GREEN		YELLOW
>0.1%–1%	GREEN		LIGHT GREEN
≤0.1%	GREEN		

COLOR	CONCERN	CLINICAL CONSIDERATIONS[p]	RECOMMENDATIONS[p]
RED	TKI-resistant disease[o]	• Evaluate patient adherence and drug interactions • Consider *BCR::ABL1* kinase domain mutational analysis[q] • Consider bone marrow cytogenetic analysis to assess additional chromosomal abnormalities (ACAs)	Switch to alternate TKI (CML-5) (other than imatinib) and evaluate for allogeneic HCT
YELLOW	Possible TKI resistance[o]	• Evaluate patient adherence and drug interactions • Consider *BCR::ABL1* kinase domain mutational analysis[q] • Consider bone marrow cytogenetic analysis to assess for MCyR at 3 mo or CCyR at 12 mo	Switch to alternate TKI (CML-5) or Continue same TKI (CML-G)[r] and Consider evaluation for allogeneic HCT
LIGHT GREEN	TKI-sensitive disease	• Evaluate patient adherence and drug interactions • If treatment goal is long-term survival: ≤1% optimal • If treatment goal is treatment-free remission: ≤0.1% optimal	• If optimal: continue same TKI (CML-G) • If not optimal: shared decision-making with patient[o,s]
GREEN	TKI-sensitive disease	• Monitor response (CML-E) • Evaluate patient adherence and drug interactions	Continue same TKI (CML-G)[t]

(NCCN, 2023)

For those discontinuing TKI therapy, the NCCN recommends molecular monitoring every one to two months in the first six months following discontinuation, bimonthly monitoring during months seven to twelve, and quarterly monitoring thereafter (indefinitely) in individuals who remain in MMR (MR3; *BCR::ABL1* ≤0.1% IS) (NCCN, 2023).

Acute Lymphoblastic Leukemia (ALL)

Regarding ALL, the NCCN recommends testing of marrow or peripheral blood lymphoblasts using various techniques. The guidelines state the following:

"The diagnosis of ALL generally requires demonstration of ≥20% bone marrow lymphoblasts" predicated "on hematopathology review of bone marrow aspirate and biopsy materials, which includes:

- Morphologic assessment of Wright-Giemsa-stained bone marrow aspirate smears, and hematoxylin and eosin (H&E)-stained core biopsy and clot sections
- Comprehensive flow cytometric immunophenotyping
- Baseline flow cytometric and/or molecular characterization of leukemic clone to facilitate subsequent minimal/measurable residual disease (MRD) analysis
- Karyotyping of G-banded metaphase chromosomes" (NCCN, 2024c).

Regarding molecular characterization of ALL, is is stated that

- "Cytogenetic and molecular prognostic risk stratification for B-cell ALL (B-ALL)
- Optimal risk stratification and treatment planning require testing marrow or peripheral blood lymphoblasts for specific recurrent genetic abnormalities using:

- Interphase fluorescence in situ hybridization (FISH) testing, including probes capable of detecting the major recurrent genetic abnormalities
- Reverse transcriptase polymerase chain reaction (RT-PCR) testing BCR::ABL1 in B-ALL (quantitative or qualitative) including determination of transcript size (ie, p190 vs. p210)
- Comprehensive testing by next-generation sequencing (NGS) for gene fusions and pathogenic mutations is recommended.

- Additional optional tests include:
  - Assessment with chromosomal microarray (CMA)/array comparative genomic hybridization (cGH) in cases of aneuploidy or inadequate karyotype" (NCCN, 2024c).

According to the NCCN, "*BCR::ABL1*–like or Ph–like ALL is a subgroup of B-cell lineage ALL associated with unfavorable prognosis", and it should be noted that "Although this subgroup is Ph-negative, there is an otherwise similar genetic profile to the Ph-positive ALL subgroup including mutation of the *IKZF1* gene." Nevertheless, "this subtype is typically associated with gene fusions and mutations that activate tyrosine kinase pathways as the common mechanism of transformation", and these gene fusions and mutations include *ABL1, ABL2, CRLF2, CSF1R, EPOR, JAK1, JAK2, JAK3, TYK2, PDGFRβ, PDGFRα, FGFR, EBF1, FLT3, IL7R, NTRK3, PTL2B*, and *SH2B3* genes" (NCCN, 2024c).

As a part of surveillance for individuals with ALL, the NCCN highlights that "An assessment of bone marrow aspirate can be considered as clinically indicated at a frequency of 3 to 6 months for the first 5 years; if a bone marrow aspirate is performed, flow cytometry with additional studies that may include comprehensive cytogenetics, FISH, molecular tests, and MRD assessments should be carried out. While there is insufficient evidence to guide MRD monitoring for patients with Ph-negative disease following completion of maintenance therapy, the approval of blinatumomab, and potentially future therapies for MRD-positive relapse, may warrant testing in this regard." The NCCN also states that "Periodic MRD assessments should be considered (no more than every 3 months) for patients who have achieved a complete molecular remission (undetectable levels)". However, "the frequency may be increased if MRD levels are detectable" (NCCN, 2023, 2024c).

Pediatric Acute Lymphoblastic Leukemia (PEDALL)

The NCCN also produces guidelines focusing on Pediatric Acute Lymphoblastic Leukemia (PEDALL). For PEDALL, the NCCN provides the following recommendation for genetic characterization.

"GENETIC CHARACTERIZATION

Optimal risk stratification and treatment planning require testing marrow or peripheral blood lymphoblasts for specific recurrent genetic abnormalities using:

- Karyotyping of G-banded metaphase chromosomes
- Interphase fluorescence in situ hybridization (FISH) testing, including probes capable of detecting the major recurrent genetic abnormalities
- Reverse transcriptase-polymerase chain reaction (RT-PCR) testing for *BCR::ABL1* in B-ALL (quantitative or qualitative) including determination of transcript size (i.e., p190 vs. p210)
    - If *BCR::ABL1* negative: encourage testing for gene fusions and mutations associated with *BCR::ABL1*–like (Ph-like) ALL
- Assessment of various potentially actionable or prognostic mutations and gene fusions via next-generation sequencing (NGS) or alternative methods
- Additional optional tests include:
    - Additional assessment (eg, microarray comparative genomic hybridization [CGH] and/or NGS) in cases of aneuploidy or inadequate karyotype
    - Whole transcriptome sequencing to identify B-lymphoblastic leukemia/lymphoma (B-ALL/LL) subtypes defined by gene expression profile (ie, *ETV6::RUNX1*-like, *PAX5alt*, *MYCr*)" (NCCN, 2024b).

As a part of surveillance under their "Procedures and Molecular Testing" of individuals with PEDALL, the NCCN recommends testing of "Bone marrow aspirate and cerebrospinal fluid (CSF) for suspected relapse". They note that "If bone marrow aspirate is done: Flow cytometry with additional studies that may include comprehensive cytogenetics, FISH, molecular testing, and MRD testing" and suggest that one can "Consider periodic *BCR::ABL1* transcript-specific quantification (Ph+ ALL)" (NCCN, 2024b).

The guidelines also state that "The *BCR-ALB1*-like (Ph-like) phenotype is associated with recurrent gene fusions and mutations that activate tyrosine kinase pathways and includes gene fusions involving *ABL1, ABL2, CRLF2, CSF1R, EPOR, JAK2 or PDGFRB* and mutations involving *CRLF2, FLT3, IL7R, SH2B3, JAK1, JAK3, and JAK2* (in combination with *CRLF2* gene functions). Testing of these abnormalities at diagnosis may aid in risk stratification" (NCCN, 2024b).

European LeukemiaNet (ELN) Working Party

In 2022, an international expert panel on behalf of the ELN published recommendations for the diagnosis and management of AML.

ELN remarks that "Germline predisposition risk should be considered for all patients diagnosed with a hematopoietic malignancy regardless of age, because some germline predisposition alleles, like those in DDX41, can drive hematopoietic malignancies in older age" and notes key features of clinical presentation warranting consideration of clinical testing for a germline predisposition allele(s), including

"Personal history of ≥ two cancers, one of which is a hematopoietic malignancy (order does not matter)

Personal history of a hematopoietic malignancy plus:

- Another relative within two generations with another hematopoietic malignancy, or
- Another relative within two generations with a solid tumor diagnosed at age 50 or younger, or
- Another relative within two generations with other hematopoietic abnormalities

Presence of a deleterious gene variant in tumor profiling that could be a germline allele, especially if that variant is present during remission*

Age of diagnosis of hematopoietic malignancy at an earlier age than average (eg, MDS diagnosed ≤ 40 y)

Germline status of a variant is confirmed by:

Its presence in DNA derived from a tissue source not likely to undergo somatic mutation frequently (eg, cultured skin fibroblasts or hair follicles) AND at a variant allele frequency consistent with the germline (generally considered between 30-60%), or

Its presence in at least two relatives at a variant allele frequency consistent with the germline" (Döhner et al., 2022). It is also noted that "Certain gene alleles (eg, *CHEK2* I200T and truncating *DDX41* variants) are overwhelmingly likely to be germline and should prompt consideration of germline testing when identified even once" (Döhner et al., 2022).

Furthermore, ELN lists tests and procedures recommended to be performed at diagnosis for a patient with AML in the Table 4, captured below.

Table 4. Tests and procedures at diagnosis for a patient with AML

Tests and procedures		
Tests to establish the diagnosis		**Additional tests and procedures**
Complete blood count and differential count*		Complete physical examination[c]
Bone marrow aspirate†		Performance status (ECOG/WHO score)
Bone marrow trephine biopsy‡		Geriatric assessment[d] (optional)
Immunophenotyping by flow cytometry (see Table 5)		Biochemistry, coagulation tests[e]
Genetic analyses	Results preferably available within	Hepatitis A, B, C; HIV-1 testing; CMV, EBV, HSV, VZV
Cytogenetics§	• 5-7 d	Serum pregnancy test[f]
Screening for gene mutations required for establishing the diagnosis and to identify actionable therapeutic targets#		Eligibility assessment for allogeneic HCT (incl. HLA-typing)[g]
• *FLT3*,¶ *IDH1*, *IDH2*	• 3-5 d	Chest x-ray, 12-lead electrocardiogram, echocardiography or MUGA (on indication)
• *NPM1*	• 3-5 d	Computed tomography of the chest (on indication)[h]
• *CEBPA*,# *DDX41*, *TP53*; *ASXL1*, *BCOR*, *EZH2*, *RUNX1*, *SF3B1*, *SRSF2*, *STAG2*, *U2AF1*, *ZRSR2*	• 1st cycle	Lumbar puncture (on indication)[i]
Screening for gene rearrangements**		Information on oocyte and sperm cryopreservation[j]
• *PML::RARA*, *CBFB::MYH11*, *RUNX1::RUNX1T1*, *KMT2A* rearrangements, *BCR::ABL1*, other fusion genes (if available)	• 3-5 d	Biobanking[k]
Additional genes recommended to test at diagnosis††		
• *ANKRD26*, *BCORL1*, *BRAF*, *CBL*, *CSF3R*, *DNMT3A*, *ETV6*, *GATA2*, *JAK2*, *KIT*, *KRAS*, *NRAS*, *NF1*, *PHF6*, *PPM1D*, *PTPN11*, *RAD21*, *SETBP1*, *TET2*, *WT1*		
Medical history		
Demographics and medical history‡‡		
Detailed family history[a]		
Patient bleeding history[b]		
Analysis of comorbidities		

(Döhner et al., 2022).

According to ELN, "Conventional cytogenetic analysis is mandatory in the evaluation of AML. If conventional cytogenetics fails, fluorescence in situ hybridization is an alternative to detect specific abnormalities like RUNX1::RUNX1T1, CBFB::MYH11, KMT2A (MLL), and MECOM (EVI1) gene fusions, or myelodysplasia-related chromosome abnormalities, eg, loss of chromosome 5q, 7q, or 17p material". ELN also asserts that "Molecular genetic testing should screen for all the genetic abnormalities that define disease and risk categories or that are needed for targeted treatment modalities" listed above in their Table 4, and that for "patients with mutant NPM1 and core-binding factor (CBF)- AML, it is recommended to perform baseline molecular assessment by quantitative polymerase chain reaction (qPCR) or droplet digital PCR (dPCR) to facilitate MRD monitoring after treatment" (Döhner et al., 2022). ELN recognizes that "Immunophenotyping by multiparameter flow cytometry (MFC) is required to diagnose AML accurately by identifying cell surface and intracellular markers" and that "It is also important to identify leukemia-associated

immunophenotypes (LAIP) for subsequent MRD monitoring by MFC. In cases where an aspirate is unobtainable and circulating blasts are absent, myeloid phenotype may be confirmed on a core biopsy using immunohistochemistry" (Döhner et al., 2022). Cell-surface and cytoplasmic markers of interest for the diagnosis of AML and MPAL as reported by ELN is shown below (Table 5). Lastly, this ELN special report included an updated table of risk classifications at initial diagnosis based on new data (Table 6).

Table 5. Expression of cell-surface and cytoplasmic markers for the diagnosis of AML and MPAL

Diagnosis of AML	
Diagnosis of AML	
Precursor marker	CD34, CD117, HLA-DR
Myeloid markers	Cytoplasmic MPO, CD33, CD13
Myeloid maturation markers	CD11b, CD15, CD64, CD65
Monocytic markers	CD14, CD36, CD64, CD4, CD38, CD11c
Megakaryocytic markers	CD41 (glycoprotein IIb/IIIa), CD61 (glycoprotein IIIa), CD36
Erythroid markers	CD235a (glycophorin A), CD71, CD36
Diagnosis of MPAL	
Myeloid lineage	MPO (flow cytometry, immunohistochemistry or cytochemistry), or monocytic differentiation (at least 2 of the following: non-specific esterase cytochemistry, CD11c, CD14, CD64, lysozyme), or at least two myeloid markers, ie, CD177, CD33, CD13
T-lineage	Strong cytoplasmic CD3 (with antibodies to CD3 ε chain) or surface CD3
B-lineage[9]	Strong CD19 with at least one of the following strongly expressed: cytoplasmic CD79a, cCD22 or CD10, or weak CD19 with at least two of the following strongly expressed: CD79a, cCD22 or CD10
Core MRD markers	CD34, CD117, CD45, CD33, CD13, CD56, CD7, HLA-DR If monocytic: CD64, CD11b, CD4 (in addition)

Table 6. 2022 ELN risk classification by genetics at initial diagnosis*

Risk category†	Genetic abnormality
Favorable	• t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1*†,‡ • inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*†,‡ • Mutated *NPM1*†,§ without *FLT3*-ITD • bZIP in-frame mutated *CEBPA*‖
Intermediate	• Mutated *NPM1*†,§ with *FLT3*-ITD • Wild-type *NPM1* with *FLT3*-ITD (without adverse-risk genetic lesions) • t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*†,¶ • Cytogenetic and/or molecular abnormalities not classified as favorable or adverse
Adverse	• t(6;9)(p23.3;q34.1)/*DEK*::*NUP214* • t(v;11q23.3)/*KMT2A*-rearranged# • t(9;22)(q34.1;q11.2)/*BCR*::*ABL1* • t(8;16)(p11.2;p13.3)/*KAT6A*::*CREBBP* • inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2, MECOM(EVI1)* • t(3q26.2;v)/*MECOM*(*EVI1*)-rearranged • −5 or del(5q); −7; −17/abn(17p) • Complex karyotype,** monosomal karyotype†† • Mutated *ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1, and/or ZRSR2*‡‡ • Mutated *TP53*[a]

An ELN expert panel has released guidelines for the assessment of measurable residual disease (MRD) of AML that were updated in 2021. First, for molecular MRD recommendations, "techniques for molecular MRD assessment should reach an LOD [limit of detection] of 10^{-3} or lower. To achieve this LOD, qPCR, dPCR, or error-corrected NGS using UMIs [unique molecular identifiers] is recommended (Grade of Recommendation: B)."

Other recommendations for molecular MRD testing include

- "For patients with mutant *NPM1*, CBF AML (*RUNX1-RUNX1T1* or *CBFB-MYH11*), or APL (*PML-RARA*), we recommend molecular MRD assessment by qPCR or dPCR. (Grade of Recommendation: A)"
- "Leukemia-specific PCR assays (eg, for *NPM1, PML-RARA,* or *CBF* AML) are preferred over fewer specific markers, such as *WT1* or *EV11* expression (Grade of Recommendation: B)"
- "Targeted NGS-MRD using specific mutations identified at diagnosis vs agnostic panel approaches has different strengths and limitations, but both approaches can be considered, depending on sensitivity, turnaround time, resource use, setting (research, clinical trial, or clinical routine), and ability to standardize methodology and reporting. (Grade of Recommendation: B)"
- "If a panel approach is used for NGS-MRD, emerging variants not found at diagnosis should be reported only if confidently detected above background noise. (Grade of Recommendation: B)"
- "For NGS-MRD, we recommend considering all detected mutations as potential MRD markers, with the limitations detailed in recommendations B9 to B11 (listed below) (Grade of Recommendation: B)"
    - "Germline mutations (VAF of ~50 in genes *ANKRD26*, *CEBPA*, *DDX41*, *ETV6*, *GATA2*, *RUNX1*, and *TP53*) should be excluded as NGS-MRD markers, as they are noninformative for MRD. (Grade of Recommendation: A)"
    - "Mutations in *DNMT3A*, *TET2*, and *ASXL1* (DTA) can be found in age-related clonal hematopoiesis and should be excluded from MRD analysis. (Grade of Recommendation: A)"
    - "Mutations in signaling pathway genes (*FLT3-ITD*, *FLT3-TKD*, *KIT*, and *RAS*, among others) most likely represent residual AML when detected, but are often subclonal and have a low negative predictive value. These mutations are best used in combination with additional MRD markers. (Grade of Recommendation: B)" (Heuser et al., 2021).

International Workshop on Chronic Lymphocytic Leukemia (iwCLL)

In the iwCLL guidelines for the diagnosis, indications for treatment, response assessment, and supportive management of CLL, the iwCLL reference the World Health Organization in describing "CLL as leukemic, lymphocytic lymphoma, being only distinguishable from small lymphocytic lymphoma (SLL) by its leukemic manifestation" and adduce that "CLL, by definition, is always a disease of neoplastic B cells, whereas the entity formerly described as T-CLL is now called T-cell prolymphocytic leukemia" (Hallek et al., 2018). The iwCLL states that "The diagnosis of CLL requires the presence of ≥5 × 109/L B lymphocytes in the peripheral blood, sustained for at least 3 months. The clonality of these B lymphocytes needs to be confirmed by demonstrating

immunoglobulin light chain restriction using flow cytometry." They also assert that "CLL or SLL might be suspected in otherwise healthy adults who have an absolute increase in clonal B lymphocytes, but who have <5 × 109/L B lymphocytes in the blood. However, in the absence of lymphadenopathy or organomegaly (as detected by physical examination or imaging studies), or of disease-related cytopenias or symptoms, the presence of <5 × 109/L B lymphocytes is defined as monoclonal B lymphocytosis (MBL)", explaining that "The presence of a cytopenia caused by a typical marrow infiltrate establishes the diagnosis of CLL regardless of the number of peripheral blood B lymphocytes or of the lymph node involvement." Meanwhile, "The definition of SLL requires the presence of lymphadenopathy and the absence of cytopenias caused by a clonal marrow infiltrate. Additionally, the number of B lymphocytes in the peripheral blood should be <5 × 109/L. In SLL, the diagnosis should be confirmed by histopathological evaluation of a lymph node biopsy or biopsy of other tissues"(Hallek et al., 2018).

They also mention that "It is important to verify that the patient has CLL and not some other lymphoproliferative disease that can masquerade as CLL, such as hairy cell leukemia or leukemic manifestations of mantle cell lymphoma, marginal zone lymphoma, splenic marginal zone lymphoma with circulating villous lymphocytes, or follicular lymphoma. To achieve this, it is necessary to evaluate the blood smear, the immunophenotype, and, in some cases, the genetic features of the circulating lymphoid cells" (Hallek et al., 2018).

British Society for Haematology (BSH)

The Haemato-oncology Task Force of BCSH (British Committee for Standards in Haematology) had produced a draft outline of guidelines for the diagnosis and management of AML in pregnancy, which was subsequently reviewed by the British Society of Haematology due to a consultation process resulting in the name change from BCSH to BSH in 2016. These guidelines state that "As for non-pregnant patients, acute myeloid leukaemia (AML) should be diagnosed using the World Health Organization (WHO) classification (Grade 1A)" and [w]here a diagnosis of leukemia is suspected, care must be taken to ensure that marrow samples are directed for immunophenotypic, cytogenetic and molecular analysis to allow accurate sub-typing and understanding of prognostic features" (Ali et al., 2015).

On the management of older patients with frailty and acute myeloid leukemia, BSH asserts that "Older adults who are suspected of having AML and are deemed to be fit to receive anti-leukaemia therapy should undergo the same diagnostic workup as any other patient (Table 1)" (Dennis et al., 2022).

At diagnosis, "Patients should have a bone marrow examination (aspirate and trephine biopsy) for blast enumeration [with a 300 (or 500 where indicated) differential cell count]" and "flow cytometry to characterise the leukaemic clone immunophenotype to confirm lineage, and because this provides a means of assessing measurable residual disease (MRD) in the absence of a molecular marker". Moreover, "For patients with a high white blood count at presentation, diagnostic workup may be performed on the peripheral blood in lieu of a bone marrow examination, and this may also be a suitable approach for frail patients, for whom best supportive care is the most appropriate treatment option. Consideration should also be given (with appropriate patient consent) to taking trial samples at the time of diagnostic marrow sampling" (Dennis et al., 2022).

The BSH notes that "Risk stratification remains informed by cytogenetic analysis, and, given that some treatments (e.g., CPX-351) are currently only licensed in the UK for therapy-related AML or AML with myelodysplasia-related changes (AML-MRC), knowledge of cytogenetic abnormalities is a prerequisite to offer the most appropriate treatment." But while "This is likely to be most efficiently achieved using a multi-target next-generation sequencing (NGS) panel approach with a maximum turnaround time of 21 days", "we [BSH] recommended rapid screening (turnaround time within 72 hours) for mutations of *NPM1*, *FLT3*, *IDH1/2* and *TP53*, given that the presence of *NPM1* and I*DH1/2* mutations may inform treatment decisions, as these mutations have been shown to confer a superior response to venetoclax/azacitidine), whilst *TP53* mutations confer resistance to chemotherapy and an overall poor outcome (Dennis et al., 2022).

The BSH also recommends that "At relapse, patients who remain fit to receive anti-leukaemia therapy, should be re-screened for actionable/targetable mutations. At the least, this should include re-screening for mutations in FLT3 (both internal tandem duplication; ITD and tyrosine kinase domain; TKD), given the availability of gilteritinib", along with "*IDH1/2* mutations (if trial recruitment is an option). It should be noted that *FLT3* mutations may be acquired or lost at relapse". As such,

- All patients should have their disease assessed by morphology, immunophenotyping, cytogenetics and molecular studies at presentation.
- At relapse, patients should be re-screened for *FLT3* mutations as a minimum.
- Peripheral blood is a suitable alternative to bone marrow for the diagnostic evaluations if there are circulating blast cells.
- All cases should be discussed at an appropriate local or regional haemato-oncology MDT (Dennis et al., 2022).

Table 1, produced by BSH and referenced earlier, is captured below:

TABLE 1. Diagnostic investigations for AML in the older adult

Diagnostic	Diagnosis	Relapse
Bone marrow aspirate	√	√
Bone marrow trephine biopsy	√	√
Flow cytometric immunophenotyping	√	√
Cytogenetic analysis (G-banding and FISH panels) (within 5 working days)	√	√[a]
Rapid *FLT3* ITD and TKD mutation screen (within 72 hours)	√	√
Rapid *NPM1* mutation screen (within 72 hours)	√	
Multi-target NGS panel including minimum of:	√	
IDH1/2 screen	√[b,c]	
TP53 screen	√[b,c]	
ASXL1 screen	√	
RUNX1 screen	√	

Abbreviations: AML, acute myeloid leukaemia; FISH, fluorescence in situ hybridisation.

[a]If no unfavourable risk cytogenetic abnormalities were found at diagnosis, or if the patient has experienced a prolonged remission (>12 months), then cytogenetics should be rechecked at relapse.

[b]Rapid mutation screening assays for *IDH1/2* and *TP53* are recommended as these mutations may impact early treatment decisions.

[c]National Genomic Test directory for Cancer (https://www.england.nhs.uk/publication/national-genomic-test-directories/) currently recommends screening for mutations in following genes at diagnosis; *NPM1*, *CEBPA*, *RUNX1*, *FLT3*, *IDH1*, *IDH2*, *KIT*, *WT1*, *ASXL1*, *SRSF2*, *STAG2*, *RAD21*, *TP53*, *KRAS*, *NRAS*, *MLL* (*KMT2A*)-PTD, *PPM1D*.

(Dennis et al., 2022).

In a paper on best practices for laboratory testing of UK patients with AML, BSH recommends that "For a suspected acute leukaemia, most multiparametric flow cytometry laboratories apply a two-stage diagnostic panelan acute leukaemia screen (such as the Euroflow A LOT combination)" in order to confirm leukaemic blasts and allow lineage assessment, "followed immediately by an AML-specific panel if appropriate". Furthermore, "extended secondary testing may be required to diagnose blastic plasmacytoid dendritic cell neoplasm (BPDCN) or ambiguous leukaemias or acute megakaryoblastic leukaemia" (Mehta et al., 2023).

European Society for Medical Oncology (ESMO)

The ESMO released guidelines for the diagnosis of acute myeloid leukemia in adult patients. They recommend molecular testing for *c-KIT, FLT3-ITD, FLT3-TKD, NPM1, CEBPA, IDH1, IDH2,* and *TP53* mutations. They state that "next-generation sequencing (NGS) of a panel of genes commonly mutated in AML provides important additional prognostic and therapeutic information" (Heuser et al., 2020).

Acute Lymphoblastic Leukemia (ALL)

The ESMO also published clinical practice guidelines for ALL in 2016 and note that "standard cytogenetics/FISH and especially RT-PCR are routinely performed to obtain a rapid diagnosis of Ph+ ALL and identify certain intermediate/high- and high-risk karyotypes or gene, mainly:

a. t(4;11)(q21;q23)/MLL-AFA4, abn11q23/MLL, t(1;19)(q23; p13)/PBX-E2A, t(8;14) or other abn14q32 in non-Burkitt ALL
b. del(6q), del(7p), del(17p), −7, +8, low hypodiploidy, i.e., with 30–39 chromosomes/near triploidy with 60–78 chromosomes
c. complex (≥5 unrelated clonal abnormalities), and
d. T-ALL lacking NOTCH1/FBXW7 mutations and/or with RAS/PTEN abnormalities

The more prognostically favorable cytogenetic/genetic subsets are t(12;21)(p13;q22)/TEL-AML1 + ALL (rare in adults) and hyperdiploid ALL, and NOTCH-1/FBXW7-mutated T-ALL" (Hoelzer et al., 2016).

Chronic Lymphocytic Leukemia

According to ESMO, "the diagnosis of CLL is established by the following criteria:

- Presence of ≥5 × 109/l monoclonal B lymphocytes in the peripheral blood. The clonality of the circulating B lymphocytes needs to be confirmed by demonstrating light chain restriction using flow cytometry.
- The leukaemia cells found in the blood smear are characteristically small, mature-appearing lymphocytes with a narrow border of cytoplasm and a dense nucleus lacking discernible nucleoli and having partially aggregated chromatin. Larger, atypical lymphocytes or prolymphocytes may be seen but must not exceed 55%" (Eichhorst et al., 2021).

Also worth noting is that "CLL cells co-express the B-cell surface antigens CD19 and CD20 together with CD5, CD23, CD43 and CD200. The levels of surface CD20, surface immunoglobulin (Ig) and CD79b are characteristically low compared with those found on normal B cells" and that "Each clone of leukaemia cells is restricted to expression of

either kappa or lambda Ig light chains, or has no apparent expression of either of the two." ESMO also states that "Other lymphoma entities to be differentiated from CLL are mantle cell lymphoma (MCL), leukaemic marginal zone lymphoma (MZL) (in particular the splenic variant) and lymphoplasmacytic lymphoma". This differentiation can be made as "tumour cells may express B-cell surface antigens and CD5, but in most cases, they do not express CD23, in particular MZL. For cases that express CD23, reverse transcription polymerase chain reaction (RT-PCR) for determination of cyclin D1 overexpression, and FISH for detecting a translocation (11;14), but also CD200 expression, are useful for establishing the diagnosis of MCL." Moreover, "SOX11 staining may be used on tumour biopsies. A diagnosis of MZL is supported by negative or low CD43 expression and high expression of CD180" (Eichhorst et al., 2021).

Ultimately, the ESMO proposes two recommendations regarding the diagnosis of CLL:

- "Diagnosis is usually possible by immunophenotyping of peripheral blood only [III, A].
- LN biopsy and/or bone marrow biopsy may be helpful if immunophenotyping is not conclusive for the diagnosis of CLL [IV, A]" (Eichhorst et al., 2021).

During diagnostic and staging work-up, the ESMO recommends also that

- "Binet and Rai staging systems with clinical symptoms are relevant for treatment indication [III, A].
- del(17p), *TP53* mutations and IGHV status are relevant for choice of therapy and should be assessed before treatment [III, A].
- Routine evaluation of del(17p), *TP53* mutation and IGHV status in early and asymptomatic stage is not recommended [V, D].
- Routine imaging during a watch-and-wait period is not recommended unless there are clinical symptoms [V, E]" (Eichhorst et al., 2021).

The ESMO also recommends that "After the first year, when all patients should be seen at 3-monthly intervals, patients can be followed every 3-12 months depending on burden and dynamics of the disease" using history and physical examinations including a careful palpation of all LN areas, spleen and liver and complete blood cell count and differential count (Eichhorst et al., 2021).

Chronic Myeloid Leukemia

The ESMO has published guidelines for diagnosis, treatment, and follow-up of CML. These guidelines include a table which is shown below:

Table 2: Recommendations for diagnostic work-up, assessment of response and monitoring (Hochhaus et al., 2017)

Test	Baseline (diagnostic work-up)	To assess the response	To monitor the response and the treatment
Blood counts and differential	Yes	Every 15 days until a CHR [complete hematological response] without significant cytopaenias has been achieved	Every 3 months
BM [bone marrow], cytology	Yes	No	No
BM, karyotype	Yes	At 3 and 6 months	Then every 6 months until CCyR [complete cytogenetic response] has been achieved
Blood, iFISH	No	No	Only if cytogenetics of BM metaphases cannot be analyzed or is normal and molecular response cannot be assessed
Blood, RT-PCR (qualitative)	Yes	No	No
Blood, qRT-PCR (quantitative, BCR–ABL %)	No	Every 3 months	Every 4–6 weeks in first year after treatment discontinuation
Mutational Analysis	Only in AP [accelerated phase] or BP [blast phase]	No	Only in the case of failure

The ESMO has also stated that a "diagnosis must be confirmed by cytogenetics showing t(9;22)(q34;q11), and by multiplex RT-PCR showing BCR–ABL1 transcripts" (Hochhaus et al., 2017). Other warning signs include "Major route cytogenetic aberrations (+8, iso(17q), +19, +22q-), chromosome 3 aberrations and BM fibrosis at diagnosis signs"; further, a quantification of BCR-ABL mRNA is required every 3 months (Hochhaus et al., 2017). Finally, the ESMO acknowledges that mutation analysis is "due" in case of failure of first-line therapy or if BCR-ABL transcript levels increase. However, ESMO recommends against baseline mutational analysis in patients with newly diagnosed CML-CP (Hochhaus et al., 2017).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On April 28, 2017 the FDA approved the LeukoStrat® CDx *FLT3* Mutation Assay as a "PCR-based, in vitro diagnostic test designed to detect internal tandem duplication (ITD) mutations and the tyrosine kinase domain mutations D835 and I836 in the *FLT3* gene in genomic DNA extracted from mononuclear cells obtained from peripheral blood or bone marrow aspirates of patients diagnosed with acute myelogenous leukemia (AML). The LeukoStrat® CDx FLT3 Mutation Assay is used as an aid in the selection of patients with AML for whom RYDAPT® (midostaurin) treatment is being considered. The Leukostrat® CDx FLT3 Mutation Assay is to be performed only at Laboratory for Personalized Molecular Medicine (LabPMM) LLC, a single site laboratory located at 6330 Nancy Ridge Dr., San Diego, CA 92121."

On August 1, 2017 the FDA approved the Abbott RealTime *IDH2* as an "in vitro polymerase chain reaction (PCR) assay for the qualitative detection of single nucleotide variants (SNVs) coding nine *IDH2* mutations (R140Q, R140L, R140G, R140W, R172K, R172M, R172G, R172S, and R172W) in DNA extracted from human blood (EDTA) or bone marrow (EDTA). Abbott RealTime IDH2 is for use with the Abbott m2000rt System. Abbott RealTime IDH2 is indicated as an aid in identifying acute myeloid

leukemia (AML) patients with an isocitrate dehydrogenase-2 (IDH2) mutation for treatment with IDHIFA® (enasidenib)."

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81120	IDH1 (isocitrate dehydrogenase 1 [NADP+], soluble) (eg, glioma), common variants (eg, R132H, R132C)
81121	IDH2 (isocitrate dehydrogenase 2 [NADP+], mitochondrial) (eg, glioma), common variants (eg, R140W, R172M)
81170	ABL1 (ABL proto-oncogene 1, non-receptor tyrosine kinase) (eg, acquired imatinib tyrosine kinase inhibitor resistance), gene analysis, variants in the kinase domain
81175	ASXL1 (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; full gene sequence
81176	ASXL1 (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; targeted sequence analysis (eg, exon 12)
81206	BCR/ABL1 (t(9:22)) (eg, chronic myelogenous leukemia) translocation analysis; major breakpoint, qualitative or quantitative
81207	BCR/ABL1 (t(9:22)) (eg, chronic myelogenous leukemia) translocation analysis; minor breakpoint, qualitative or quantitative
81208	BCR/ABL1 (t(9:22)) (eg, chronic myelogenous leukemia) translocation analysis; other breakpoint, qualitative or quantitative
81218	CEBPA (CCAAT/enhancer binding protein [C/EBP], alpha) (eg, acute myeloid leukemia), gene analysis, full gene sequence
81245	FLT3 (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia), gene analysis; internal tandem duplication (ITD) variants (ie, exons 14, 15)
81246	FLT3 (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia), gene analysis; tyrosine kinase domain (TKD) variants (eg, D835, I836)

CPT	Code Description
81261	IGH@ (Immunoglobulin heavy chain locus) (eg, leukemias and lymphomas, B-cell), gene rearrangement analysis to detect abnormal clonal population(s); amplified methodology (eg, polymerase chain reaction)
81262	IGH@ (Immunoglobulin heavy chain locus) (eg, leukemias and lymphomas, B-cell), gene rearrangement analysis to detect abnormal clonal population(s); direct probe methodology (eg, Southern blot)
81263	IGH@ (Immunoglobulin heavy chain locus) (eg, leukemia and lymphoma, B-cell), variable region somatic mutation analysis
81272	KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, gastrointestinal stromal tumor [GIST], acute myeloid leukemia, melanoma), gene analysis, targeted sequence analysis (eg, exons 8, 11, 13, 17, 18)
81273	KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, mastocytosis), gene analysis, D816 variant(s)
81310	NPM1 (nucleophosmin) (eg, acute myeloid leukemia) gene analysis, exon 12 variants
81334	RUNX1 (runt related transcription factor 1) (eg, acute myeloid leukemia, familial platelet disorder with associated myeloid malignancy) gene analysis, targeted sequence analysis (eg, exons 3-8)
81351	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; full gene sequence
83152	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; targeted sequence analysis (eg, 4 oncology)
81401	Molecular pathology procedure, Level 2 (eg, 2-**10** SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons) Gene: *DNMT3A*
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis) Genes: *WT1, TP53*
81450	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis

CPT	Code Description
81451	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
81455	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
81479	Unlisted molecular pathology procedure
88237	Tissue culture for neoplastic disorders; bone marrow, blood cells
88271	Molecular cytogenetics; DNA probe, each (eg, FISH)
88272	Molecular cytogenetics; chromosomal in situ hybridization, analyze 3-5 cells (eg, for derivatives and markers)
88273	Molecular cytogenetics; chromosomal in situ hybridization, analyze 10-30 cells (eg, for microdeletions)
88274	Molecular cytogenetics; interphase in situ hybridization, analyze 25-99 cells
88275	Molecular cytogenetics; interphase in situ hybridization, analyze 100-300 cells
88291	Cytogenetics and molecular cytogenetics, interpretation and report
0016U	Oncology (hematolymphoid neoplasia), RNA, BCR/ABL1 major and minor breakpoint fusion transcripts, quantitative PCR amplification, blood or bone marrow, report of fusion not detected or detected with quantitation Proprietary test: QuantideX® Lab/Manufacturer: University of Iowa, Department of Pathology, Asuragen
0023U	Oncology (acute myelogenous leukemia), DNA, genotyping of internal tandem duplication, p.D835, p.I836, using mononuclear cells, reported as detection or non-detection of FLT3 mutation and indication for or against the use of midostaurin Proprietary test: LeukoStrat® CDx *FLT3* Mutation Assay Lab/Manufacturer: LabPMM LLC/Invivoscribe Technologies, Inc.
0040U	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis, major breakpoint, quantitative Proprietary test: MRDx® Lab/Manufacturer: MolecularMD
0046U	FLT3 (fms-related tyrosine kinase 3) (eg, acute myeloid leukemia) internal tandem duplication (ITD) variants, quantitative Proprietary test: *FLT3* ITD MRD by NGS Lab/Manufacturer: LabPMM LLC/Invivoscribe Technologies, Inc.

CPT	Code Description
0049U	NPM1 (nucleophosmin) (eg, acute myeloid leukemia) gene analysis, quantitative Proprietary test: NPMI MRD by NGS Lab/Manufacturer: LabPMM LLC/Invivoscribe Technologies, Inc.
0413U	Oncology (hematolymphoid neoplasm), optical genome mapping for copy number alterations, aneuploidy, and balanced/complex structural rearrangements, DNA from blood or bone marrow, report of clinically significant alterations Proprietary test: DH Optical Genome Mapping/Digital Karyotyping Assay Lab/Manufacturer: Bionano Genomics

Liquid Biopsy

Policy Number: AHS – G2054 – Liquid Biopsy	Prior Policy Name and Number, as applicable: • AHS-G2054 Detection of Circulating Tumor Cells and Cell Free DNA in Cancer Management • Consolidated: AHS-M2140 – Liquid Biopsy
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

The National Cancer Institute (NCI) defines "liquid biopsy" as a test done on a sample of blood, urine, or other bodily fluid to look for cancer cells from a tumor or small pieces of DNA, RNA, or other molecules released by tumor cells into a person's body fluids. Liquid biopsies are non-invasive blood tests since circulating tumor cells (CTCs) and cell-free tumor DNA (cfDNA) fragments are shed into the bloodstream from existing tumors and can be detected in blood (Curigliano, 2014; Haber & Velculescu, 2014). The presence of CTCs can be indicative of metastatic disease (Alix-Panabieres & Pantel, 2013).

For guidance concerning Tumor Mutational Burden Testing (TMB) and/or Microsatellite instability (MSI) analysis please refer to AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing policy.

II. Related Policies

Policy Number	Policy Title
AHS-G2125	Urinary Tumor Markers for Bladder Cancer
AHS-M2160	Molecular Testing of Pulmonary Specimens
AHS-M2166	Gene Expression Profiling and Protein Biomarkers for Prostate
AHS-M2168	Proteogenomic Testing of Individuals with Cancer
AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals diagnosed with non-small cell lung cancer (NSCLC), cell-free DNA/circulating tumor DNA (cfDNA/ctDNA) testing **MEETS COVERAGE CRITERIA** in **any** of the following situations:
   a) When tissue-based testing is infeasible (i.e., quantity not sufficient for tissue-based test or invasive biopsy is medically contraindicated).
   b) In the initial diagnostic setting when there is insufficient tissue to allow testing for broad molecular analysis following pathological confirmation of NSCLC (if an oncogenic driver is not identified, follow-up tissue-based analysis should be considered).
   c) In the initial diagnostic setting when tissue-based molecular analysis does not completely assess all recommended biomarkers due to tissue quantity or testing methodologies available. Recommended biomarkers include:
      i) *ALK* rearrangements.
      ii) *BRAF* mutations.
      iii) *EGFR* mutations.
      iv) *ERBB2* (*HER2*) mutations.
      v) *KRAS* mutations.
      vi) *MET*ex14 skipping mutations.
      vii) *NTRK1/2/3* fusions.
      viii) *RET* rearrangements.
      ix) *ROS1* rearrangements.
      x) PD-L1 expression levels.
   d) To aid in biomarker evaluation for treatment selection in the initial diagnostic setting (when the feasibility of timely tissue-based testing is uncertain).
2) For individuals diagnosed with HR-positive/HER2-negative breast cancer and who are being considered for targeted therapy, cfDNA/ctDNA testing for *PIK3CA* **MEETS COVERAGE CRITERIA**.

3) For individuals diagnosed with castration-resistant prostate cancer, cfDNA/ctDNA testing of the following biomarkers **MEETS COVERAGE CRITERIA**:
   a) Androgen receptor variant 7 (AR-V2) to guide therapy selection in the post-abiraterone/enzalutamide metastatic CRPC setting.
   b) Somatic analysis of *BRCA1* and *BRCA2* to select patients for rucaparib treatment.

4) For individuals meeting the above criteria, cfDNA/ctDNA testing (annually) **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) For all other situations not described above, liquid biopsy testing for screening, detecting, and/or monitoring any other malignancy or tumor **DOES NOT MEET COVERAGE CRITERIA**.

6) For all situations not addressed above, analysis of PD-L1 by liquid biopsy **DOES NOT MEET COVERAGE CRITERIA**.

7) For the screening, detection, and/or diagnosis of cancer, urinary liquid biopsy (i.e., use of cell-free DNA ["UcfDNA"] or circulating tumor DNA obtained in a urine sample) (e.g., SelectMDX) **DOES NOT MEET COVERAGE CRITERIA**.

8) Liquid biopsy testing on CSF samples **DOES NOT MEET COVERAGE CRITERIA**.

9) Cell capture-enumeration assays of CTCs (e.g., CELLSEARCH® CTC) **DO NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
AACC	American Association for Clinical Chemistry
ALK	*Anaplastic lymphoma receptor tyrosine kinase*
AMP	The Association for Molecular Pathology
AR	*Androgen receptor*
AR-V7	*Androgen receptor splice variant 7*
ASCO	American Society of Clinical Oncology
BRAF	*B-Raf proto-oncogene*
BRCA1	*Breast cancer type 1 susceptibility gene*
BRCA1/2	*Breast cancer type 1/2 susceptibility gene*
BRCA2	*Breast cancer type 2 susceptibility gene*

CAM	Cell adhesion molecule
CAP	College of American Pathologists
CF	Cell-free
cfDNA	Cell-free tumour deoxyribonucleic acid
CGP	Comprehensive somatic genomic profiling
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
c-MET	*Cellular mesenchymal epithelial transition*
CNS	Central nervous system
CRC	Colorectal cancer
CRPC	Castration-resistant prostate cancer
CSCO	Chinese Society of Clinical Oncology
CSF	Cerebrospinal fluid
CSF-CTC	Circulating tumor Cells in cerebrospinal fluid
CTCs	Circulating tumor cells
ctDNA	Circulating tumor deoxyribonucleic acid
CTLA-3	Cytotoxic T-lymphocyte-associated protein 3
DLX1	Distal-less 1
DNA	Deoxyribonucleic acid
DRE	Digital rectal examination
EAU	European Association of Urology
EGFR	*Epidermal growth factor receptor*
EpCAM	Epithelial cell adhesion molecule
ER+ MBCs	Estrogen receptor-positive metastatic breast cancer
ERCC1	*Excision repair cross-complementation group 1*
ER-CTCs	Estrogen receptor-negative circulating tumor cells
ESMO	European Society for Medical Oncology
ESTRO	European Society of Urogenital Radiology
EV	Extracellular vesicle
ExoRNA	Exosome ribonucleic acid
FDA	Food and Drug Administration
FFPE	Formalin-fixed paraffin-embedded
GC	Gastric cancer
gDNA	Genomic deoxyribonucleic acid
HCC	Hierarchical condition category
HDL	High-density lipoprotein
hENT1	*Human equilibrative nucleoside transporter 1*
HER2	Human epidermal growth factor receptor 2
HOXC6	Homeobox C6
IASLC	International Association for the Study of Lung Cancer

InDels	Insertions/Deletions
KLK3	*Kallikreins 3*
KRAS	*Kirsten rat sarcoma viral oncogene homolog*
LAG-3	Lymphocyte-activation gene 3
LM	Leptomeningeal metastasis
MDX	Molecular diagnostics
MET	*MET Proto-Oncogene*
MRI	Myotubularin 1
mRNA	Messenger ribonucleic acid
MSI	Microsatellite instability
MSI-H	Microsatellite instability-high
NACB	National Academy of Clinical Biochemistry
NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute
NGS	Next-generation sequencing
NIH	National Institute of Health
NK	Natural killer
NRAS	*Neuroblastoma rat sarcoma*
NSCLC	Non-small cell lung cancer
PCR	Polymerase chain reaction
PD-L1	Programmed death-ligand 1
PFS	Progression-free survival
PIK3CA	*Phosphatidylinositol 3-Kinase*
PSA	Prostate-specific antigen
RET	*Rearranged during transfection*
RGQ	Rapid gas quenching
RNA	Ribonucleic acid
RNases	Ribonucleases
RRM1	*Ribonucleotide reductase, M1 subunit*
RT-PCR	Reverse transcriptase polymerase chain reaction
SIOG	International Society of Geriatric Oncology
SNVs	Single nucleotide variants
tDNA	Tissue deoxyribonucleic acid
TEXs	Tumor-derived exosomes
TIM-3	T cell immunoglobulin and mucin-domain containing-3
TKIs	Tyrosine kinase inhibitors
TMB	Tumor mutational burden
TOP1	*DNA topoisomerase 1*
TOP2A	*DNA topoisomerase 2 alpha*

TOP2B	*DNA topoisomerase 2 beta*
TP	*Tumour protein*
TUBB3	*Tubulin beta 3 class III*
UcfDNA	Urinary cell-free deoxyribonucleic acid
utDNA	Urine-derived tumor deoxyribonucleic acid
XRCC1	*X-ray repair cross-complementing 1*

V. Scientific Background

The science of noninvasive disease monitoring has advanced greatly since circulating cell-free DNA (cfDNA) was first reported in body fluids by Mandel and Metais. Since then, the evolution of sensitive cfDNA detection technologies has enabled the development of liquid biopsies with many clinical applications. For example, in oncology, the use of liquid biopsy allows for patient stratification, screening, monitoring treatment response and detection of minimal residual disease after surgery or recurrence. Liquid biopsies have grown in importance because the genetic profile of tumors can affect how well patients respond to a certain treatment. However, this characterization is currently achieved through a biopsy despite the inherent problems in procurement of tissue samples and the limitations of tumor analyses. For example, the invasive nature of a biopsy poses a risk to patients and can have a significant cost (Brock et al., 2015).

Tumor sampling from some cancer types also remains difficult resulting in inadequate amount of tissue for genetic testing (Brock et al., 2015). In the case of advanced or metastatic non-small cell lung cancers (NSCLC), as many as 69% of cases do not have accessible tissue (Douillard et al., 2009). Even when tissue can be collected, preservation methods such as formalin fixation can cause false positive results for genetic tests (Quach et al., 2004). Finally, due to tumor heterogeneity, biopsies often suffer from sample bias (Bedard et al., 2013). Liquid biopsies are becoming more popular as they provide an opportunity to genotype in a less invasive and expensive manner. However, the low sensitivity (between 60-80%) and higher number of false negative cases compared to traditional tissue biopsy are limitations associated with liquid biopsies (Sequist & Neal, 2024).

Approaches to Liquid Biopsy Analysis

Circulating tumor cells (CTCs)

According to Brock et al. (2015), CTCs are cells shed into the vasculature from a primary tumor and may constitute seeds for subsequent growth of additional tumors (metastasis) in distant organs. CTCs generally confer the advantage of containing RNA, DNA, and protein from tumor cells including both nuclear and cytoplasmic biomarkers,

which is not attainable from ctDNA or exosomes (Yu et al., 2021). They have been detected in various metastatic carcinomas (Mavroudis, 2010) but are extremely rare in healthy subjects and patients with nonmalignant diseases (Brock et al., 2015). Clinical evidence indicates that patients with metastatic lesions are more likely to have CTCs amenable to isolation but their frequency is low, often ~1-10 CTCs per mL of whole blood (Miller et al., 2010). As one mL of blood contains ~7×10^6 white blood cells and ~5×10^9 red blood cells, technologies capable of reproducibly isolating a single CTC from the background of all other blood components are fundamental. While such levels of sensitivity are challenging, there are several novel developments in this area, including positive selection, negative selection, physical properties or even enrichment-free assays to efficiently isolate these rare CTCs (Alix-Panabieres & Pantel, 2013). However, Bettegowda et al. (2014)) stated that an advantage of ctDNA is that it can be analyzed from bio-banked biofluids, such as frozen plasma (Bettegowda et al., 2014).

Typically, CTCs are defined as cells with an intact viable nucleus, cytokeratin positive, epithelial cell adhesion molecule (EpCAM) positive and with the absence of CD45 (Brock et al., 2015). Unfortunately, EpCAM and other markers are not always expressed on CTCs (Grover et al., 2014). In addition, non-tumor epithelial cells are known to circulate in the blood of patients with prostatitis or patients undergoing surgery (Brock et al., 2015; Murray et al., 2013). The heterogeneity of CTCs is a major challenge from a technical standpoint. This has led to alternative strategies of CTC enrichment such as the CTC-iChip which does not rely on tumor antigen expression (Brock et al., 2015; Karabacak et al., 2014).

Sequencing the genetic material from CTCs has demonstrated that the majority are not cancer cells, even when the isolated cell(s) fit the phenotypic criteria of being a CTC. One study by Marchetti et al. (2014) developed a protocol to recover the CTC enriched samples from the cartridge of the Veridex platform and found that from 37 NSCLC patients, the EGFR mutation allele abundance ranged between 0.02% and 24.79% with a mean of 6.34%. Brock et al. (2015) concluded that the number of CTCs found in the blood is therefore highly dependent on how the platform defines a cell as a CTC (Brock et al., 2015; Marchetti et al., 2014). The CellSearch CTC test, a Food and Drug Administration (FDA) approved actionable CTC test, requires that samples are processed within 96 hours of collection after being drawn into the *Cellsave* preservative tube. This test does not analyze the molecular genetics of the tumor; rather *Cellsave* is a platform for CTC numeration. A positive test (more than five detected CTCs for metastatic breast and prostate cancer and more than three CTCs for metastatic colorectal cancer per 7.5 mL of blood) is associated with decreased progression-free survival and decreased overall survival in these patients (Aggarwal et al., 2013).

Overall, although CTCs have produced some promising results in evaluating prognosis of patients with varying cancers, further studies are needed to assess the clinical utility of these biomarkers (Adamczyk et al., 2015; Bidard et al., 2016; Foukakis & Bergh, 2022; Ignatiadis & Dawson, 2014).

Cell-free DNA (cfDNA)

There is currently an intensive research effort to understand the utility of cfDNA in various clinical fields, such as cancer research, non-invasive prenatal testing and transplant rejection diagnostics (Brock et al., 2015). In a systematic review and meta-analysis of 20 studies and 2012 cases covering assessment of EGFR mutational status in NSCLC, Luo et al. (2014) found a sensitivity of 0.674, a specificity of 0.935, and area under the curve of 0.93. The authors concluded that detection of EGFR mutation by cfDNA is of adequate diagnostic accuracy and cfDNA analysis could be a promising screening test for NSCLC (Luo et al., 2014).

In a study, Jiang et al. (2015)observed that most cfDNA in plasma is reportedly fragmented, around 150-180 bp in length with a higher prevalence of tumor associated mutations in the shorter fragments. Per authors, when analyzing the mutation abundance with massively parallel sequencing, a significant correlation was found between mutations and fragments less than 150 bp. Notably, the size of the majority of cfDNA fragments overlaps well with the size of histone DNA (Jiang et al., 2015).

A direct comparison of mutation detection on cfDNA *vs.* CTCs showed a higher abundance of the mutation on the cfDNA from the same patient; moreover, recent large studies comparing the effectiveness of cfDNA analysis to tissue biopsy in NSCLC showed the clinical value of the liquid biopsy approach (Douillard et al., 2014). This positive result led to an approval to use cfDNA analysis for *EGFR* mutation analysis for IRESSA in Europe (in patients where a tumor sample was not evaluable), making it the first *EGFR* tyrosine kinase inhibitor for which cfDNA testing is included in the label. Although promising, challenges remain when using cfDNA to characterize the mutation status of a tumor. In addition to the low copy number of mutant alleles, the median half-life of cfDNA in circulation ranges from 15 minutes to a few hours (Brock et al., 2015).

Brock et al. (2015), in their review, observed that the total concentration of cfDNA in the blood of cancer patients varies considerably with tumor specific mutations ranging from undetectable (less than one copy per five mL of plasma) to patients with over a hundred thousand copies of the mutation per mL of plasma. The authors note that "the challenge of how to maximize the yield of the cfDNA and pair this with a platform

sensitive enough to detect rare variants in the background of wild-type DNA remains. Optimally, the ability to detect mutations in plasma should not be limited to a subpopulation of patients with very high mutant copy numbers in circulation" (Brock et al., 2015). This has been proven to be challenging in early stage cancers (Yu et al., 2021).

While many analytical platforms report the mutation load with an allelic frequency compared to the wild-type DNA platforms relying solely on the allelic frequency without recording the number of mutations have limitations. This is because the allelic frequency of a gene is affected by the amount of wild-type DNA not related to the tumor. Therefore, it is important to consider the processes that affect the amount of wild-type DNA in circulation (Brock et al., 2015). For example, exercise increases cfDNA levels almost 10-fold (Breitbach et al., 2014). Other pre-analytical variables such as blood collection, the cellular process leading to its release, and extraction protocols affect the amount and size range of cfDNA fragments in a sample (Devonshire et al., 2014).

Exosomes

In the last few years, the exosome field has grown exponentially impacting various areas of research. Studies demonstrating that exosomes are actively released vesicles (carrying RNA, DNA, and protein) and can function as intercellular messengers. Yanez-Mo et al. (2015) highlights these developments in a review outlining the biological properties of exosomes and other extracellular vesicles (EVs). However, Gould and Raposo (2013) observed that the exosome field still lags behind as the standardization of extracellular vesicle (EV) types are not yet firmly established. The majority of exosomes range in size from 30-200 nanometers (nm) in diameter and are isolated from all bio-fluids, including serum, plasma, saliva, urine and cerebrospinal fluid (Brock et al., 2015).

Due to the size of an exosome, on average just over 100 nanometers, the entire transcriptome cannot be packaged inside every vesicle. By way of comparison, retrovirus particles with a similar size can package only around 10 kb, so it is likely that a single vesicle of that size carries only a limited number of transcripts. However, exosomes are extremely abundant (10^{11} per mL of plasma) and when isolating the vesicle fraction, most of the transcriptome can be detected (Brock et al., 2015). Per Huang et al. (2013)and Kahlert et al. (2014), exosomal RNA can be used for mutation detection as well as global profiling of most types of RNA, and the profile alone (without mutation characterization) can be utilized for diagnostics (Brock et al., 2015). In the study 'Immune modulation of T-cell and NK (natural killer) cell activities by TEXs (tumor-derived exosomes)', Whiteside (2013) observed that exosome investigations

have focused on the important physiologic and pathophysiologic functions of these vesicles in micro-metastasis, angiogenesis and immune modulation and as a means for detection of tumor specific mutations in bio-fluids (Whiteside, 2013). Consequently, in 2012, interest in this new field increased when the National Institute of Health (NIH) dedicated the large strategic Common Fund to study these new entities of extracellular RNA. The goal of this effort is to better understand how exosomes can be utilized for biomarkers and therapeutics as well as understanding this new mechanism of intercellular communication (NIH, 2024).

Mutation detection and RNA profiling

Analysis of nucleic acids present in bodily fluids can provide a better understanding of the disease, as summarized in Table below.

Analysis capability	Examples	CTCs	cfDNA	Exosomes
Mutations	Point mutations, InDels, amplifications, deletions, translocations	Yes	Yes	Yes
Epigenetic modifications	Methylation patterns	Yes	Yes	Yes
RNA transcription profiles	Levels/activity of mRNA, microRNA, long non-coding RNA, RNA splice variants	Yes	No	Yes
Phenotypic studies of cells from the tumor	Cell morphology, protein localization, *in vivo* studies	Yes	No	No
Inflammatory response, stromal and other systemic changes	Inflammatory RNA and protein markers	No	No	Yes
Analysis of RNA as well as DNA and protein profiles from tumor cells	Separate or in combination	Yes	No	Yes
Can utilize bio-banked samples	Frozen plasma, urine and other bio-fluids	No	Yes	Yes

CTCs, circulating tumor cells; cfDNA, cell-free DNA; InDels, insertions/deletions. (Brock et al., 2015)

RNA profiling from biofluids is also difficult. However, since exosomes contain RNA, it was possible to separate the fragile RNA from the large amounts of RNases and PCR inhibitors. As cell-free RNA in blood is immediately degraded, RNAs in serum and plasma were either protected inside vesicles, in protein complexes or associated with HDL particles (Brock et al., 2015). The levels of these microRNAs are tightly regulated in normal cells, and dysregulation has been implicated in several human diseases, e.g., cardiovascular (Thum & Condorelli, 2015) and neurological, and is strongly linked to cancer development and progression. However, microRNAs represent only a minor fraction of the transcriptome. By contrast, the nucleic acids in exosomes can be isolated and the entire transcriptome examined (Brock et al., 2015).

The most significant hurdle for all forms of liquid biopsy remains the relative rarity of nucleic acid derived from a tumor against the background of normal material found in most patient samples. In fact, the majority of cell, cell-free nucleic acids, microRNAs and exosomes in a liquid biopsy will have originated from normal cells with numbers fluctuating as a consequence of biological variations (Brock et al., 2015).

Furthermore, although liquid biopsy was first introduced with serum, other liquid media, such as urine and cerebrospinal fluid (CSF), have been used to evaluate other conditions. Cell-free DNA is not necessarily confined to blood, and other media have been proposed.

Urine

Urine's primary advantage over blood is that it is non-invasive, allowing for more convenient testing. Urinary cell-free DNA (UcfDNA) has been proposed as a biomarker for the detection and diagnosis of certain cancers, particularly bladder and prostate cancer (Lu & Li, 2017). An example of this is SelectMDX. SelectMDX evaluates two mRNA cancer-related biomarkers (HOXC6 and DLX1 with *KLK3* as a reference gene) to assist a clinician in deciding to continue routine screening or to order a prostate biopsy. This test is considered a "non-invasive urine test" (a liquid biopsy) and reports a binary result of "increased risk" or "very low risk" (MDx, 2023). Van Neste et al. evaluated this test at a 0.90 area under curve in a validation cohort. The authors concluded that the mRNA signature was one of the most significant components of the validation results (Van Neste et al., 2016). Shore et al. (2019) assessed the effect of SelectMDX results on clinical decision making and found that out of 253 patients SelectMDX evaluated as "negative," only 12% underwent a biopsy (Shore et al., 2019).

Xu et al. (2021) assessed the diagnostic value of urinary exosomes for urological tumors. The authors performed a systematic review and meta-analysis of 16 studies with a total of 3224 patients. Diagnostic value was calculated based on the number of

true positives, false positives, true negatives, and false negatives. The sensitivity of using urinary exosomes for the diagnosis of urological tumors was 83% and the specificity was 88%. Sensitivity and specificity results were similar regardless of urinary exosome content type and tumor type. The authors conclude that "urinary exosomes may serve as novel non-invasive biomarkers for urological cancer detection" (Xu et al., 2021).

Cerebrospinal Fluid (CSF)

Cerebrospinal Fluid is a colorless, clear liquid produced by the choroid plexus. CSF acts to control flow of molecules to the central nervous system (CNS). Due to the tight control of the CSF, it may play a significant role in assessing several conditions. CSF is traditionally used to evaluate conditions such as meningitis, but it has also been used to assess central nervous system cancers, such as leptomeningeal metastases (Demopoulos, 2022; Johnson & Sexton, 2023). In addition to widely-known measures of pathology in CSF (opening pressure, total protein, glucose, cell count with differential), circulating tumor cells in CSF have also been proposed as markers for epithelial tumors (Demopoulos, 2022).

Lin et al. (2017) evaluated the diagnostic accuracy of circulating tumor cells in CSF (CSF-CTC) in patients with leptomeningeal metastasis (LM). There were 30 of 95 total patients diagnosed with LM based on a combination of CSF cytology and MRI. CSF-CTCs were detected in 43 patients (median 19.3 CSF-CTC/mL). Based on receiver operating curve analysis, the optimal cutoff was found to be one CSF-CTC/mL, identifying patients at a rate of 93% sensitivity, 95% specificity, positive predictive value 90%, and negative predictive value 97% (Lin et al., 2017). Diaz et al. (2022)studied the clinical utility of CSF-CTC by evaluating how CSF-CTC quantification was able to predict the outcome of LM. The authors performed a single institution retrospective study of 101 LM patients with solid tumors. The CSF-CTC count significantly predicted survival continuously ($p=0.0027$). The authors conclude that "CSF-CTCs quantification predicts survival in newly diagnosed LM, and outperforms neuroimaging" and suggest CSF-CTC can be used for LM prognosis and to assess disease burden (Diaz et al., 2022).

Mathios and Phallen (2022) published a review paper noting "significant strides" towards understanding the molecular mechanisms of brain cancer. Research advances in the field include a focus on the "tumor microenvironment" and identifying molecular biomarkers with liquid-based analyses (such as CSF in liquid biopsy). While it is a rapidly advancing area of research, clinical utility is currently limited, that is, there are currently "no approved noninvasive tests that are clinically useful" for gliomas. The authors point to Cristiano et al. (2019) as an example of a study that analyzed genome-wide cfDNA fragment features (in a variety of cancers); the authors were able to

distinguish patients with cancer from non-cancer patients (as well as isolate the tissue of origin). In another glioma-specific study, Mouliere et al. (2018) detected five of 13 patients' brain tumors (38%) using a cfDNA fragmentation-based approach to analyze cfDNA fragments and copy number alterations in CSF. In conclusion, the authors note that, despite recent excitement over promising studies, liquid biopsy approaches to brain cancer are still "in their infancy" (Mathios & Phallen, 2022).

Proprietary Testing

The FDA approval of use of Roche Cobas *EGFR* Mutation Test in plasma was based on evaluation of plasma samples from the ENSURE study (Wu et al., 2015), a multicenter, open-label, randomized, Phase III study of stage IIIB/IV NSCLC patients. A total of 98.6% of the patients enrolled (214/217) had a plasma sample available for testing. The agreement between the Cobas *EGFR* Mutation Test in plasma and tissue was evaluated for detection of *EGFR* mutations. In 76.7% of tissue-positive specimens, plasma was also positive for an *EGFR* mutation. Plasma was negative for *EGFR* mutation in 98.2% (95.4%, 99.3%) of tissue-negative cases. The patients whose plasma results were positive for exon 19 deletion and/or an L858R mutations treated with erlotinib had improved progression-free survival (PFS) compared to those treated with chemotherapy (FDA, 2016).

Another commercially available, FDA-approved test is Guardant360 by Guardant Health Inc. Guardant360 is a gene panel that sequences 74 genes (including 18 amplifications and six fusions) associated with NSCLC and reports the percentage of cfDNA (Guardant, 2023). The manufacturer purports that this genetic test will allow providers to make better treatment decisions based on the mutations present in the patient (Health, 2023). The gene panel was analytically validated, with 99.8% accuracy on 1000 consecutive samples (Lanman et al., 2015).

FoundationOne has also created a proprietary FDA-approved test that examines cell-free DNA. FoundationOne's liquid CDx test evaluates 324 genes using circulating cell-free DNA and is FDA-approved to report short variants in 311 genes (FoundationOne, 2022, 2024). A prior version of this test (covering 62 genes) was evaluated based on 2666 reference samples. The assay reached >99% sensitivity of short variants of allele frequencies of >0.5%, >95% sensitivity of allele frequencies 0.25%-0.5%, and >70% sensitivity of allele frequencies 0.125%-0.25%. Out of 62 healthy volunteers, no false positives were detected (Clark et al., 2018).

Biodesix is another laboratory that offers a liquid biopsy panel. Biodesix offers two tests; one called GeneStrat, tests *EGFR, ALK, ROS1, RET, BRAF*, and *KRAS* (Biodesix, 2023). Sensitivities of 78%-100% for *EGFR, ALK,* and *KRAS* with the GeneStrat test were

shown in multiple validation studies (Mellert et al., 2017). GeneStrat also detected over 88% of *RET* or *ROS1*-positive patients (Mellert et al., 2018). Biodesix also offers GeneStrat NGS, a broad 52 gene panel also evaluated through blood-based liquid biopsy technology.

Other firms that offer liquid biopsy testing include ResolutionBio (now part of Agilent) which offers Agilent Resolution ctDx FIRST ("companion diagnostic to KRAZATI™ (adagrasib) for the detection of *KRAS* G12C in non-small cell lung cancer [NSCLC]") and Agilent Resolution ctDx LUNG, which focuses on actionable genes for lung cancer such as EGFR and ALK; Circulogene (tests *BRAF, EGFR, KRAS, ALK, ROS1,* PD-L1, and MSI), Neogenomics (InvisionFirst, 37-gene panel including 10 actionable genes), and Biocept (CNSide™). As liquid biopsy is a rapidly emerging field, it is possible that many more tests will find their way into the clinical setting (Biocept, 2023; Circulogene, 2023; Neogenomics, 2023; ResolutionBio, 2024).

In addition to panels designed to target cancer or cancer type specific mutations, tests are beginning to emerge that perform the role of a genetic screen in asymptomatic individuals. One such test includes the GRAIL-Galleri multi-cancer early detection (MCED) test, which claims to look for a signal shared by at least 50 types of cancer with a single blood test (Grail, 2024).

According to Turnbull C. (2024) the Galleri-MCED test has an overall sensitivity of only 27.5% for early-stage cancer. The test sensitivity improves to 52.8% by restricting analysis to 12 cancers that the Galleri authors specified as being of high unmet need. However, for several of these 12 cancers, including pancreatic, oesophageal, biliary, and liver, the mortality gains from population screening may be low because these cancers are mainly diagnosed in individuals older than 70 years and prognosis is poor regardless of stage (Turnbull C., 2024).

Klein et al. (2021) held a Circulating Cell-free Genome Atlas substudy including 4077 participants in an independent validation set of Galleri (cancer: n=2823; non-cancer: n=1254, non-cancer status confirmed at year-one follow-up). Specificity for cancer signal detection was 99.5%. Overall sensitivity for cancer signal detection was 51.5% with the sensitivity increasing with stage. Stage I-III sensitivity was 67.6% in the 12 pre-specified cancers and was 40.7% in all cancers. Cancer signals were detected across more than 50 cancer types. Overall accuracy of cancer signal origin prediction in true positives was 88.7%. The study concluded that "The MCED test demonstrated high specificity and accuracy of cancer signal origin prediction and detected cancer signals across a wide diversity of cancers. These results support the feasibility of this blood-based MCED test as a complement to existing single-cancer screening tests" (Klein et al., 2021).

Clinical Utility and Validity

Seeberg et al. (2015) conducted a prospective study to assess the prognostic and predictive value of CTCs in 194 patients with colorectal liver metastasis referred to surgery. A total of 153 patients underwent a resection (41 patients had an unresectable tumor), and CTCs were detected in 19.6% of patients. Patients with unresectable tumors had a 46% CTC positivity rate compared to 11.7% for resectable tumors. Patients with two or more CTCs experienced reduced time to relapse/progression. Two or more CTCs was a strong predictor of progression and mortality in all subgroups of patients. The authors concluded that "CTCs predict nonresectability and impaired survival. CTC analysis should be considered as a tool for decision-making before liver resection in these patients" (Seeberg et al., 2015).

Groot Koerkamp et al. (2013) performed systematic review and meta-analysis to investigate the prognostic value of CTCs in patients with resectable colorectal liver metastases or widespread metastatic colorectal cancer (CRC). The results of 12 studies representing 1,329 patients were suitable for pooled analysis. The overall survival and progression-free survival were worse in patients with CTCs, with hazard ratios of 2.47 for overall survival rate and 2.07 for progression-free survival. The authors concluded that "the detection of CTCs in peripheral blood of patients with resectable colorectal liver metastases or widespread metastatic CRC is associated with disease progression and poor survival" (Groot Koerkamp et al., 2013).

Zhang et al. (2012) conducted a meta-analysis of published literature on the prognostic value of CTC in breast cancer. Forty-nine eligible studies enrolling 6,825 patients were identified. The presence of CTC was significantly associated with shorter survival in the total population and the prognostic value of CTC was significant in both early and metastatic breast cancer. The authors concluded that "the detection of CTC is a stable prognosticator in patients with early-stage and metastatic breast cancer. Further studies are required to explore the clinical utility of CTC in breast cancer" (Zhang et al., 2012).

Pinzani et al. (2021) assessed that the clinical validity of CTCs has been demonstrated in cancer screening, prognosis, and monitoring treatment responses. In the original article by Cabel et al. (2017), using the Cellsearch® technique in early non-metastatic cancer has reported low CTC detection rates (5-30% depending on cancer type), with limited specificity since "some circulating epithelial cells can be found in individuals with inflammatory disease or even in some healthy individuals." However, in the preliminary report of another study, it was found that a CTC count >25 could "distinguish lung cancer from benign lesions in patients with abnormal lung imaging. CTC count was also shown to be an "independent prognostic factor in non-small cell

lung cancer and small cell lung cancer;" despite this, CTCs are rare in the non-metastatic setting, and thus cannot be completely utilized as an independent prognostic factor in the localized setting. With respect to the independent cancers, Cabel et al. (2017) summarizes the clinical validity of CTC detection in Figure 1.

On the clinical utility of CTC, Cabel et al. (2017) initially stated "the clinical utility of CTC detection (i.e. does it improve patient outcome) has yet to be demonstrated before it can be implemented in routine clinical practice." In recent time, it was seen that specific CTC features may have clinical utility in "[predicting] the sensitivity to specific immunotherapies," and in the case of ER+ MBCs, ER-CTCs can develop and reflect "acquisition of therapy resistance by the primary tumor" (Pinzani et al., 2021).

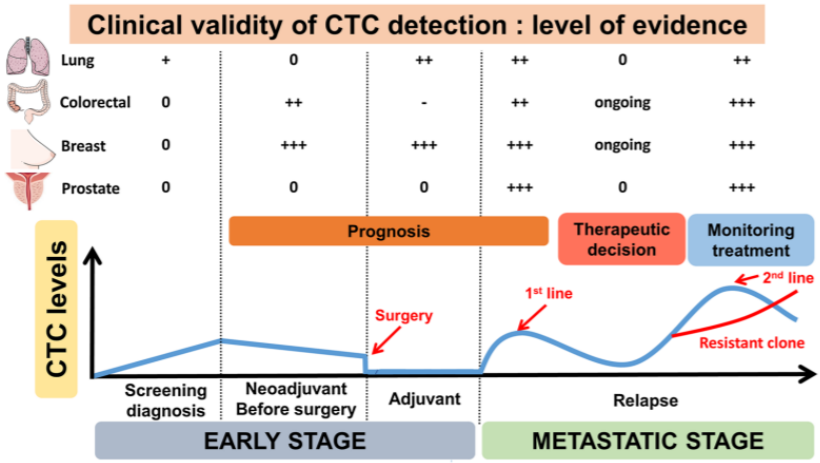

Figure 1. Clinical validity of circulating tumor cells (CTC): level of evidence according to clinical settings (Cabel et al., 2017).

Oxnard et al. (2016) found that: "Sensitivity of plasma genotyping for detection of T790M was 70%. Of 58 patients with T790M-negative tumors, T790M was detected in plasma of 18 (31%). ORR and median PFS were similar in patients with T790M-positive plasma (Objective response rate [ORR], 63%; progression-free survival [PFS], 9.7 months) or T790M-positive tumor (ORR, 62%; PFS, 9.7 months) results. Although patients with T790M-negative plasma had overall favorable outcomes (ORR, 46%; median PFS, 8.2 months), tumor genotyping distinguished a subset of patients positive for T790M who had better outcomes (ORR, 69%; PFS, 16.5 months) as well as a subset of patients negative for T790M with poor outcomes (ORR, 25%; PFS, 2.8 months)" (Oxnard et al., 2016). The authors concluded that "upon availability of validated plasma T790M assays, some patients could avoid a tumor biopsy for T790M genotyping" (Oxnard et al., 2016).

A review by Sacher et al. (2016) genotyped 180 patients with NSCLC using plasma droplet PCR (plasma ddPCR). This was done to validate the plasma droplet PCR

technique, and the study identified 115 *EGFR* mutations and 25 *KRAS* mutations. The plasma ddPCR was measured to have 82% sensitivity for the *EGFR* 19 del, 74% for L858R, 77% for T790M, and 64% for *KRAS*. The positive predictive value was 100% for every mutation apart from T790M at 79%. The authors concluded that the technique "detected *EGFR* and *KRAS* mutations rapidly with the high specificity needed to select therapy and avoid repeat biopsies". The authors also noted that this assay "may also detect *EGFR* T790M missed by tissue genotyping due to tumor heterogeneity in resistant disease" (Sacher et al., 2016).

Kim et al. (2017) evaluated the clinical utility of Guardant360. This study used the Guardant360 panel to detect mutations in patients with metastatic NSCLC and other cancers. Somatic mutations were detected in 59 patients, 25 of which had actionable mutations. Out of the 73-patient NSCLC cohort, 62 were found to have somatic mutations and 34 had actionable mutations. After these genetic findings were identified, molecularly matched therapy was provided to 10 patients with gastric cancer (GC) and 17 with NSCLC. Response rate was 67% in GC and 87% in patients with NSCLC, while disease control rate was 100% for both types (Kim et al., 2017).

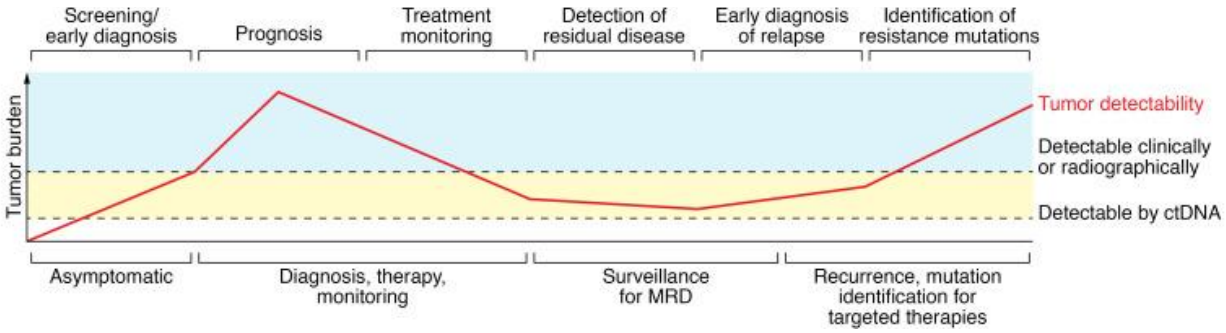
Odegaard et al. (2018) validated the Guardant360 cell-free DNA sequencing test and aimed to "demonstrate its clinical feasibility". The authors found that the test could detect variants down to "0.02% to 0.04% allelic fraction/2.12 copies with ≤0.3%/2.24-2.76 copies". Clinical validation in a cohort of over 750 patients demonstrated high accuracy and specificity, with positive percent agreement (with PCR) of 92%-100% and negative percent agreement of over 99%. In terms of feasibility, the authors performed the test in 10593 patients and found the technical success rate to be over 99.6% and the clinical sensitivity to be 85.9%. The authors also noted that 16.7% of these mutations were targetable with FDA-approved treatments (with 72% with "treatment or trial recommendations") with as many as 34.5% of non-small cell cancer samples having a targetable mutation (Odegaard et al., 2018).

Aggarwal et al. (2019) evaluated the utility of plasma-based sequencing in improving mutation detection in patients with non-small cell lung cancer. The authors first performed next-generation sequencing (NGS) on tissue, then plasma-based sequencing. A total of 229 patients had concurrent sequencing, and NGS alone detected 47 targetable mutations. Addition of plasma sequencing brought that number to 82 targetable mutations. Furthermore, 36 of 42 patients that received "plasma next-generation sequencing–indicated therapy" achieved a "complete or a partial response or stable disease". The authors concluded that "adding plasma next-generation sequencing testing to the routine management of metastatic non–small cell lung cancer appears to increase targetable mutation detection and improve delivery of targeted therapy" (Aggarwal et al., 2019).

Leighl et al. (2019) evaluated the utility of "comprehensive cell-free DNA analysis" to identify genomic biomarkers in patients with newly diagnosed metastatic non-small cell lung cancer (NSCLC). A total of 282 patients were included. Tissue genotyping (current standard of care) identified a guideline-recommended biomarker in 60 patients, whereas cell-free DNA identified a relevant biomarker in 77 patients. Concordance between the two methods was 80% (48 biomarkers detected in both methods). For FDA-approved targets (*EGFR*, *ALK*, *ROS1*, *BRAF*), concordance was >98.2% with 100% positive predictive value for cell-free DNA. Cell-free DNA was also found to have a faster median turnaround time (nine days compared to 15 for tissue genotyping), and "guideline-complete" (assessment of all eight guideline-recommended biomarkers [*EGFR*, *ALK*, *ROS1*, *BRAF*, *RET*, *MET* amplification and exon 14 skipping, and HER2]), was significantly more likely (268 patients vs 51) (Leighl et al., 2019).

Dudley et al. (2019) have developed a novel high-throughput sequencing method that uses urine-derived tumor DNA (utDNA) known as utDNA CAPP-Seq (uCAPP-Seq) to detect bladder cancer. This technique was used to analyze samples from 118 patients with early-stage bladder cancer and 67 healthy adults. "We detected utDNA pretreatment in 93% of cases using a tumor mutation-informed approach and in 84% when blinded to tumor mutation status, with 96% to 100% specificity" (Dudley et al., 2019). These results show that utDNA can be used to diagnose early-stage bladder cancer with high sensitivity and specificity.

Wang et al. (2018) performed a meta-analysis to determine the diagnostic performance of cell-free DNA (both blood and urine) assays in bladder cancer. Eleven studies encompassing 802 patients were included. The authors evaluated cell-free DNA assays at the following statistics: "sensitivity 0.71, specificity 0.78 positive likelihood ratio 3.3, negative likelihood ratio 0.37, diagnostic odds ratio nine, and area under curve 0.80. No publication bias was identified. The authors concluded that "cell-free DNA has a high diagnostic value in bladder cancer" (Wang et al., 2018).



Hopefully, cfDNA can be used to indicate prognoses of personalized peptide vaccine therapy in patients with NSCLC. Waki et al. (2021) identified that cfDNA integrity "decreased after the first cycle of vaccination" and that those with "high prevaccination cfDNA integrity survived longer than those with low prevaccination integrity (median survival time (MST): 17.9 versus 9.0 months, respectively; hazard ratio (HR): 0.58, p= .0049)," showing that monitoring cfDNA levels could contribute to quantifying treatment success and predicting patient lifespans.

For exosome-based liquid biopsy, Yu et al. (2021) have proposed a synergistic alternative of combining cfDNA and exosomal RNA to "increase the sensivity of

mutation detection… the exosome component enables a combination of exosomal RNA, cfDNA, and disease specific proteins… the unique composition of the exosome compartment makes these vesicles particularly amenable for multi-analyte testing, since they carry cancer-informative DNA, RNA, proteins, lipids, oligosaccharides, and metabolites. In one study, a high sensitivity (92%) for *EGFR* mutations was found for utilizing exosomal RNA and ctDNA together and remained high in a subpopulation that's been difficult for ctDNA assays to detect (88% sensitivity). ExoRNA and ctDNA combined analyses on *BRAF, KRAS,* and *EGFR* mutations in exosomes and respective ctDNA have also better correlated the biomarkers with treatment outcomes when compared to ctDNA alone (Yu et al., 2021).

Lee et al. (2021) analyzed the clinical utility of ctDNA to reliably detect *EGFR* in ctDNA. The authors compared *EGFR* analysis results between tissueDNA (tDNA) and ctDNA from 554 NSCLC cases. ctDNA analysis detected *EGFR* mutation in 57.3% of cases. ctDNA detection correlated with metastatic stage and disease progression ($p<0.001$). The authors followed up after an average of 41.09 month and found that, "survival analysis revealed ctDNA status and M stage ($p < 0.001$) to be independent predictors of overall survival in the multivariate analysis." The authors conclude that ctDNS is clinically useful for *EGFR* analysis, but note the possibility of false negatives and recommend using tDNA to confirm ctDNA results in some situations (Lee et al., 2021). Syeda et al. (2021) evaluated the use of ctDNA as a biomarker for melanoma. The authors measured changes in ctDNA and survival following "BRAF, MEK, or BRAF plus MEK inhibitor therapy" in patients participating in two clinical trials. The $BRAF^{V600}$-mutant was measured in ctDNA before and during treatment. "Elevated baseline $BRAF^{V600}$ mutation-positive ctDNA concentration was associated with worse overall survival outcome." The authors conclude that $BRAF^{V600}$-mutation ctDNA analysis can be used as a biomarker to predict clinical outcomes (Syeda et al., 2021).

Dang and Park (2022) completed a systematic review on the use of ctDNA for liquid biopsy and the potential challenges as a primary cancer screening marker for minimal residual disease. They cite that more studies need to be performed to evaluate the positive and negative predictive values of existing tests utilizing ctDNA for this purpose. Despite this, the figure below details their understanding of positive benefits in the potential utility of ctDNA across the cancer spectrum (Dang & Park, 2022):

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN guidelines for non-small cell lung cancer (NSCLC) strongly advise "broader molecular profiling with the goal of identifying rare driver mutations for which effective drugs may already be available, or to appropriately counsel patients regarding the availability of clinical trials... Broad molecular profiling is a key component of the improvement of care of patients with NSCLC." Furthermore, the NCCN states that "Data suggest that plasma genotyping (also known as plasma ctDNA testing or liquid biopsy) may be considered at progression instead of tissue biopsy to detect whether patients have T790M; however, if the plasma biopsy is negative, then tissue biopsy is recommended" (NCCN, 2023k).

However, the NCCN goes on to state that "cell-free/circulating tumor DNA testing should not be used in lieu of histologic tissue diagnosis." The NCCN notes that specificity is generally very high for cell-free tumor testing but is lacking in sensitivity (up to 30% false-negative rate) and that standards for analytic performance characteristics of cell-free tumor DNA have not been well established. The use of cell-free or circulating tumor DNA may be considered in specific clinical situations, such as if a patient is medically unfit for an invasive tissue sampling or if there is insufficient material for a molecular analysis following pathologic confirmation of an NSCLC diagnosis in the initial diagnostic setting (but "follow-up tissue-based analysis for all patients in which an oncogenic driver is not identified should be planned)." The NCCN notes that "data suggest that plasma ctDNA testing can be used to identify *ALK*, *BRAF, EGFR, HER2, MET* exon 14 skipping, *RET, ROS1* and other oncogenic biomarkers that would otherwise not be identified in patients with metastatic NSCLC" (NCCN, 2023k).

For NSCLC, the NCCN provides the following specific recommendations for liquid biopsy:

> "The use of cell-free/circulating tumor DNA testing can be considered in specific clinical circumstances, most notably:

- If a patient is medically unfit for invasive tissue sampling
- In the initial diagnostic setting, if following pathologic confirmation of a NSCLC diagnosis there is insufficient material for molecular analysis, cell-free/circulating tumor DNA can be used; however, follow-up tissue-based analysis for all patients in which an oncogenic driver is not identified should be planned (see NSCL-18 for oncogenic drivers with available targeted therapy options).
- In the initial diagnostic setting, if tissue-based testing does not completely assess all recommended biomarkers owing to tissue quantity or testing methodologies available, consider repeat biopsy and/or cell-free/circulating tumor DNA testing.
- In the initial diagnostic setting, if the feasibility of timely tissue-based testing is uncertain, concurrent cfDNA testing may aid in biomarker evaluation for treatment selection, provided negative results are considered per above limitations" (NCCN, 2023k).

The NCCN lists "comprehensive germline and somatic profiling to identify candidates for additional targeted therapies" as part of the workup for recurrent stage IV (M1) breast cancer." They go on to specifically note that "tissue or plasma-based circulating tumor DNA (ctDNA) assays may be used. Tissue-based assays have greater sensitivity, but ctDNA may reflect tumor heterogeneity more accurately." The NCCN also states that assessment of the PIK3CA mutation may be performed through liquid biopsy if the tumor is HR-positive, HER2 negative, and if therapy with alpelisib plus fulvestrant is being considered. Finally, for the management of breast cancer with liquid biopsy techniques, the NCCN states that "the clinical use of Circulating Tumor Cells (CTC) or circulating DNA (ctDNA) in metastatic breast cancer is not yet included in the NCCN Guidelines for Breast Cancer for disease assessment and monitoring", though the sentence that follows would indicate that this statement refers to a count of CTCs, not their use for genotyping: "Patients with persistently increased CTC after three weeks of first-line chemotherapy have a poor PFS and OS" (NCCN, 2023e).

The NCCN states that AR-V7 testing in CTCs "can be considered to help guide selection of therapy in the post-abiraterone/enzalutamide metastatic CRPC [castration-resistant prostate cancer] setting." The NCCN does not comment on any particular liquid medium over another (e.g., urine, CSF, serum). However, the NCCN does specify the use of circulating DNA for rucaparib treatment, stating that "the preferred method of selecting patients for rucaparib treatment is somatic analysis of *BRCA1* and *BRCA2* using a circulating tumor DNA sample" (NCCN, 2023a). SelectMDx is also acknowledged by the NCCN; "the panel believes that SelectMDx score is potentially informative in patients who have never undergone biopsy, and it can therefore be considered in such individuals" (NCCN, 2023m).

With regards to circulating tumor DNA (ctDNA) in colon cancer, the NCCN "panel believes that there are insufficient data to recommend the use of multigene assays, Immunoscore, or post-surgical ctDNA to estimate risk of recurrence or determine adjuvant therapy" (NCCN, 2023g).

For neuroendocrine tumors, NCCN notes that CTCs have been studied as prognostic markers, but state that more research is required. There is no single biomarker available that is satisfactory as a diagnostic, prognostic, or predictive marker (NCCN, 2023j).

For a primary CNS lymphoma, the NCCN remarks that cerebrospinal fluid analysis may "possibly" include gene rearrangement evaluation. For leptomeningeal metastases, the NCCN notes that assessment of ctDNA in CSF "increases sensitivity of tumor cell detection and assessment of response to treatment" (NCCN, 2023f).

For pancreatic adenocarcinomas, the NCCN acknowledges that circulating cell-free DNA is being investigated as a biomarker for screening. The NCCN also notes that if tumor tissue is not available, cell-free DNA testing may be considered (NCCN, 2023l).

For esophageal, esophagogastric junction cancers, and gastric cancers, the NCCN states "testing using a validated NGS-based [next generation sequencing] genomic profiling assay performed in a CLIA-approved laboratory may be considered. A negative result should be interpreted with caution, as this does not exclude the presence of tumor mutations or amplifications" (NCCN, 2023h).

For acute myeloid leukemia, the NCCN notes that "morphologically detectable," circulating leukemic blasts from peripheral blood may be used to detect molecular abnormalities (NCCN, 2023b).

For bladder cancer, the NCCN mentions RT-PCR testing for *FGFR2/3* gene alterations but does not specify whether this can be done through a liquid biopsy or cell-free DNA. The only comment made is that the laboratory should be CLIA-approved (NCCN, 2023d).

The NCCN guidelines for small cell lung cancer and hepatocellular carcinoma do not address use of CTCs, ctDNA, or liquid biopsy for patient management (NCCN, 2023i, 2023n). In biliary tract cancers, the NCCN states that "a cell-free DNA (cfDNA) test may also be considered for identifying gene mutations. This technique may not reliably identify gene fusions or rearrangements depending on the panel used and the specific partner gene" (NCCN, 2023c).

American Society of Clinical Oncology (ASCO)

In 2016, ASCO published updated recommendations for the use of tumor markers in treatment of metastatic breast cancer. ASCO found that although CTCs may be prognostic, they are not predictive for clinical benefit when used to guide or influence decisions on systemic therapy for metastatic breast cancer. ASCO recommends clinicians to not use these markers as adjunctive assessments (Van Poznak et al., 2015). Similarly, ASCO recommended against use of CTCs to guide decisions about adjuvant systemic therapy for individual's with early stage invasive breast cancer (Andre et al., 2019).

In 2019, ASCO stated that clinicians "should not use circulating biomarkers as a surveillance strategy for detection of recurrence in patients who have undergone curative-intent treatment of stage I-III NSCLC or SCLC". ASCO states that further data is required to validate this approach (Schneider et al., 2019).

In 2018, ASCO and the College of American Pathologists (CAP) released a joint review on "circulating tumor DNA analysis in patients with cancer." In it, they note that apart from the assays that have received "regulatory appeal", most assays have "insufficient evidence" for both clinical validity and clinical utility. They note discordant results between circulating DNA assays and tissue genotyping. Furthermore, they remark on the lack of evidence for use in monitoring therapy effectiveness, diagnosing early-stage cancer, or cancer screening.

However, they point to evidence that well-validated assays may support initiation of targeted therapy (Merker et al., 2018).

National Academy of Clinical Biochemistry (NACB), now known as the American Association for Clinical Chemistry (AACC)

In 2010, the NACB issued practice guidelines for the use of tumor markers in liver, bladder, cervical, and gastric cancers. It found that CTCs had "questionable" clinical utility in the assessment of liver cancer and did not recommend their use (Sturgeon et al., 2010).

The NACB published an updated guideline in 2020. For liver cancer, they note circulating cell-free serum DNA as "undergoing evaluation" for "predictive marker for distant metastasis of hepatitis C virus–related HCC." The plasma proteasome is also undergoing evaluation for "assessment of early HCC in patients with chronic viral chronic hepatitis; assessment of metastatic potential of HCC." Finally, circulating methylated DNA is undergoing evaluation for HCC screening, detection, and

prognosis. No other circulating tumor markers for bladder, cervical, and gastric cancers were mentioned (Sturgeon et al., 2020).

College of American Pathologists (CAP), the International Association for the Study of Lung Cancer (IASLC), and the Association for Molecular Pathology (AMP)

An expert panel was convened to review and update the CAP-IASLC-AMP Molecular Testing Guideline for Selection of Lung Cancer Patients for EGFR and ALK Tyrosine Kinase Inhibitors. This panel consists of practicing pathologists, oncologists, and a methodologist.

The panel states there is "insufficient evidence to support the use of circulating cell-free plasma DNA (cfDNA) molecular methods for the diagnosis of primary lung adenocarcinoma". According to the panel, there is also "insufficient evidence to support the use of circulating tumor cell (CTC) molecular analysis for the diagnosis of primary lung adenocarcinoma, the identification of EGFR or other mutations, or the identification of EGFR T790M mutations at the time of EGFR TKI-resistance" (Lindeman et al., 2018).

However, the panel acknowledges that "In some clinical settings in which tissue is limited and/or insufficient for molecular testing, physicians may use a cell-free plasma DNA (cfDNA) assay to identify EGFR mutations" (Lindeman et al., 2018).

In 2021, the IASLC published an updated consensus statement on liquid biopsy testing. They note that liquid biopsy "includes a variety of methodologies for circulating analytes. From a clinical point of view, plasma circulating tumor DNA is the most extensively studied and widely adopted alternative to tissue tumor genotyping in solid tumors, including NSCLC" (Rolfo et al., 2021).

The following recommendations were presented in a consensus statement:

1. In clinical practice, ctDNA collection, sample handling, and automated processing should be performed using standardized and clinically validated procedures to reduce operator variability and false-negative results.
2. Because of the growing number of guideline-recommended oncogene targets to be assessed in advanced NSCLC, testing of plasma ctDNA should be performed by a clinically validated NGS platform rather than single-gene, PCR-based approaches, both in treatment-naive patients and those associated with multiple mechanisms of acquired resistance (MOR) to targeted agents. Where plasma NGS is not available owing to technical and economic constraints, single-gene or low multiplex-based approaches may represent appropriate alternatives. Use of limited PCR analysis for

EGFR mutations as the initial step in molecular assessment, for example, remains highly relevant in areas of the world where the EGFR mutation rate is high. Nevertheless, single-gene testing should not be considered complete, and if negative, serial testing for additional actionable biomarkers must be pursued.
3. The benefit of tissue and plasma NGS is now established in several clinical practice settings. It is anticipated, owing to broad-based coverage of requisite oncogenes, decreased turnaround times, and emerging data on cost effectiveness, that in the near future, NGS will become increasingly available worldwide. Implementation of a multidisciplinary MTB to assist clinicians in treatment decision-making is advisable, as described previously.
4. In patients with oncogene-addicted NSCLC, liquid biopsy is emerging as not only complementary to tissue-based analysis but also acceptable as the initial approach ("plasma first") for biomarker evaluation at the time of diagnosis and for monitoring the efficacy of targeted therapies. Finally, a plasma-first approach is appropriate for identification of MOR to targeted therapies in many clinical settings.
5. Indications for liquid biopsy in patients with nononcogene-addicted NSCLC are less well defined at this time, although there are several promising areas of investigation. As noted previously, bTMB is an emerging biomarker, pending completion of ongoing prospective randomized trials and refinement of methodology.

American Society for Clinical Pathology, College of American Pathologists, Association for Molecular Pathology, and American Society of Clinical Oncology

These joint guidelines from these societies were published regarding molecular biomarkers for colorectal cancer. Despite the potential of liquid biopsy for assessment of tumor recurrence and treatment resistance, the technique "awaits robust validation and further studies to determine their clinical utility" (Sepulveda et al., 2017).

European Society for Medical Oncology (ESMO) and Chinese Society of Clinical Oncology (CSCO)

These guidelines state that liquid biopsy can be used as "the initial test for the detection of a T790M mutation [for EGFR in NSCLC], and if tests are negative, a re-biopsy should be attempted if feasible" (Wu et al., 2018).

European Association of Urology (EAU), European Society for Radiotherapy and Oncology (ESTRO), European Society of Urogenital Radiology (ESUR), International Society of Geriatric Oncology (SIOG)

The joint guidelines on prostate cancer state that "In asymptomatic [individuals] with a prostate-specific antigen level between three to ten ng/mL and a normal [digital rectal examination], use one of the following tools for biopsy indication:

- risk-calculator - provided it is correctly calibrated to the population prevalence; magnetic resonance imaging of the prostate - STRONG
- an additional serum, urine or tissue-based test – WEAK."

These joint guidelines acknowledged SelectMDX as a test to isolate urine biomarkers, but the guidelines noted "the clinically added value of SelectMDX in the era of upfront MRI and targeted biopsies remains unclear" (Mottet et al., 2023).

American Society of Colon and Rectal Surgeons (ASCRS)

The ASCRS released clinical practice guidelines for the management of colon cancer. The guidelines state that "the use of multigene assays, CDX2 expression analysis, and ctDNA may be used to complement multidisciplinary decision-making for patients with stage II or III colon cancer" (Vogel et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/overview-and-quick-search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

There are four FDA-approved liquid biopsy tests as of January 10, 2023. The cobas EGFR Mutation Test v2 from Roche Diagnostics is an assay purported to detect epidermal growth factor receptor (EGFR) gene mutations in NSCLC patients. The test is intended as a companion diagnostic test for the cancer drug Tarceva (FDA, 2016), and a similar test for the T790M mutation has been produced by the same company. A second test is the Cell Search® Circulating Tumor Cell (CTC) Test, which is used to predict and analyze outcomes for individuals with metastatic breast, prostate, or colon cancer (CellSearch, 2024). A third test is Guardant360® CDx, which detects ctDNA and other common genetic errors in order to help in the choice of a therapeutic or treatment (Health, 2023). Lastly, FoundationOne® Liquid CDx is an FDA-approved

liquid biopsy test that detects ctDNA and may be able to assist a provider in determining the type of treatment that will be most effective (FoundationOne, 2022).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81162	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis and full duplication/deletion analysis (ie, detection of large gene rearrangements)
81163	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full sequence analysis
81164	BRCA1 (BRCA1, DNA repair associated), BRCA2 (BRCA2, DNA repair associated) (eg, hereditary breast and ovarian cancer) gene analysis; full duplication/deletion analysis (ie, detection of large gene rearrangements)
81194	NTRK (neurotrophic receptor tyrosine kinase 1, 2, and 3) (eg, solid tumors) translocation analysis
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
81235	EGFR (epidermal growth factor receptor) (eg, non-small cell lung cancer) gene analysis, common variants (eg, exon 19 LREA deletion, L858R, T790M, G719A, G719S, L861Q)
81275	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; variants in exon 2 (eg, codons 12 and 13)
81276	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; additional variant(s) (eg, codon 61, codon 146)
81309	PIK3CA (phosphatidylinositol-4, 5-biphosphate 3-kinase, catalytic subunit alpha) (eg, colorectal and breast cancer) gene analysis, targeted sequence analysis (eg, exons 7, 9, 20)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)

CPT	Code Description
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81462	Solid organ neoplasm, genomic sequence analysis panel, cell-free nucleic acid (eg, plasma), interrogation for sequence variants; DNA analysis or combined DNA and RNA analysis, copy number variants and rearrangements
81479	Unlisted molecular pathology procedure
86152	Cell enumeration using immunologic selection and identification in fluid specimen (eg, circulating tumor cells in blood)
86153	Cell enumeration using immunologic selection and identification in fluid specimen (eg, circulating tumor cells in blood); physician interpretation and report, when required
0011M	Oncology, prostate cancer, mRNA expression assay of 12 genes (10 content and 2 housekeeping), RT-PCR test utilizing blood plasma and urine, algorithms to predict high-grade prostate cancer risk Proprietary test: NeoLAB™ Prostate Liquid Biopsy Lab/Manufacturer: NeoGenomics Laboratories
0091U	Oncology (colorectal) screening, cell enumeration of circulating tumor cells, utilizing whole blood, algorithm, for the presence of adenoma or cancer, reported as a positive or negative result Proprietary test: FirstSightCRC Lab/Manufacturer: CellMax Life
0155U	Oncology (breast cancer), DNA, PIK3CA (phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha) (eg, breast cancer) gene analysis (ie, p.C420R, p.E542K, p.E545A, p.E545D [g.1635G>T only], p.E545G, p.E545K, p.Q546E, p.Q546R, p.H1047L, p.H1047R, p.H1047Y), utilizing formalin-fixed paraffin-embedded breast tumor tissue, reported as PIK3CA gene mutation status Proprietary test: therascreen® PIK3CA RGQ PCR Kit Lab/Manufacturer: QIAGEN
0177U	Oncology (breast cancer), DNA, PIK3CA (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha) gene analysis of 11 gene variants utilizing plasma, reported as PIK3CA gene mutation status Proprietary test: therascreen® PIK3CA RGQ PCR Kit Lab/Manufacturer: QIAGEN
0179U	Oncology (non-small cell lung cancer), cell-free DNA, targeted sequence analysis of 23 genes (single nucleotide variations, insertions and deletions,

CPT	Code Description
	fusions without prior knowledge of partner/breakpoint, copy number variations), with report of significant mutation(s) Proprietary test: Resolution ctDx Lung™ Lab/Manufacturer: Resolution Bioscience
0229U	BCAT1 (Branched chain amino acid transaminase 1) and IKZF1 (IKAROS family zinc finger 1) (eg, colorectal cancer) promoter methylation analysis Proprietary test: Colvera® Lab/Manufacturer: Clinical Genomics Pathology Inc
0317U	Oncology (lung cancer), four-probe FISH (3q29, 3p22.1, 10q22.3, 10cen) assay, whole blood, predictive algorithm-generated evaluation reported as decreased or increased risk for lung cancer Proprietary test: LungLB® Lab/Manufacturer: LungLife AI®
0332U	Oncology (pan-tumor), genetic profiling of 8 DNA-regulatory (epigenetic) markers by quantitative polymerase chain reaction (qPCR), whole blood, reported as a high or low probability of responding to immune checkpoint–inhibitor therapy Protietary test: EpiSwitch® CiRT (Checkpoint-inhibitor Response Test) Lab/Manufacturer: Next Bio-Research Services, LLC
0333U	Oncology (liver), surveillance for hepatocellular carcinoma (HCC) in high-risk patients, analysis of methylation patterns on circulating cell-free DNA (cfDNA) plus measurement of serum of AFP/AFP-L3 and oncoprotein des-gamma-carboxy-prothrombin (DCP), algorithm reported as normal or abnormal result Protietary test: HelioLiver™ Test Lab/Manufacturer: Fulgent Genetics, LLC
0337U	Oncology (plasma cell disorders and myeloma), circulating plasma cell immunologic selection, identification, morphological characterization, and enumeration of plasma cells based on differential CD138, CD38, CD19, and CD45 protein biomarker expression, peripheral blood Protietary test: CELLSEARCH® Circulating Multiple Myeloma Cell (CMMC) Test Lab/Manufacturer: Menarini Silicon Biosystems, Inc
0338U	Oncology (solid tumor), circulating tumor cell selection, identification, morphological characterization, detection and enumeration based on differential EpCAM, cytokeratins 8, 18, and 19, and CD45 protein biomarkers, and quantification of HER2 protein biomarker–expressing cells, peripheral blood

CPT	Code Description
	Protietary test: CELLSEARCH® HER2 Circulating Tumor Cell (CTC-HER2) Test Lab/Manufacturer: Menarini Silicon Biosystems, Inc
0343U	Oncology (prostate), exosome-based analysis of 442 small noncoding RNAs (sncRNAs) by quantitative reverse transcription polymerase chain reaction (RT-qPCR), urine, reported as molecular evidence of no-, low-, intermediate- or high-risk of prostate cancer Protietary test: miR Sentinel™ Prostate Cancer Test Lab/Manufacturer: miR Scientific, LLC
0356U	Oncology (oropharyngeal or anal), evaluation of 17 DNA biomarkers using droplet digital PCR (ddPCR), cell-free DNA, algorithm reported as a prognostic risk score for cancer recurrence. Proprietary test: NavDx® Lab/Manufacturer: Naveris, Inc
0368U	Oncology (colorectal cancer), evaluation for mutations of APC, BRAF, CTNNB1, KRAS, NRAS, PIK3CA, SMAD4, and TP53, and methylation markers (MYO1G, KCNQ5, C9ORF50, FLI1, CLIP4, ZNF132 and TWIST1), multiplex quantitative polymerase chain reaction (qPCR), circulating cell-free DNA (cfDNA), plasma, report of risk score for advanced adenoma or colorectal cancer Proprietary test: ColoScape™ Colorectal Cancer Detection Lab/Manufacturer: DiaCarta Clinical Lab
0388U	Oncology (non-small cell lung cancer), next-generation sequencing with identification of single nucleotide variants, copy number variants, insertions and deletions, and structural variants in 37 cancer-related genes, plasma, with report for alteration detection Proprietary test: InVisionFirst®-Lung Liquid Biopsy Lab/Manufacturer: Inivata, Inc
0395U	Oncology (lung), multi-omics (microbial DNA by shotgun next-generation sequencing and carcinoembryonic antigen and osteopontin by immunoassay), plasma, algorithm reported as malignancy risk for lung nodules in early-stage disease Proprietary test: OncobiotaLUNG Lab/Manufacturer: Micronoma™
0410U	Oncology (pancreatic), DNA, whole genome sequencing with 5-hydroxymethylcytosine enrichment, whole blood or plasma, algorithm reported as cancer detected or not detected Proprietary test: Avantect™ Pancreatic Cancer Test Lab/Manufacturer: ClearNote™ Health

Lynch Syndrome

Policy Number: AHS – M2004 – Lynch Syndrome	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Lynch syndrome (LS) (also known as hereditary non-polyposis colorectal cancer; HNPCC) is the most common form of hereditary colorectal (CRC) and endometrial cancers (EMC), resulting from an autosomal dominant inactivation of any of four mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) leading to microsatellite instability (MSI) (Rumilla et al., 2011) and associated with an increased risk of colorectal, endometrial, stomach, small bowel, and ovarian cancers (Hunter et al., 2015; Lynch et al., 2009; Moreira et al., 2012).

For guidance concerning Tumor Mutational Burden Testing (TMB) and/or Microsatellite instability (MSI) analysis please refer to the AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing policy.

II. Related Policies

Policy Number	Policy Title
AHS-M2003	Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate
AHS-M2024	Genetic Testing for Polyposis Syndromes
AHS-M2026	Testing for Colorectal Cancer Management
AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

Consideration of both maternal and paternal family histories is necessary in the evaluation of individuals for risk of carrying a Lynch syndrome gene mutation; each lineage must be considered separately.

1) For asymptomatic individuals in a family with a pathogenic familial Lynch Syndrome (LS) gene mutation who are at least 18 years of age and who have received genetic counseling, the following testing **MEETS COVERAGE CRITERIA**:
    a) Testing restricted to the known familial mutation.
    b) Comprehensive genetic testing, including muti-gene panel testing, when the specific familial mutation is unknown.

2) For individuals with a diagnosis of any LS-related cancer (see Note 1) who have received genetic counseling, multi-gene panel testing (see Note 2, Note 3) **MEETS COVERAGE CRITERIA** when one of the following conditions is met:
    a) When the individual has a personal history of a tumor with MMR deficiency, determined by PCR, NGS, or IHC.
    b) When the individual was diagnosed before 50 years of age.
    c) When the individual has at any age had one or more additional LS-related cancers.
    d) When the individual has at least one first- or second-degree relative diagnosed before 50 years of age with LS-related cancer.
    e) When the individual has at least two first- or second-degree relatives diagnosed at any age with LS-related cancers.
    f) The individual has a gene mutation associated with LS-related cancers that was detected by tumor genomic profiling in the absence of germline mutation testing.

3) For individuals with a known family history (see Note 4) of LS related cancer (see Note 1) who have received genetic counseling and are at least 18 years of age, multi-gene panel testing (see Note 2, Note 3) **MEETS COVERAGE CRITERIA** only if the family mutation is unknown (i.e., family member is unavailable for testing or testing results are unavailable) and one of the following conditions is met:
    a) The individual has at least one first-degree relative diagnosed before 50 years of age with LS-related cancer diagnosed.
    b) The individual has at least one first-degree relative diagnosed with LS-related cancer and another synchronous or metachronous LS-related cancer.

c) The individual has at least two first- or second-degree relatives diagnosed with LS-related cancer, with at least one of the relatives diagnosed by 50 years of age.

d) The individual has at least three first- or second-degree relatives diagnosed with LS-related cancers, regardless of their age at diagnosis.

e) The individual has at least a 5% risk of having a pathogenic MMR gene variant based on predictive models (PREMM5, MMRpro, MMRpredict).

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

4) For all other purposes, including, but not limited to, testing of the general population, genetic testing for susceptibility to LS related cancer **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: According to the NCCN, "LS-related cancers include colorectal, endometrial, gastric, ovarian, pancreas, urothelial [renal pelvis, ureter, and/or bladder], brain . . . , biliary tract, and small intestinal cancers, as well as sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas as seen in Muir-Torre syndrome" (NCCN, 2023).

Note 2: When germline multigene panel testing is performed in individuals with LS-related cancer, the panel should include "at minimum the following CRC risk-associated genes: *APC, MUTYH, MLH1, MSH2, MSH6, PMS2, EPCAM, BMPR1A, SMAD4, PTEN, STK11,* and *TP53*" (NCCN, 2023).

Note 3: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

Note 4: Close blood relatives include 1st-degree relatives (e.g., parents, siblings, and children), 2nd-degree relatives (e.g., grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings), and 3rd-degree relatives (great-grandparents, great-aunts, great-uncles, great-grandchildren, and first cousins), all of whom are on the same side of the family.

ICG-HNPCC	The International Collaborative Group on Hereditary Non-Polyposis Colorectal Cancer
IHC	Immunohistochemistry
LDTs	Laboratory-developed tests
LS	Lynch syndrome
MGPT	Multigene panel test
MLH1	*MutL homolog 1*
MLH6	*MutL homolog 6*
MMR	Mismatch repair
MMR-D	Mismach repair protein deficiency
MSH2	*MutS homolog 2*
MSH6	*MutS homolog 6*
MSI	Microsatellite instability
MUTYH	*MutY DNA glycosylase*
NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute
NGS	Next-generation sequencing

NICE	National Institute for Health and Care Excellence
NSGC	National Society of Genetic Counsellors
NTHL1	*Nth like deoxyribonucleic acid glycosylase 1*
O/E	Observed-to-expected ratio
PCR	Polymerase chain reaction
PMS2	*Post meiotic segregation increased 2 (S. cerevisiae)/PMS1 homolog 2*
POLD1	*Deoxyribonucleic acid polymerase delta 1*
POLE	*Deoxyribonucleic acid polymerase epsilon, catalytic subunit*
PREMM5	Prediction model for gene mutations 5
SEOM	Spanish Society of Medical Oncology
TP53	*Tumor protein 53*
TTD	Grupo Español de Tumores Digestivos
UGI	Upper gastrointestinal
USMSTF	United States Multi-Society Task Force

V. Scientific Background

Lynch syndrome (LS) is recognized by a hereditary predisposition to colorectal, endometrial, and other cancers due to inactivation by germline mutations or epigenetic silencing in any of four DNA mismatch repair genes—*MLH1, MSH2, MSH6,* and *PMS2*. Mutations in *MLH1* and *MSH2* are most common (90%) followed by *MSH6* (10%) and *PMS2* (6%) (Jansen et al., 2014). Mutations of the upstream *EPCAM* gene which result in silencing of the *MSH2* gene produce a phenotype very similar to LS (Ligtenberg et al., 2009). LS accounts for approximately 3% to 5% of all colorectal cancers (Yilmaz et al., 2020) and 2% to 5% of endometrial cancers (Hampel et al., 2005). In addition to colorectal and endometrial cancers, patients may present with ovarian, urinary tract, stomach, small bowel, hepatobiliary, sebaceous gland and central nervous system neoplasms (Barrow et al., 2013).

The lifetime risk of colorectal cancer (CRC) is greatly increased in LS patients but varies significantly from 10-74% dependent on which MMR gene is inactivated (Brosens et al., 2015). The average age at CRC diagnosis in LS patients is 44 to 61 years with tumors primarily arising proximal to the splenic flexure (Giardiello et al., 2014). There is also a high rate of metachronous CRC (16% at 10 years; 41% at 20 years) in LS patients (Win et al., 2013). The histopathology of LS colorectal cancer is often poorly differentiated with signet cell histology, abundant extracellular mucin, tumor infiltrating lymphocytes, and a lymphoid host response to tumor (Peltomäki PT, 2010). LS patients have improved survival rates compared to similar stage spontaneous CRC (Brosens et al., 2015). Lifetime risk of endometrial cancer is significantly increased to 15 – 71% of

individuals with mutation specific variability (Giardiello et al., 2014). Increased lifetime risks have also been observed in urinary, ovarian, stomach, hepatobiliary, small bowel, brain, pancreatic and prostate cancers (Brosens et al., 2015).

Cancer Risks in Individuals with Lynch Syndrome Age ≤70 Years Compared to the General Population (Brosens et al., 2015).

Cancer Type	General Population Risk	Lynch Syndrome (*MLH1* and *MSH2* heterozygotes)	
		Risk	Mean Age of Onset
Colon	4.8%	52%-82%	44-61 years
Endometrium	2.7%	25%-60%	48-62 years
Stomach	<1%	6%-13%	56 years
Ovary	1.4%	4%-12%	42.5 years
Hepatobiliary tract	<1%	1.4%-4%	Not reported
Urinary tract	<1%	1%-4%	~55 years
Small bowel	<1%	3%-6%	49 years
Brain/central nervous	<1%	1%-3%	~50 years
Sebaceous neoplasms	<1%	1%-9%	Not reported

Several sets of clinical criteria have been developed to identify patients with LS. In 1990, the International Collaborative Group on Hereditary Nonpolyposis Colorectal Cancer (HNPCC) established criteria (Amsterdam I Criteria) for HNPCC (Vasen et al., 1991), which were updated to be more sensitive in 1999 (Vasen et al., 1999). The Revised Bethesda Guidelines are a third set of clinicopathologic criteria developed in 2004 to improve identification of individuals who deserve investigation for LS; however, they state, "The goal of the Bethesda Guidelines is to identify HNPCC patients, not to identify MSI-H tumors from patients in sporadic populations that may have better prognoses or different therapeutic implications" (Umar et al., 2004).

Analytical Validity

Currently, there exist two main approaches to diagnosing Lynch syndrome. One approach leverages molecular screening of colorectal and endometrial tumor specimens for evidence of defective MMR function (MMR-D) or high-level MSI (MSI-H) to identify patients with cancer who should undergo germline testing for pathogenic MMR gene variants. The other focuses on using direct germline testing performed on patients whose family histories of cancer are suspicious for Lynch syndrome. In recent years, molecular testing has gained traction for identification of individuals with Lynch syndrome due to its robust sensitivity and specificity, testing of which can be

generalized into one of four categories: polymerase chain reaction (PCR)-based MSI testing, immunohistochemical staining (or immunohistochemistry [IHC]) for the MMR proteins, *MLH1* promoter methylation analysis (or somatic *BRAF V600E* mutation analysis), and next-generation somatic (and/or germline) sequencing assays (Yurgelun & Hampel, 2018).

The specificity and sensitivity of these methods can be polemical, and thus engender questions of what tests to even employ. Stinton et al. (2021) conducted a systematic review of literature published up to August 2019 to assess the immunohistochemistry and microsatellite instability-based testing (with or without *MLH1* promoter methylation testing) for Lynch syndrome in individuals with endometrial cancer. Thirteen studies consisting of approximately 3500 people were examined, and the researchers determined that, after adjusting for studies with highly selective inclusion criteria, sensitivity ranged from 60.9%-83.3% for immunohistochemistry, 69.2-89.9% for microsatellite instability-based testing, and 72.4-92.3% for studies combining immunohistochemistry, microsatellite instability-based testing, and *MLH1* promoter methylation testing. According to the authors, they "found no statistically significant differences in test accuracy estimates (sensitivity, specificity) in head-to-head studies of immunohistochemistry versus microsatellite instability-based testing" and thus concluded that "sensitivity of the index tests were generally high, though most studies had much lower specificity." However, though the authors "found no evidence that test accuracy differed between IHC and MSI based strategies", they acknowledged that the evidence base is still quite small and at risk of bias (Stinton et al., 2021).

The complexity of Lynch syndrome likewise evokes the use of complex diagnostic algorithms, oftentimes involving multiple subsequent germline and somatic tests. The utility and efficacy of these algorithms are also points of contention, given the novelty of said algorithms. Through retrospectively reviewing a consecutive series of 702 patients with colorectal cancer and endometrial cancer undergoing paired tumor/germline analysis of the LS genes at a clinical diagnostic laboratory, Salvador et al. (2019) asserted that "Paired testing identified a cause for MMRd tumors in 76% and 61% of patients without and with prior LS germline testing, respectively," leading the researchers to support inclusion of tumor sequencing as well as comprehensive LS germline testing in the LS testing algorithm.

Statistical models to predict risk of MMR mutations include PREMM5, MMRpredict, and MMRpro. The PREMM5 clinical prediction algorithm, available at http://premm.dfci.harvard.edu/, "estimates the cumulative probability of an individual carrying a germline mutation in the *MLH1, MSH2, MSH6, PMS2,* or *EPCAM* genes" using an individual's personal and family history of colorectal cancer, endometrial cancer, or

other LS-related cancers with the results given as a percentage of overall predicted probability of mutation in one of the four LS-related genes (DFCI, 2020). A study using the clinical and germline data from more than 18,000 individuals published in 2017 validated the use of the PREMM5 model. The report shows that for the four LS-related genes, PREMM5 can distinguish "carriers from noncarriers with an area under the curve (AUC) of 0.81 (95% CI, 0.79 to 0.82), and performance was similar in the validation cohort (AUC, 0.83; 95% CI, 0.75 to 0.92). Prediction was more difficult for *PMS2* mutations (AUC, 0.64; 95% CI, 0.60 to 0.68) than for other genes." The authors conclude, " $PREMM_5$ provides comprehensive risk estimation of all five LS genes and supports LS genetic testing for individuals with scores ≥ 2.5%" (Kastrinos et al., 2017). Kastrinos et al. (2018) published another article the following year stating that a threshold of ≥ 2.5% is now recommended to improve the identification of *PMS2* carriers by enhancing the model's sensitivity (a threshold of ≥ 5% was previously recommended).

MMRpro, statistical model and software using family history of colorectal and endometrial cancers, is available for free download at http://www4.utsouthwestern.edu/breasthealth/cagene/. "The results give useful information about an individual's colon cancer risk before he or she decides to undergo invasive screenings or expensive genetic testing" (Harvard, 2019). A study released in 2015 concluded that MMRpro was comparable to the PREMM1,2,6 model in discriminating both clinic- and population-based cohorts (Kastrinos et al., 2016). Another study in 2017 investigated the use of MMRpro in predicting *MLH1* mutations since, unlike the other LS-related genes, immunohistochemistry is less sensitive as a prescreening test for these mutations. By limiting the scope of the study to *MLH1* mutations, MMRpro outperforms the PREMM1,2,6 algorithm (AUC 0.83 versus 0.68, respectively). The authors state, "Considering a threshold of 5%, MMRpro would eliminate unnecessary germline mutation analysis in a significant proportion of cases while keeping very high sensitivity. We conclude that MMRpro is useful to correctly predict who should be screened for a germline *MLH1* gene mutation and propose an algorithm to improve the cost-effectiveness of LS diagnosis" (Cabreira et al., 2017).

Likewise, the MMRpredict algorithm, available at http://hnpccpredict.hgu.mrc.ac.uk/, is jointly operated by the Colon Cancer Genetics Group at the University of Edinburgh and MRC Human Genetics Unit of Edinburgh. This algorithm predicts the probability of a mutation carrier of an affected individual using criteria consisting of the age at time of diagnosis, gender, tumor location, synchronicity of tumor, and family history (MRC, 2023). A 2018 study shows that MMRpredict performs better than the PREMM5 model in identifying *PMS2* mutation carriers (AUCs 0.72 and 0.51, respectively), and the efficacy of the PREMM5 model is more dependent on the location of the tumor. Both

algorithms were comparable in predicting *MLH1* and *MSH2* mutation carriers (Goverde et al., 2018). These data apparently contradict earlier findings where a previous version of the PREMM model, PREMM1,2,6, performed better than MMRpredict in predicting carriers of *MLH1, MSH2*, or *MSH6* gene mutations. "For clinic- and population-based cohorts, O/E [observed-to-expected ratio] deviated from 1 for MMRPredict (0.38 and 0.31, respectively) and MMRPro (0.62 and 0.36) but were more satisfactory for PREMM1,2,6 (1.0 and 0.70). MMRPro or PREMM1,2,6 predictions were clinically useful at thresholds of 5% or greater and in particular at greater than 15%" (Kastrinos et al., 2016).

Mercado et al. (2012) published a study to assess the sensitivity and specificity of PREMM1,2,6, MMRpredict, and MMRpro in 692 endometrial cancer cases (563 population-based and 129 clinic-based cases). Pathogenic mutations were identified in 3% of the population-based participants and in 62% of the clinic-based participants. "PREMM(1,2,6), MMRpredict, and MMRpro were able to distinguish mutation carriers from noncarriers (AUC of 0.77, 0.76, and 0.77, respectively), among population-based cases. All three models had lower discrimination for the clinic-based cohort, with AUCs of 0.67, 0.64, and 0.54, respectively" (Mercado et al., 2012). For PREMM1,2,6, a sensitivity of 93% and a specificity of 5% was identified in population-based participants and a sensitivity of 99% and specificity of 2% was identified in clinic-based cases. For MMRpredict, a sensitivity of 71% and a specificity of 64% was identified in population-based participants and a sensitivity of 90% and specificity of 0% was identified in clinic-based cases. For MMRpro, a sensitivity of 57% and a specificity of 85% was identified in population-based participants and a sensitivity of 95% and specificity of 10% was identified in clinic-based cases (Mercado et al., 2012). These authors state that the PREMM1,2,6, MMRpredict, and MMRpro seem to have limited utility in the determining which endometrial cancer patients would benefit from Lynch syndrome testing.

Clinical Utility and Validity

As use of clinical criteria and modeling to identify patients with LS has less than optimal sensitivity and can vary in efficacy between different ethnic populations (Lee et al., 2016), universal screening for LS has been recommended (Cohen et al., 2016; Kidambi et al., 2015). Analysis by immunohistochemical testing for the MLH1/MSH2/MSH6/PMS2 proteins and/or MSI testing are commonly used to screen for LS phenotypes (Syngal et al., 2015). Tumors with loss of *MLH1* should undergo analysis to exclude *BRAF* mutation or *MLH1* promoter hypermethylation according to the USPSTF (Giardiello et al., 2014). Moreover, patients with evidence of LS should be

referred for genetic evaluation (EGAPP, 2009; Robson et al., 2015; Sepulveda et al., 2017).

Adar et al. (2018) completed a study to determine the value of screening both CRC and endometrial cancer (EMC) tumors in the same population. An immunohistochemistry (IHC) screening program evaluated all patients at two centers newly diagnosed with CRC and/or EMCs. "Genetic testing was recommended for those who had tumors with absent mutS homolog 2 (*MSH2*), *MSH6*, or postmeiotoic segregation increased 2 (*PMS2*) expression and for those who had tumors with absent mutL homolog 1 (*MLH1*) expression and no v-Raf murine sarcoma viral oncogene homolog B (*BRAF*) mutation or *MLH1* promoter methylation" (Adar et al., 2018). Scores from the PREMM1,2,6 and PREMM5 prediction models were also obtained, along with traditional Amsterdam II criteria and revised Bethesda criteria. Of the 1774 total patients screened for LS (1290 with CRC and 484 with EMC), genetic testing was recommended for 169 patients. LS was diagnosed in 16 patients with CRC and 8 patients with EMC based on traditional detection methods (Amsterdam II criteria, revised Bethesda criteria, PREMM1,2,6 and PREMM5 prediction models). Of the patients genetically tested, the LS diagnosis rate was higher. Specifically, "The Amsterdam II criteria, revised Bethesda criteria, and both PREMM calculators would have missed 62.5%, 50.0%, and 12.5% of the identified patients with LS, respectively" (Adar et al., 2018). The results of this study show that risk assessment tools are likely to miss a percentage of LS diagnoses.

Laish et al. (2021) conducted a retrospective cohort study on young patients with colorectal adenomatous polyps that aimed to "evaluate the yield of germline mutational analysis in diagnosis of LS." All patients were 45 years or younger, with at least one adenoma removal, and underwent genetic testing by a multigene panel or LS-Jewish founder mutation panel. They found that from the 92 patients that underwent both panels, "18 patients were identified with pathogenic mutations in actionable genes, including LS-associated genes in 6 (6.5%), *BRCA2* in 2 (2.5%), *GREM1* in 1 (1.2%), and low-penetrance genes – *APC* I1307K and *CHECK2*- in 9 (11.4%) patients." Generally, routine screening for establishing LS in young patients with adenomas is not recommended due to low yield, but the researchers proposed that due to these findings, genetic screening should be offered when they fulfill the clinical guidelines for LS.

VI. Guidelines and Recommendations

Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group

In 2009, the EGAPP Working Group recommended (EGAPP, 2009):

1. Offering genetic testing for Lynch Syndrome to individuals with newly diagnosed colorectal cancer to reduce morbidity and mortality in relatives. However, they do not recommend a specific testing protocol.
2. That individuals with newly diagnosed CRC should be routinely offered counseling and educational materials aimed at informing them and their relatives of the potential benefits and harms associated with genetic testing to identify Lynch Syndrome.
3. "Microsatellite instability (MSI) testing or immunohistochemical (IHC) testing (with or without *BRAF* mutation testing) of the tumor tissue are examples of preliminary testing strategies that could be used to select patients for subsequent diagnostic testing. Diagnostic testing involves MMR gene mutation (and deletion/duplication) testing of the proband, usually using a blood sample. Lynch syndrome is most commonly caused by mutations in the two MMR genes MLH1 and MSH2; less commonly by mutations in MSH6 and PMS2."

The EGAPP was launched by the CDC Office of Public Health Genomics in 2004. EGAPP's website, which includes the 2009 Lynch Syndrome guidelines, states that the page is archived and is no longer being updated (EGAPP, 2016).

National Comprehensive Cancer Network (NCCN)

In their *Genetic/Familial High-Risk Assessment: Colorectal*, the NCCN lists the following criteria for the evaluation of Lynch Syndrome:

- "Known LS pathogenic variant in the family
- An individual with a LS-related cancer and any of the following:
  - Diagnosed <50 y
  - A synchronous or metachronous LS-related cancer regardless of age
  - 1 first-degree or second-degree relative with LS-related cancer diagnosed <50 y
  - ≥2 first-degree or second-degree relatives with LS-related cancers regardless of age
- Family history of any of the following:
  - ≥1 first-degree relative with colorectal or endometrial cancer diagnosed <50 y
  - ≥1 first-degree relative with colorectal or endometrial cancer and a synchronous or metachronous LS-related cancer regardless of age
  - ≥2 first-degree or second-degree relatives with LS-related cancer including ≥1 diagnosed <50 y
  - ≥3 first-degree or second-degree relatives with LS-related cancers regardless of age

- Increased model-predicted risk for LS
  - An individual with a ≥5% risk of having an MMR gene pathogenic variant based on predictive models (ie, PREMM5, MMRpro, MMRpredict)
    - Individuals with a personal history of colorectal and/or endometrial cancer with a PREMM5 score of ≥2.5% should be considered for multi-gene panel testing.
    - For individuals without a personal history of colorectal cancer and/or endometrial cancer, some data have suggested using a PREMM5 score threshold of ≥2.5% rather than ≥5% to select individuals for MMR genetic testing. Based on these data, it is reasonable for testing to be done based on the ≥2.5% score result and clinical judgment. Of note, with the lower threshold, there is an increase in sensitivity, but a decrease in specificity.
- Personal history of a tumor with MMR deficiency determined by PCR, NGS, or IHC diagnosed at any age" (NCCN, 2023)

The NCCN considers LS-related cancers to "include colorectal, endometrial, gastric, ovarian, pancreas, urothelial, brain (usually glioblastoma), biliary tract, and small intestinal cancers, as well as sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas as seen in Muir-Torre syndrome." When there is no known familial mutation, the NCCN recommends germline multigene panel test (MGPT) evaluation for LS and other hereditary cancer syndromes (NCCN, 2023).

The NCCN also "recommends tumor screening for MMR deficiency for all CRC and endometrial cancers regardless of age at diagnosis. Tumor screening for CRCs for MMR deficiency for purposes of screening for LS is not required if MGPT is chosen as the strategy for screening for LS, but may still be required for CRC therapy selection. Consider tumor screening for MMR deficiency for sebaceous neoplasms as well as the following adenocarcinomas: small bowel, ovarian, gastric, pancreatic, biliary tract, brain, bladder/urothelial, and adrenocortical cancers regardless of age at diagnosis." Moreover, the panel states that "Direct referral for germline testing to rule out LS may be preferred in patients with a strong family history or if diagnosed age <50y, …MSI-H, or loss of MMR protein expression" (NCCN, 2023).

Regarding "Strategies for Evaluating for Lynch syndrome in Individuals Meeting Criteria for the Evaluation of Lynch Syndrome", it is recommended that when a deleterious Lynch syndrome pathogenic variant in a family is known, "the individual should be tested for the familial pathogenic variant." Moreover, the guidelines recommend that genetic testing should also be offered to at-risk family members.

When no Lynch syndrome pathogenic variant is present in proband or in family, individuals should first refer to the Amsterdam and Bethesda criteria. However, overall, "for individuals without a previously known Lynch syndrome-associated pathogenic variant, the panel recommends additional evaluation for Lynch syndrome based on clinical criteria, including for individuals with no known Lynch syndrome pathogenic variant who meet the Amsterdam II criteria or Bethesda Guidelines, have a CRC diagnosis < 50 years of age, or have predicted risk for Lynch syndrome greater than 5% on one of the following prediction models: MMRpro, PREMM5, or MMRpredict." However, due to issues of suboptimal sensitivity of clinical criteria when it comes to identifying individuals with Lynch syndrome, "the panel recommends universal screening of all CRCs, and endometrial cancers to maximize sensitivity for Lynch syndrome detection and simplify care processes." When germline MGPT is performed, the panel should include "at minimum the following CRC risk-associated genes: *APC, MUTYH, MLH1, MSH2, MSH6, PMS2, EPCAM, BMPR1A, SMAD4, PTEN, STK11,* and *TP53*. Selection of a panel that includes additional genes beyond this minimal set should be based on personal and family history of cancer, as well as patient and provider preference" (NCCN, 2023).

In terms of initial tumor testing methodologies, "the panel recommends using only one test [either MSI or IHC testing] initially" and only "If normal results are found and Lynch syndrome is strongly suspected" that the other test be employed. Furthermore, "Where genetic testing is recommended, the panel recommends consultation with an individual with expertise in genetics, and germline testing to exclude presence of Lynch-associated P/LP variants."

NCCN does not recommend multi-gene testing when

1) "there is an individual from a family with a known P/LP variant and there is no other reason for multi-gene testing;
2) the patient's family history is strongly suggestive of a known hereditary syndrome" (NCCN, 2023).

In these scenarios, syndrome-specific panels may be considered. For patients whose personal history is not suspicious for a polyposis syndrome and who were diagnosed with CRC ≥50 years with no known MMR deficiency in the tumor, multigene testing may be considered (category 2B). Otherwise, tumor and family history-based criteria for evaluation of Lynch syndrome is recommended for these patients" (NCCN, 2023). While tumor testing can identify pathogenic/likely pathogenic variants and germline origin can sometimes be inferred with a high degree of confidence, "confirmatory germline testing is indicated for pathogenic/likely pathogenic variants with a

reasonable clinical suspicion of being of germline origin (based on patient/family history or clinical characteristics, presence of founder mutation, and in some cases variant allele frequency). Somatic pathogenic/likely pathogenic variants in several genes with germline implications are common (eg, *TP53, STK11, PTEN, APC),* and will rarely be indicative of a need for germline testing unless clinical/family history features suggest the possibility of a germline pathogenic/likely pathogenic variant. It should be noted that the absence of reported pathogenic/likely pathogenic variants in a particular gene based on tumor testing does not rule out the possibility of a germline pathogenic/likely pathogenic variant in that gene. Clinically indicated germline testing is still appropriate for patients meeting testing guidelines regardless of tumor profiling results" (NCCN, 2023).

The NCCN states also that "In children <18 years, genetic testing is generally not recommended unless results would impact medical management, such as initiation of early colonoscopy surveillance", though "Clear exceptions include when FAP, JPS, PJS, or constitutional MMR deficiency (CMMRD) syndrome are suspected or known to be present in a family, in which case testing prior to age 18 is recommended to guide medical management" (NCCN, 2023).

National Institute for Health and Care Excellence (NICE)

NICE, in 2017, released their guidelines concerning molecular testing for LS in people with CRC. The recommend the following (NICE, 2017):

- "Offer testing to all people with colorectal cancer, when first diagnosed, using immunohistochemistry for mismatch repair proteins or microsatellite instability testing to identify tumors with deficient DNA mismatch repair, and to guide further sequential testing for Lynch syndrome... Do not wait for the results before starting treatment.
- "If using immunohistochemistry, follow the steps in table 1."

Table 1: Steps in the immunohistochemistry testing strategy (NICE, 2017)		
Step 1	Do an immunohistochemistry 4-panel test for *MLH1, MSH2, MSH6* and *PMS2*.	
Step 2	If the *MLH1* immunohistochemistry result is abnormal, use sequential *BRAF* V600E and *MLH1* promoter hypermethylation testing to differentiate sporadic and Lynch syndrome-associated colorectal cancers. First do a *BRAF* V600E test.	If the *MSH2*, *MSH6* or *PMS2* immunohistochemistry results are abnormal, confirm Lynch

Step 3	If the *BRAF* V600E test is negative, do an *MLH1* promoter hypermethylation test.	syndrome by genetic testing of germline DNA.
Step 4	If the *MLH1* promoter hypermethylation test is negative, confirm Lynch syndrome by genetic testing of germline DNA.	

- "If using microsatellite instability testing, follow the steps in table 2."

Table 2: Steps in the microsatellite instability testing strategy (NICE, 2017)	
Step 1	Do a microsatellite instability test.
Step 2	If the microsatellite instability test result is positive, use sequential *BRAF* V600E and *MLH1* promoter hypermethylation testing to differentiate sporadic and Lynch syndrome-associated colorectal cancers. First do a *BRAF* V600E test.
Step 3	If the *BRAF* V600E test is negative, do an *MLH1* promoter hypermethylation test
Step 4	If the *MLH1* promoter hypermethylation test is negative, confirm Lynch syndrome by genetic testing of germline DNA.

- "Healthcare professionals should ensure that people are informed of the possible implications of test results for both themselves and their relatives, and ensure that relevant support and information is available. Discussion of genetic testing should be done by a healthcare professional with appropriate training" (NICE, 2017).

The NICE published new recommendations dealing with testing strategies for Lynch syndrome in people with endometrial cancer in 2020 (NICE, 2020). Said recommendations are provided below.

"1.1 Offer testing for Lynch syndrome to people who are diagnosed with endometrial cancer. Use immunohistochemistry (IHC) to identify tumours with mismatch repair (MMR) deficiency:

- If IHC is abnormal with loss of MLH1, or loss of both MLH1 and PMS2 protein expression, do MLH1 promoter hypermethylation testing of tumour DNA. If MLH1 promoter hypermethylation is not detected, offer germline genetic testing to confirm Lynch syndrome.
- If IHC is abnormal with loss of MSH2, MSH6 or isolated PMS2 protein expression, offer germline genetic testing to confirm Lynch syndrome.

1.2 Healthcare professionals should inform people about the possible implications of test results for both themselves and their relatives, and give support and information. Discussion of genetic testing and obtaining consent should be done by a healthcare professional with appropriate training.

1.3 Laboratories doing IHC for MMR proteins, MLH1 promoter hypermethylation testing or germline genetic testing should take part in a recognised external quality assurance programme."

In February 2022, NICE updated one of their quality statements to recommend that adults with a new diagnosis of colorectal cancer be tested for Lynch syndrome. NICE recommends offering of cascade testing to family members in addition to testing individuals newly diagnosed with colorectal cancer. NICE suggests the following laboratory testing: "IHC for mismatch repair proteins or microsatellite instability testing, *BRAF V600E* testing and *MLH1* promoter hypermethylation testing…" According to their statement, these tests should be a part of the "standard pathology report requested by oncology," and lab providers should "ensure that laboratory protocols are in place to provide genetic testing of germline DNA for Lynch syndrome in adults with a new diagnosis of colorectal cancer and in whom test results are suggestive of Lynch syndrome" (NICE, 2022).

American Society of Clinical Oncology (ASCO)

The American Society of Clinical Oncology (ASCO) recommends that "genetic testing only be conducted in the setting of pre- and post-test counseling" (Robson et al., 2010). In 2015, ASCO stated that "identifying inherited mutations in genes such as *BRCA1*, *BRCA2*, and the genes associated with Lynch syndrome allows for interventions that can significantly reduce the development of cancer and improve survival. Targeted capture assays employing NGS [next generation sequencing] technology allow for testing many genes simultaneously, including genes that would not necessarily have been tested using the phenotype-directed approach, as well as genes of less clearly established clinical utility" (Robson et al., 2015). According to ASCO, multi-gene panel testing is particularly useful in situations where there are multiple high-penetrance genes associated with a specific cancer, and "one example of such a situation is Lynch syndrome, when the results of immunohistochemical analysis are not available to direct testing" (Robson et al., 2015).

In 2023, ASCO endorsed the College of American Pathologists (CAP) Guidelines on testing for mismatch repair (MMR) and microsatellite instability (MSI) for patients considered for immune checkpoint inhibitor therapy: "For cancer patients being considered for immune checkpoint inhibitor therapy, if a MMR deficiency consistent

with Lynch syndrome is identified in the tumor, pathologists should communicate this finding to the treating physician. (Strong recommendation)" (Vikas et al., 2023).

U.S. Multi-Society Task Force on Colorectal Cancer (USMSTF)

The 2014 U.S. Multi-Society Task Force guidelines on colorectal cancer are captured below.

"Testing for MMR deficiency of newly diagnosed CRC should be performed. This can be done for all CRCs, or CRC diagnosed at age 70 years or younger, and in individuals older than 70 years who have a family history concerning for LS. Analysis can be done by IHC testing for the MLH1/MSH2/MSH6/PMS2 proteins and/or testing for MSI. Tumors that demonstrate loss of MLH1 should undergo BRAF testing or analysis of MLH1 promoter hypermethylation." Also, "Individuals who have a personal history of a tumor showing evidence of MMR deficiency (without evidence of ***MLH1*** promoter methylation); uterine cancer diagnosed at younger than age 50 years; a known family MMR gene mutation; fulfill Amsterdam criteria or revised Bethesda guidelines; and/or have a personal risk of ≥5% chance of LS based on prediction models should undergo genetic evaluation for LS" (Giardiello et al., 2014)

Updated 2017 guidelines from the U.S. Multi-Society Task Force give the following guideline for colorectal cancer screening and LS (Rex et al., 2017):

- "colonoscopy is recommended at 10-year intervals in average-risk persons and at 1- to 2-year intervals in those with Lynch syndrome."

However, for specific LS related screening techniques and recommendations, the updated 2017 article states that the Giardiello et al. (2014) guidelines are still the most current.

In 2022, the U.S. Multi-Society Task Force published updated guidelines on colorectal cancer (Patel et al., 2022). One of the recommendations was that "average-risk CRC screening" start at age 45 on a qualified basis because of the increasing incidence and mortality from colorectal cancer. However, this task force update did not mention Lynch syndrome specifically.

American Society for Clinical Pathology (ASCP), College of American Pathologists (CAP), Association for Molecular Pathology (AMP), and American Society of Clinical Oncology (ASCO)

The ASCP, CAP, AMP, and ASCO issued guidelines in 2017 stating "*BRAF* p.V600 mutational analysis should be performed in deficient MMR tumors with loss of *MLH1*

to evaluate for Lynch Syndrome risk. Presence of a *BRAF* mutation strongly favors a sporadic pathogenesis. The absence of *BRAF* mutation does not exclude risk of Lynch syndrome." In addition, they have added the following recommendation for clinicians: "clinicians should order mismatch repair status testing in patients with colorectal cancers for the identification of patients at high risk for Lynch syndrome and/or prognostic stratification" (Sepulveda et al., 2017).

American College of Gastroenterology (ACG)

In 2015, ACG issued the following practice guidelines for the management of patients with hereditary gastrointestinal cancer syndromes. The relevant guidelines are reported below.

- "All newly diagnosed colorectal cancers should be evaluated for mismatch repair deficiency.
- Analysis may be done by immunohistochemical (IHC) testing for the *MLH1/MSH2/MSH6/PMS2* proteins and/or testing for microsatellite instability; tumors that demonstrate loss of *MLH1* should undergo *BRAF* testing or analysis for *MLH1* promoter hypermethylation.
- Individuals who have a personal history of a tumor showing evidence of mismatch repair deficiency (and no demonstrated *BRAF* mutation or hypermethylation of *MLH1*), a known family mutation associated with LS, or a risk of ≥5% chance of LS based on risk prediction models should undergo genetic evaluation for LS.
- Genetic testing of patients with suspected LS should include germline mutation genetic testing for the *MLH1, MSH2, MSH6, PMS2*, and/or *EPCAM* genes or the altered gene(s) indicated by IHC testing" (Syngal et al., 2015).

American Society of Colon and Rectal Surgeons (ASCRS)

The American Society of Colon and Rectal Surgeons published guidelines based on 2014 U.S. Multi-Society Task Force on Colorectal Cancer. There, they recommend the following:

"Universal testing (tumor testing):

- Testing for MMR deficiency of newly diagnosed CRC should be performed
- This can be done for all CRCs or CRC diagnosed at age ≤70 y and in individuals >70 y who have a family history concerning for LS
- Analysis can be done by IHC testing for the MLH1/MSH2/MSH6/PMS2 proteins and/or testing for MSI

- Tumors that demonstrate loss of MLH1 should undergo BRAF testing or analysis of MLH1 promoter hypermethylation
- To facilitate surgical planning, tumor testing on suspected CRC should be performed on preoperative biopsy specimens, if possible

Traditional testing (germline testing):

- Individuals who have a personal history of a Lynch syndrome–related tumor showing evidence of MMR deficiency (without evidence of MLH1 promoter methylation)
- Personal history of uterine cancer diagnosed at age <50 y
- A known family MMR gene mutation
- Fulfill Amsterdam criteria or revised Bethesda guidelines
- Have a personal risk of ≥5% chance of LS based on prediction models" (Herzig et al., 2017).

Spanish Society of Medical Oncology (SEOM)

The SEOM published guidelines on hereditary colorectal cancer. These guidelines include the following recommendations:

- "Different screening strategies for LS of all newly diagnosed CRC and EC [endometrial cancers] can be considered including tumor tests for defective MMR function and/or high-level MSI and/or NGS tumor sequencing including *BRAF*.
- In case of lack of expression of *MLH1* and *PMS2* by immunohistochemistry, BRAFV600E mutation and/or *MLH1* promoter hypermethylation should be carried out to rule out sporadic cases.
- Patients with molecular profiles compatible with LS should be referred to GCU for appropriate counseling and NGS germline genetic testing.
- In families with fulfillment of rBC or a ≥ 2.5% likelihood of LS on the PREMM5 prediction model, prevalent and/or previous CRC and/or EC should follow the same screening procedure before considering referral to GCU (evidence level B, strength 1).
- Multigene panel testing for hereditary CRC and polyposis should include the genes:
  - *APC, BMPR1A, EPCAM, MLH1, MSH2, MSH6, MUTYH, PMS2, PTEN, SMAD4* and *STK11* (evidence level A, strength 1).
  - *AXIN2, BLM, GREM1, NTHL1, POLD1, POLE* and *TP53* (evidence level B, strength 2).
- Criteria for referral to a GCU and *APC/MUTYH* or multigene panel testing (evidence level B, strength 1):

- 1. Patients with > 10 synchronous adenomatous colonic polyps histologically confirmed.
- 2. Family history of adenomatous colonic polyps (> 10 in > 1 relative), at young age and extracolonic manifestations.
- 3. Gastric polyps (> 100), in body and fundus, preponderantly fundic glands polyps. Proton pump inhibitor use must be excluded.
- 4. Consider in: hepatoblastoma, desmoid tumor, cribriform-morular variant of papillary thyroid carcinoma, multifocal or bilateral congenital hypertrophy of retinal pigmented epithelium.
- 5. Known familial mutation in at-risk relatives" (Guillen-Ponce et al., 2020).

Spanish Society of Medical Oncology (SEOM), Multidisciplinary Spanish Group of Digestive Cancer (GEMCAD), Spanish Group of Digestive Tumors (TTD)

These guidelines were the result of the consensus of ten oncologist experts in treatment from two Spanish digestive cooperative groups (Grupo Español Multidisciplinar de Cáncer Digestivo, GEMCAD, and Grupo Español de Tumores Digestivos, TTD), the Spanish Society of Medical Oncology (SEOM), and an external review panel comprising two experts designated by SEOM. Using the Infectious Diseases Society of America–US Public Health Service Grading System for Ranking Recommendations in Clinical Guidelines, the collaborators assigned levels of evidence and grades of recommendation.

The authors recommend the following upon suspicion of CRC based on suggestive symptoms or screening tests:

- "A complete colonoscopy with biopsy to confirm the diagnosis is mandatory. Virtual colonoscopy is an alternative to detect potential synchronous colorectal lesions if a full colonoscopy is not feasible [I, A].
- CT scan of the chest, abdomen, and pelvis is the best technique to assess distant metastases [IV, A].
- MRI and PET-CT may be considered in selected cases [IV, B].
- Patients with mCRC should be evaluated by a multidisciplinary team to define patient management: resectable, potentially resectable, and un-resectable disease [III, A].
- The recommended staging system is that of the 8th edition of the AJCC [I, A]" (Fernández Montes et al., 2023).

The value of molecular profiling and identification of specific biomarkers in metastatic colon cancer are also acknowledged as predictive and prognostic indicators of disease and response to targeted therapies. As such, they note that

- "KRAS, NRAS exons 2, 3, and 4, and BRAF V600E mutations should be tested at the time of mCRC diagnosis [I, A].
- Assessment of mismatch repair deficiency (IHC or MSI-H) is recommended to assist genetic counseling for Lynch syndrome [II, B] and for its predictive value of benefit from ICI [I, A].
- Identification of HER 2 amplification or overexpression [III, C] and NTRK fusions are recommended in subsequent lines for access to clinical trials with targeted therapies [III, A].
- Liquid biopsy might be considered to monitor emergent mutations of resistance to targeted therapy, especially prior to re-challenge with anti-epidermal growth factor receptor (anti-EGFR) treatment, though this is not supported by our national authorities [II, B].
- Testing for DPYD deficiency is strongly recommended prior to initiating 5-fluorouracil-based chemotherapy [III, A]" (Fernández Montes et al., 2023).

Collaborative Group of the Americas on Inherited Gastrointestinal Cancer (CGA-IGC)

The Collaborative Group of the Americas on Inherited Gastrointestinal Cancer published a position statement on multigene panel testing for patients with colorectal cancer and/or polyposis, in which they addressed several key questions. The questions and results relevant to this policy are summarized below.

"Question 1: Which minimal set of genes should be included on a multigene panel for evaluation of hereditary CRC or polyposis?"

The CGA-IGC notes that "All commercially available panels do not include the same genes, and some panels might fail to include genes relevant to the evaluation of hereditary CRC and/or polyposis". However, they have defined 11 genes in which PV have been associated with hereditary or familial CRC or polyposis, and "considers this list of genes to be the minimal set of genes that should clinically be tested in all patients suspected of hereditary CRC or polyposis, and recommends this testing be conducted by multigene panel" (Heald et al., 2020). It should also be noted that the authors state that "Multigene panel testing is recommended over targeted gene testing due to overlapping clinical phenotypes, inconsistent definitions for oligopolyposis, challenges with accurately classifying polyp histology (particularly with hamartomatous polyps), and variable modes of inheritance (both dominant and recessive inheritance)" (Heald et al., 2020).

Their table of aforementioned list of 11 genes is pulled in below.

Minimal and additional genes to include on multigene panel test for evaluation of colorectal cancer and/or polyposis

Genes	Cumulative CRC risk by age 70	Prevalence	Inheritance	Cancer/polyposis phenotype
Genes associated with Lynch syndrome				
MLH1	4–79% [83–85]	1:1946 [16]	AD	CRC, EC, OV,GC, SBC, PC, HTC, UTC, PC, SC, BT
MSH2	35–77% [83–85]	1:2841 [16]		
MSH6	12–50% [83–85]	1:758 [16]		
PMS2[a]	10–19% [85, 86]	1:714 [16]		
EPCAM[b]	75% [85]	Unknown		
Genes associated with polyposis		syndromes		
APC	69–100% [3]	2.29:100,000 to 3.2:100,000	AD	Adenomatous polyposis, CRC, SBC, GC, TC, HB, desmoids
BMPR1A	38%[c] [87, 88]	1:16,000 to 1:100,000	AD	Juvenile polyposis, CRC, GC, SBC
MUTYH	71.7–75.4% [33]	1:8073 [16] (biallelic)1:45 [16] (monoallelic)	AR	Adenomatous polyposis, CRC, SBC, TC
PTEN	9–16% [89, 90]	1:200,000 [91]	AD	Mixed polyposis (hamartomas, ganglioneuromas, serrated, adenomatous), BC, TC, EC, CRC, KC, melanoma
STK11	39% [23, 92]	1:25,000 to 1:280,000 [93]	AD	Peutz-Jeghers polyps, CRC, BC, PC, GC, SBC, OC, EC, SCT, LC
SMAD4	38%[c] [87, 88]	1:16,000 to 1:100,000	AD	Juvenile polyposis, CRC, GC, SBC

AD autosomal dominant, *AR* autosomal recessive, *BC* breast cancer, *BT* brain tumor, *CRC* colorectal cancer, *EC* endometrial cancer, *GC* gastric cancer, *HB* hepatoblastoma, *HTC* hepatobiliary tract cacner, *KC* kidney cancer, *LC* lung cancer, *PC* pancreatic cancer, *SBC* small bowel cancer, *SC* sebaceous carcinoma, *SCT* sex cord tumor, *TC* thyroid cancer, *UTC* urinary tract cancer

[a]Laboratory analysis should be able to distinguish exons 12–15 in *PMS2* from the transcribed pseudocopy of *PMS2* (*PMS2CL*)
[b]Large rearrangement analysis only
[c]Estimated cumulative lifetime colorectal cancer risk

(*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*, *APC*, *BMPR1A*, *MUTYH*, *PTEN*, *STK11*, *SMAD4*) (Heald et al., 2020)

"Question 2: Which additional set of genes should be considered on a multigene panel for evaluation of hereditary CRC or polyposis?"

According to the authors, "Beyond the minimal list of genes recommended for multigene panel testing for patients with suspected hereditary CRC, CGA-IGC recommends that 16 additional genes be considered." Their table of 16 genes is captured below.

Additional genes with (a) low to moderately increased risk of colorectal cancer (CRC), (b) preliminary but limited data on CRC risk, and (c) genes with pathogenic variants found in CRC patients that are actionable in regard to other cancers but CRC causation not proven. Testing for these genes can be considered in specific circumstances

Genes	Odds ratio	Prevalence	Inheritance	Cancer/polyposis phenotype
(a) Genes associated with low to moderately increased risk of CRC				
ATM	2.81–2.97 [27]	1:100 [94]	AD	BC, PC
CHEK2	1.56–1.88[a] [95]	1:100 to 1:200 [28]	AD	BC, CRC
TP53	Not defined, but skewed towards younger age at diagnosis [96, 97]	1:5000 to 1:20,000	AD	ACC, BC, BT, CRC, LC, leukemia, sarcoma
(b) Genes with preliminary but limited data				
SCG5/GREM1[b]	Not defined, presumed to be high	Unknown	AD	Mixed (serrated, juvenile, adenomatous) polyposis, CRC
POLD1	Not defined	Unknown	AD	Adenomatous polyposis, BT, CRC, EC
POLE	Not defined	Unknown	AD	Adenomatous polyposis, CRC
AXIN2	Not defined	Unknown	AD	Adenomatous polyposis, CRC
NTHL1	Not defined	Unknown	AR	Adenomatous polyposis, CRC
MSH3	Not defined	Unknown	AR	Adenomatous polyposis, CRC
GALNT12	Not defined	Unknown	AD	CRC
RPS20	Not defined	Unknown	AD	CRC
(c) Genes with PV found in CRC patients that are actionable but CRC causation not proven				
BRCA1	Not defined	1:400 to 1:500 [98] 1:40 (Ashkenazi Jewish) [99]	AD	BC, OC, PrC, melanoma
BRCA2	Not defined	1:400 to 1:500 [98] 1:40 (Ashkenazi Jewish) [99]	AD	BC, OC, PrC, melanoma
CDKN2A	Not defined	Unknown	AD	PC, melanoma
PALB2	3.42–4.91 [27]	Unknown	AD	BC, PC

(*ATM*, *CHEK2*, *TP53*, *POLD1*, *POLE*, *AXIN2*, *NTHL1*, *MSH3*, *GALNT12*, *BSP20*, *BRCA1*, *BRCA2*, *CDKN2A*, *PALB2*)

(Heald et al., 2020)

"Question 3: Who should undergo multigene panel testing for hereditary CRC syndromes?"

The authors state that though conventional wisdom believes that "inherited cancer syndromes only occur in those with striking personal and/or family histories of cancer", multigene panel testing is endorsed for epithelial ovarian cancer, metastatic prostate cancer, triple negative breast cancer, and pancreatic cancer due to "the absence of typical "red flags" (family history of cancer and/or young age of onset)". Because "traditional criteria fail to identify individuals at risk for hereditary CRC", the CGA-IGC proposes indications for panel testing in the table referenced below.

Table 5

CGA-IGC recommendations for individuals who should be considered for multigene panel testing for evaluation of hereditary colorectal cancer and/or polyposis

Individuals who should undergo multigene panel testing[a]
Colorectal cancer diagnosed age < 50 years[b]
Multiple Lynch syndrome primary tumors[b,c]
Colorectal cancer[b] and at least one first degree relative with colorectal or endometrial cancer
$PREMM_5$ score ≥ 2.5% or MMRpro or MMRpredict score ≥ 5%
Mismatch repair-deficient colorectal cancer, not attributed to *MLH1* promoter methylation
Patients meeting any other genetic testing criteria [4, 6]
≥ 10 cumulative colorectal adenomas
≥ 3 cumulative gastrointestinal hamartomatous polyps[d]

Open in a separate window

[a]In some instances, the individual affected with colorectal cancer/polyposis is unavailable for testing. In this case, genetic testing should be offered to any first-degree relative (FDR) with a family history meeting these criteria. Consideration can be given to testing second-degree relatives with a family history meeting these criteria when the affected family member and FDRs are unavailable to be tested

[b]Irrespecitve of microsatellite instability (MSI)/immunohistochemistry (IHC) status

[c]Colorectal cancer, endometrial cancer, ovarian cancer, urothelial cancer, small bowel cancer, gastric cancer, hepatobiliary cancer, pancreatic cancer, sebaceous carcinoma, glioblastoma

[d]Including hamartomas, ganglioneuromas, Peutz-Jeghers polyps, and/or juvenile polyps

(Heald et al., 2020)

"Question 4: How should a patient with a dMMR CRC be evaluated using both germline and somatic testing?"

In the ideal situation, "the CGA-IGC endorses a simultaneous paired germline-somatic panel. However, considerations about whether to order sequential or simultaneous germline and tumor sequencing include a number of factors. If the patient's personal and/or family history are consistent with LS, it is more likely that they will have LS, so it may be efficient to order germline testing alone given that follow-up tumor testing will probably not be necessary. If the patient has an insurance that might only cover one genetic test, it might be best to order paired tumor and normal testing since it may not be possible to reflex to tumor testing if no PV is found on germline testing. In some cases (e.g. older patients with no family history with loss of MLH1 and PMS2 without *MLH1* methylation), it may actually be more likely that the patient has biallelic somatic

MMR gene PV rather than a germline MMR gene PV, and paired germline and somatic testing may be a reasonable first approach to testing". Finally, they also recommend that "patient preferences should be taken into account as some may prefer to get a complete answer quickly rather than drawing out the testing process by ordering the tests sequentially" (Heald et al., 2020).

National Society of Genetic Counselors (NSGC) and the Collaborative Group of the Americas on Inherited Colorectal Cancer (CGA-IGC)

The following guidelines were provided by the NSGC and the Collaborative Group of the Americas on Inherited Colorectal Cancer:

- "Microsatellite instability (MSI) and immunohistochemistry (IHC) tumor analyses should be performed on CRC or endometrial cancers as the first-line testing strategy for any patient being evaluated for LS (this includes individuals with CRC or endometrial cancer who meet Amsterdam I or II criteria or Bethesda guidelines).
- *MLH1* promoter methylation and *BRAF* V600E mutation testing may help to reduce the number of germline genetic tests needed when IHC reveals absence of *MLH1* and *PMS2*. However, NSGC and the CGA-ICC did not find enough data to recommend one test over the other or both concomitantly.
- IHC may occasionally yield atypical results. If IHC reveals absent *MLH1* or *MSH2* only, consider genetic testing of those genes individually. If IHC reveals loss of more than two MMR proteins, consider repeating the IHC analysis. If the results persist or if repeat testing was not performed, consider following the algorithm based on the most likely true results (i.e., if *MSH2, MSH6* and *MLH1* or *PMS2* are all absent, follow the loss of *MSH2/MSH6* pathway; if *MLH1, PMS2* and *MSH6* or *MSH2* are all absent, follow the *MLH1* and *PMS2* pathway). Further, it is worth noting that there is a mononucleotide microsatellite in *MSH6* that may cause loss of *MSH6* with another MMR germline mutation leading to aberrant IHC staining patterns
- When MSI testing is stable, but IHC shows absence of one or more MMR proteins, clinical judgment should be used to determine whether tumor studies should be repeated or germline genetic testing should be pursued
- MSI testing should include, at a minimum, the five markers included in the NCI panel
- While we recognize that some third party payers may not cover MSI and/or IHC analyses on the tumor of a patient's family member(s) (e.g., the family member is deceased), in our expert opinion, we deem testing the family member(s)' tumor is justified because: 1) LS is one of a few hereditary cancer syndromes that has a

validated screening test to determine if germline genetic testing is warranted; 2) if an affected family member is living, it is likely that MSI and IHC will be covered by that relative's insurance; 3) a negative germline genetic test for all four MMR genes in an unaffected patient is uninformative; 4) the cost of direct germline genetic testing for each MMR gene ranges from $1000 to $1500, whereas the cost of MSI and IHC together is ~$1000; 5) if IHC is abnormal, additional tumor tests (*BRAF* and *MLH1* promoter methylation) may help determine if germline genetic testing is necessary and if it is warranted, testing can be targeted to one or two genes limiting overall costs; and 6) normal MSI and IHC results on an affected individual would significantly lower the likelihood that LS is the explanation for the cancer in the family and germline genetic testing would most likely not be needed.

- Direct germline genetic testing (refers to both DNA sequencing and a technology that detects large rearrangements, insertions, deletions and duplications) may be considered on an affected or unaffected patient being evaluated for LS when MSI and IHC testing are not feasible.
    - In the event that a tumor block is not available, a family member(s) is not willing or able to participate in testing, there are financial concerns or there is insufficient tissue to do either MSI or IHC testing, when indicated (e.g., high familial risk is present such as Amsterdam criteria), direct germline genetic testing may be considered. It should be noted, however, that negative germline testing in an affected individual who has not had MMR IHC can also be uninformative because there are some individuals with unidentifiable MMR gene mutations that would be followed as having LS based on abnormal IHC" (Weissman et al., 2012).

European Society for Medical Oncology (ESMO)

The ESMO published guidelines in 2015 for familial risk-colorectal cancer. The ASCO has endorsed these guidelines, with minor modifications.

The ASCO endorsement panel has "determined that the recommendations of the ESMO guideline are clear, thorough, and based on the most relevant scientific evidence". The ASCO endorsed the ESMO guidelines (below) with a few minor qualifying statements (in bold):

- "Tumor **testing for DNA mismatch repair (MMR) deficiency** with immunohistochemistry for MMR proteins and/or MSI should be **assessed** in all CRC patients. As an alternate strategy, tumor testing should be carried out in

individuals with CRC younger than 70 years, or those older than 70 years who fulfill any of the revised Bethesda guidelines.

- If loss of MLH1/PMS2 protein expression is observed in the tumor, analysis of *BRAF* V600E mutation or analysis of methylation of the *MLH1* promoter should be carried out first to rule out a sporadic case. **If tumor is MMR deficient and somatic *BRAF* mutation is not detected or MLH1 promoter methylation is not identified, testing for germline mutations is indicated.**
- If loss of any of the other proteins (MSH2, MSH6, PMS2) is observed, germline genetic testing should be carried out **for the genes corresponding to the absent proteins (e.g., MSH2, MSH6, EPCAM, PMS2, or MLH1).**
- Full germline genetic testing **for Lynch syndrome** should include DNA sequencing and large rearrangement analysis.
- Full germline genetic testing of *APC* should include DNA sequencing and large rearrangement analysis.
- Germline testing of *MUTYH* can be initiated by screening for the most common mutations (*G396D, Y179C*) in the white population followed by analysis of the entire gene in heterozygotes. Founder mutations among ethnic groups should be taken into account. **For nonwhite individuals, full sequencing of *MUTYH* should be considered"** (Stoffel et al., 2015).

In 2019, the ESMO updated their clinical practice guidelines for hereditary gastrointestional cancers, including those for Lynch syndrome. In this set of recommendations, the ESMO maintains that tumor testing with IHC for MMR proteins and/or MSI is recommended in individuals with CRC and that if loss of *MLH1* is observed in the tumour, analysis of *BRAF V600E* mutation or analysis of the methylation of the *MLH1* promoter should be carried out first to rule out a sporadic case. They also maintained that full germline genetic testing should include DNA sequencing and large rearrangement analysis, as in the previous guidelines, but also proposed that for those with Lynch syndrome,

- "Somatic MMR gene testing for patients with unexplained abnormal tumour screening is suggested [III, B]
- Clinical risk can be assessed using Amsterdam criteria II or the revised Bethesda guidelines
- MMR IHC and/or MSI screening, with MLH1 promotor hypermethylation analysis in cases of MLH1 expression loss, is recommended for [individuals] with endometrial cancer [III, B]
- Follow-up recommendations in mutation carriers include colonoscopy every 1–2 years [III, A], and gynaecological examination (with TV US, CA 125 and endometrial biopsy) on a yearly basis from age 30 to 35 years [IV, C]. In all cases,

age of onset in the youngest member of the family is to be considered and surveillance be started 5 years earlier [V, B]. High-quality colonoscopy carried out in dedicated centres is advised [IV, C]. UGI endoscopy surveillance (every 1–3 years, from age 30–35 years) may be considered in patients at high risk. Prophylactic gynaecological surgery might be an option for. . .carriers who have completed childbearing or are postmenopausal [IV, C]" (Stjepanovic et al., 2019).

In 2023, ESMO published guidelines for Metastatic colorectal cancer diagnosis, treatment, and follow-up. The guidelines stated that "deficient mismatch repair (dMMR)/microsatellite instability (MSI) testing in mCRC can assist clinicians with genetic counselling, including for identification of Lynch syndrome, and should be done to select patients for immune checkpoint inhibition (ICI) as part of the initial molecular work-up" (Cervantes, 2023).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On October 27, 2017, the FDA approved VENTANA MMR IHC Panel for patients diagnosed with colorectal cancer (CRC) to detect mismatch repair (MMR) proteins deficiency as an aid in the identification of probable Lynch syndrome and to detect BRAFV600E protein as an aid to differentiate between sporadic CRC and probable Lynch syndrome.

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81288	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; promoter methylation analysis
81292	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81293	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81294	MLH1 (mutL homolog 1, colon cancer, nonpolyposis type 2) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81295	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81296	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81297	MSH2 (mutS homolog 2, colon cancer, nonpolyposis type 1) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81298	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis
81299	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81300	MSH6 (mutS homolog 6 [E. coli]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81301	Microsatellite instability analysis (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) of markers for mismatch repair deficiency (eg, BAT25, BAT26), includes comparison of neoplastic and normal tissue, if performed
81317	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; full sequence analysis

CPT	Code Description
81318	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; known familial variants
81319	PMS2 (postmeiotic segregation increased 2 [S. cerevisiae]) (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) gene analysis; duplication/deletion variants
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81435	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis); genomic sequence analysis panel, must include sequencing of at least 10 genes, including APC, BMPR1A, CDH1, MLH1, MSH2, MSH6, MUTYH, PTEN, SMAD4, and STK11
81436	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis); duplication/deletion analysis panel, must include analysis of at least 5 genes, including MLH1, MSH2, EPCAM, SMAD4, and STK11
81479	Unlisted molecular pathology procedure
0101U	Hereditary colon cancer disorders (eg, Lynch syndrome, PTEN hamartoma syndrome, Cowden syndrome, familial adenomatosis polyposis), genomic sequence analysis panel utilizing a combination of NGS, Sanger, MLPA, and array CGH, with MRNA analytics to resolve variants of unknown significance when indicated (15 genes [sequencing and deletion/duplication], EPCAM and GREM1 [deletion/duplication only]) Proprietary test: ColoNext® Lab/Manufacturer: Ambry Genetics®
0238U	Oncology (Lynch syndrome), genomic DNA sequence analysis of MLH1, MSH2, MSH6, PMS2, and EPCAM, including small sequence changes in exonic and intronic regions, deletions, duplications, mobile element insertions, and variants in non-uniquely mappable regions Proprietary test: Genomic Unity® Lynch Syndrome Analysis Lab/Manufacturer: Variantyx Inc

CPT	Code Description
0474U	Hereditary pan-cancer (eg, hereditary sarcomas, hereditary endocrine tumors, hereditary neuroendocrine tumors, hereditary cutaneous melanoma), genomic sequence analysis panel of 88 genes with 20 duplications/deletions using nextgeneration sequencing (NGS), Sanger sequencing, blood or saliva, reported as positive or negative for germline variants, each gene Proprietary test: GeneticsNow® Comprehensive Germline Panel Lab/Manufacturer: GoPath Diagnostics, Inc
0475U	Hereditary prostate cancerrelated disorders, genomic sequence analysis panel using next-generation sequencing (NGS), Sanger sequencing, multiplex ligation-dependent probe amplification (MLPA), and array comparative genomic hybridization (CGH), evaluation of 23 genes and duplications/deletions when indicated, pathologic mutations reported with a genetic risk score for prostate cancer Proprietary test: ProstateNowTM Prostate Germline Panel Lab/Manufacturer: GoPath Diagnostics, Inc

Microsatellite Instability and Tumor Mutational Burden Testing

Policy Number: AHS – M2178 – Microsatellite Instability and Tumor Mutational Burden Testing	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Tumor mutational burden (TMB) is the genetic characteristic of non-inherited mutations within tumor tissue, often reported as the total number of DNA mutations per one million bases (megabase). Original studies calculated TMB based on whole-exome sequencing and reported TMB as the number of mutations that exist within the exome. However, TMB testing has expanded to targeted gene sequencing panels that do not cover the entire exome. TMB may serve as a biomarker to identify patients likely to have a favorable response to immunotherapy, as high TMB levels correlate with objective response rates to immunotherapy in several different cancer types (Ritterhouse, 2019; C. Willis et al., 2019).

Microsatellites are short, repetitive segments of DNA that are highly prone to mutation. Microsatellite instability (MSI) in tumor DNA is defined as the presence of alternate sized repetitive DNA sequences that are not present in the corresponding germline DNA (Nojadeh et al., 2018). Tumors with high microsatellite instability (MSI-H) are more immunogenic and may therefore respond to drugs that activate the immune system.

II. Related Policies

Policy Number	Policy Title
AHS-G2054	Liquid Biopsy
AHS-M2004	Lynch Syndrome
AHS-M2026	Testing for Colorectal Cancer Management
AHS-M2030	Testing for Targeted Therapy of Non-Small-Cell Lung Cancer
AHS-M2065	Molecular Profiling for Cancers of Unknown Primary Origin
AHS-M2146	General Genetic Testing, Somatic Disorders
AHS-M2168	Proteogenomic Testing of Individuals with Cancer

AHS-M2171	Esophageal Pathology Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals being considered for immune checkpoint inhibitor (ICI) targeted therapy, tissue-based tumor mutational burden (TMB) **and/or** microsatellite instability (MSI) testing (Note 1) for the solid tumors outlined in Note 2 **MEETS COVERAGE CRITERIA**.

2) When tissue-based testing is infeasible (i.e., quantity not sufficient for tissue-based test or invasive biopsy is medically contraindicated) for an individual being considered for ICI targeted therapy, liquid biopsy based TMB **and/or** MSI testing for the solid tumors outlined in Note 2 **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) TMB **and/or** MSI testing for all other tumors and in any other situations not listed above **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: NGS panels designed to provide a TMB score are allowed with no restrictions on the number of genes being tested, so long as the panel is designed for TMB assessment.

Note 2: Table of all solid tumors that will be allowed for TMB or MSI testing.

Condition	TMB/MSI Targeted Therapy Indications
Ampullary adenocarcinoma	MSI/MMR and TMB testing are recommended for individuals with locally advanced/metastatic adenocarcinoma who are candidates for anti-cancer therapy.
Biliary tract cancers (gallbladder, intrahepatic cholangiocarcinoma [CCA], extrahepatic CCA)	MSI/MMR and TMB testing are recommended for unresectable or metastatic biliary tract cancers (gallbladder, intrahepatic cholangiocarcinoma [CCA], extrahepatic CCA).

Condition	TMB/MSI Targeted Therapy Indications
Bone cancers (metastatic chondrosarcoma, chordoma, Ewing sarcoma, and osteosarcoma, NOT Giant Cell Tumor of Bone)	Recommended to consider TMB or MSI testing to inform treatment.
Breast cancer	TMB and MSI/dMMR are recommended to guide treatment options for individuals with recurrent unresectable (local or regional) or stage IV (M1) disease.
Cervical cancers (squamous cell carcinoma, adenocarcinoma, or adenosquamous carcinoma)	MSI testing is recommended for recurrent, progressive, or metastatic squamous cell carcinoma, adenocarcinoma, or adenosquamous carcinoma. Comprehensive molecular profiling should be considered for squamous cell carcinoma, adenocarcinoma, or adenosquamous carcinoma.
Colon cancer	MSI/MMR testing advised in all newly diagnosed patients, as a workup in pedunculated or sessile colon polylps (adenoma), in colon cancer appropriate for resection (non-metastatic), in documented metachronous metastases by CT, MRI, and/or biopsy, and in suspected or proven metastatic synchronous adenocarcinoma (any T, any N, M1) if not already done. Stage II MSI-H patients may have a good prognosis and do not benefit from 5-FU adjuvant therapy. Adjuvant therapy should not be given to patients with low-risk stage II MSI-H tumors. MMR/MSI testing should be done during initial workup to help with the diagnosis of Lynch syndrome and inform treatment decision-making if adjuvant therapy is later indicated.
Esophageal and Esophagogastric junction (EGJ) cancers	MSI/MMR is recommended as a universal test in all individuals who have been newly diagnosed with esophageal and EGJ cancers. TMB is considered one of the targeted biomarkers for individuals with esophageal or EGJ cancer.
Gastric cancers	TMB and MSI/dMMR testing are recommended for the clinical management of advanced gastric cancer.
Head and Neck Cancers (nasopharyngeal, non-nasopharyngeal, salivary gland tumors)	TMB is recommended to guide treatment options for individuals with recurrent, unresectable, oligometastatic, or metastatic nasopharyngeal cancer. TMB and MSI/dMMR are recommended to guide treatment options for individuals with non-nasopharyngeal cancers (oral cavity [including mucosal lip], oropharynx, hypopharynx, glottic larynx, supraglottic larynx, ethmoid sinus, maxillary sinus, and occult primary). TMB is recommended as part of follow-up assessment for salivary gland tumors for recurrence with distance metastases. TMB and MSI/dMMR are recommended to guide therapy options in recurrent, unresectable, or metastatic salivary gland tumors.
Neuroendocrine/Adrenal cancers (Grade 3 neuroendocrine tumors, adrenocortical carcinoma, and for poorly differentiated neuroendocrine carcinoma/large or small cell)	TMB and MSI testing should be considered for adrenocortical carcinoma and poorly differentiated neuroendocrine carcinoma/large or small cell and TMB testing should be considered for well-differentiated Grade 3 neuroendocrine tumors. TMB and MSI testing are an appropriate evaluation when the tumor type is poorly differentiated neuroendocrine carcinoma, large or small cell carcinoma (other than the lung), or unknown primary (poorly differentiated).
Non-small cell lung cancer	Biomarker panel testing for actionable driver mutations (with or without TMB/MSI) is allowed.

Condition	TMB/MSI Targeted Therapy Indications
Occult primary cancers (cancer of unknown primary [CUP])	Suspected metastatic malignancy should undergo TMB determination or MSI/MMR testing during the workup of the tumor. Of note, the population of patients with MSI-H/dMMR occult primary tumors is low.
Ovarian cancers (epithelial ovarian, endometrioid carcinoma, low-grade serous carcinoma, fallopian tube, primary peritoneal cancers)	TMB and MSI/dMMR is recommended as part of validated molecular testing in Stage I, II, III, and IV epithelial ovarian cancer, fallopian tube cancer, and primary peritoneal cancer when disease is recurrent and CA-125 is rising or there is clinical relapse. TMB and MSI/dMMR are recommended for ovarian cancer, fallopian tube cancer, and primary peritoneal cancer as part of tumor molecular analysis in the recurrence setting. MSI/dMMR testing is recommended for all patients with endometrioid carcinoma. TMB and MSI/dMMR are recommended as part of tumor molecular analysis for monitoring and follow up for recurrence in low-grade serous carcinoma.
Pancreatic cancer (adenocarcinoma)	TMB and MSI/dMMR testing is recommended in locally advanced disease when adenocarcinoma is confirmed, in metastatic disease, and in tumors with recurrence after resection.
Pediatric central nervous system cancers (high-grade gliomas EXCEPT oligodendroglioma)	TMB is recommended to guide targeted therapy of recurrent and progressive disease for diffuse high-grade gliomas EXCEPT oligodendroglioma, *IDH*-mutant and 1p/19q codeleted or astrocytoma *IDH*-mutant.
Penile cancer	TMB and MSI/dMMR are recommended to guide treatment options for individuals with metastatic or recurrent disease.
Prostate cancers (castration-resistant prostate cancer [CRPC], adenocarcinoma)	TMB and MSI/dMMR testing should be considered when CRPC imaging studies are positive for metastases. Tumor testing recommended in MSI-H or dMMR among patients with metastatic CRPC and may be considered in patients with regional or castration-naïve metastatic prostate cancer. TMB may be considered in patients with metastatic CRPC.
Rectal cancers	Universal MSI/MMR testing is recommended in all newly diagnosed patients with rectal cancer. In addition, MSI/MMR testing is recommended as an initial workup in pedunculated polyps or sessile polyps (adenoma) with invasive cancer, rectal cancer appropriate for resection, and in suspected or proven metastatic synchronous adenocarcinoma (any T, any N, M1) if not previously done.
Small bowel cancer (adenocarcinoma)	TMB testing should be considered as part of the workup for metastatic and/or recurrent adenocarcinoma. Universal MMR or MSI testing is recommended in all newly diagnosed patients with small bowel adenocarcinoma. When not part of the initial workup, MSI testing is recommended as a workup when the tumor is in the duodenum or the jejunum/ileum and should be part of the workup for metastatic and/or recurrent adenocarcinoma.
Soft tissue sarcoma	TMB and MSI/dMMR are recommended to guide treatment options for individuals with unresectable or metastatic soft tissue sarcoma.
Testicular cancers (nonseminoma, pure seminoma)	TMB and MSI testing are recommended as a third-line therapy in nonseminoma and pure seminoma if there is progression after high-dose chemotherapy or other third-line therapies.
Thyroid cancer (anaplastic thyroid carcinoma)	TMB and MSI/dMMR are recommended as part of initial diagnostic molecular testing for anaplastic thyroid carcinoma.

Condition	TMB/MSI Targeted Therapy Indications
Thyroid cancers (papillary carcinoma, follicular carcinoma, and oncocytic carcinoma)	TMB and MSI/dMMR testing are recommended for papillary carcinoma, follicular carcinoma, and oncocytic carcinoma for advanced, progressive, or threatening disease when tumor is locally recurrent, advanced, and/or metastatic disease that is not amenable to RAI therapy.
Thyroid cancer (medullary carcinoma)	TMB testing is recommended for medullary carcinoma for recurrent or persistent locoregional disease or for symptomatic disease or progression of disease for recurrent or persistent disease with distance metastases.
Uterine cancers (endometrial carcinoma, uterine sarcoma)	MSI testing is recommended if MMR results are equivocal in endometrial carcinoma. TMB testing should be considered for endometrial carcinoma. For sarcoma, comprehensive genomic profiling (at minimum TMB/MSI, and *NTRK*) in a setting of metastatic disease is informative for predicting rare pan-tumor targeted therapy opportunities.
Vulvar cancer (squamous cell carcinoma)	MSI and TMB testing may be considered for treatment planning purposes in patients with recurrent, progressive, or metastatic disease.

MSI-H (MSI-high; MSI-positive); NCCN defines TMB-H as a TMB value of ≥10 mutations/megabase

IV. Table of Terminology

Term	Definition
5-FU	5-fluorouracil
ALK	*Anaplastic lymphoma kinase*
ANTI-PD1	Anti-programmed cell death 1
BRAF	*B-Raf proto-oncogene, serine/threonine kinase*
BRCA1	*Breast cancer 1*
BRCA2	*Breast cancer 2*
bTMB	Blood tumor mutational burden
CA-125	Cancer antigen 125
CAPEOX	Capecitabine and oxaliplatin
CCA	Cholangiocarcinoma
cfDNA	Circulating cell-free deoxyribonucleic acid
CGP	Comprehensive genomic profiling
CMS	Centers for Medicare and Medicaid Services
CNA	Copy number alteration
CNS	Central nervous system
CNV	Copy number variation
CPS	Combined positive score
CRM	Circumferential resection margin
CRPC	Castration-resistant prostate cancer
CT	Computerized tomography

ctDNA	Circulating tumor deoxyribonucleic acid
CTLA-4	Cytotoxic t-lymphocyte-associated protein 4
CUP	Cancer of unknown primary
DCB	Durable clinical benefit
dMMR	Deoxyribonucleic acid mismatch repair
DNA	Deoxyribonucleic acid
DRUP	Drug rediscovery protocol
EGFR	*Epidermal growth factor receptor*
EGJ	Esophagogastric junction
ESMO	European Society for Medical Oncology
F1CDx	FoundationOne CDx™
FBXW7	*F-box and WD40 repeat domain containing-7*
FDA	Food and Drug Administration
FFPE	Formalin-fixed, paraffin-embedded
FOLFOX	Leucovorin calcium, fluorouracil, oxaliplatin
GEA	Gastroesophageal adenocarcinoma
HLA	Human leukocyte antigen
ICI	Immune checkpoint inhibitor
IHC	Immunohistochemistry
INDELS	Insertion and deletions
iRECIST	RECIST 1.1 for immune-based therapeutics
LCD	Local coverage determination
LDT	Laboratory-developed test
LOH	Loss of heterozygosity
mCRC	Metastatic colorectal cancer
MLH1	MutL homolog 1
MMR	Mismatch repair
MRI	Magnetic resonance imaging
MSH2	MutS homolog 2
MSH6	MutS homolog 6
MSI	Microsatellite instability
MSI-H	High microsatellite instability
MSI-L	Low microsatellite instability
MSK	Memorial Sloan Kettering Cancer Center
MSS	Microsatellite stable
NCCN	National Comprehensive Cancer Network
NCD	National coverage determination
NCI	National Cancer Institute
NDB	No durable benefit

NET	Neuroendocrine tumor
NGS	Next-generation sequencing
NSCLC	Non-small cell lung carcinoma
NTRK	Neurotrophic tyrosine receptor kinase
ORR	Objective response rate
OS	Overall survival
PCR	Polymerase chain reaction
PD-1	Programmed cell death protein
PD-L1	Programmed cell death protein 1
PFS	Progression-free survival
PMS2	Mismatch repair endonuclease PMS2
POLD1	Deoxyribonucleic acid polymerase delta catalytic subunit
POLE1	Deoxyribonucleic acid polymerase epsilon catalytic subunit isoform b
PS	Performance status
R^2	Correlation
RAI	Radioactive iodine
RAS	*Retrovirus-associated deoxyribonucleic acid sequences*
RECIST	Response evaluation criteria in solid tumors
RNA	Ribonucleic acid
ROS1	*Receptor tyrosine kinase*
SBA	Small bowel adenocarcinoma
SCL	Small-cell lung cancer
SMAD4	*SMAD family member 4*
SNV	Single nucleotide variant
TF	Tumor fraction
TMB	Tumor mutational burden
TMB-H	Tumor mutational burden – high
TML	Tumor mutational load
TRAE	Treatment-related adverse events
TSO500	TruSight Oncology 500
tTMB	Tissue tumor mutation burden
TTP	Time to progression
WES	Whole exome sequencing
WTS	Whole transcriptome sequencing

V. Scientific Background

Tumor mutational burden (TMB) is an emerging biomarker associated with predicting the response to immune checkpoint inhibitors (ICIs). ICIs are therapies that have made

significant progress in helping to treat certain advanced cancers. ICIs work by releasing the brakes on the immune system's antitumor response. ICI therapy has proven most effective on tumor types with a high TMB, whereby a high TMB value indicates better treatment outcomes (Yarchoan et al., 2017).

Clinical biomarkers are widely used for making personalized and actionable decisions for cancer treatment. Many mutations result in production of numerous altered peptides—the more mutations present, the larger the number of altered peptides is produced. A subset of these peptides is expressed and processed by the major histocompatibility complex, resulting in neoantigens. These neoantigens can be recognized by the immune system to generate an antitumor response. The recognition of these neoantigens is thought to be largely stochastic and a higher number of DNA mutations means a higher number of candidate peptides being produced, resulting in a greater likelihood of these neoantigens being recognized by the immune system (Ritterhouse, 2019; Yarchoan et al., 2019).

This phenomenon is observed in patients with melanoma, non-small-cell lung carcinoma (NSCLC), small cell lung cancer, bladder cancer, colorectal cancer, microsatellite instability cancers, and pan-tumors who are on inhibitors of programmed cell death protein (PD-1) and the ligand for programmed cell death protein 1 (PD-L1). High TMB has also been associated with improved outcomes in patients on a combination of PD-1/PD-L1 and cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) inhibitors (Hellmann, Callahan, et al., 2018; Hellmann, Nathanson, et al., 2018; Le et al., 2015; Merino et al., 2020; Rizvi et al., 2015; Snyder et al., 2014; Van Allen et al., 2015).

Originally, TMB was measured with whole-exome sequencing (WES). In theory, WES is the best measure of TMB, as it covers every coding sequence within the tumor, ensuring that every mutation contributes to the TMB score. Recently, studies have shown that TMB measured using targeted panels which analyze mutations across specific genes (rather than the whole exome) correlates well with TMB measured by WES (Chalmers et al., 2017; Quy et al., 2019; Wu et al., 2019). WES method has limited clinical utility as it is considered costly, has a high turnaround time (a roughly six to eight week sequencing period), and is difficult for many clinical laboratories to use for routine patient care (Ritterhouse, 2019). Hence, targeted next-generation sequencing (NGS)-based panels that focus analysis on a subset of genes implicated in cancer biology offer several advantages for TMB estimation (Garofalo et al., 2016).

There are FDA-approved products for calculating TMB, including the FoundationOne CDx™ (F1CDx) assay and the FoundationOne Liquid CDx assay (Foundation Medicine Inc.) (FDA, 2017c, 2020b), as well as an additional FDA 510(k) authorized assay, MSK-

IMPACT (Memorial Sloan Kettering Cancer Center) (FDA, 2017a, 2017b). These tests, referred to collectively as comprehensive genomic profiling (CGP), can identify all types of "molecular alterations (i.e., single nucleotide variants, small and large insertion-deletion alterations, copy number alterations, and structural variants) in cancer-related genes, as well as genomic signatures such as microsatellite instability (MSI), loss of heterozygosity [LOH], and TMB" (Klempner et al., 2020). Studies show that TMB calculated from CGP has high concordance with TMB measured from WES. On June 16, 2020, the FDA approved pembrolizumab for the treatment of adult and pediatric patients with a TMB value of greater than 10 mutations per megabase as determined by the FoundationOne CDx™ assay (FDA, 2020a).

Microsatellites are short, repetitive segments of DNA that are highly prone to mutation. The presence of alternate sized repetitive DNA sequences that are not present in the corresponding germline DNA is defined as microsatellite instability (MSI) (Nojadeh et al., 2018). When a tumor has a high degree of microsatellite instability (MSI-H), it is more immunogenic and thus may respond to drugs that activate the immune system, such as ICIs (Zhao et al., 2019).

The National Cancer Institute (NCI) recommends two mononucleotide repeats (BAT-25 and BAT-26) and three dinucleotide repeats (D5S346, D2S123, and D17S250) as the standard sites/markers in panels for MSI testing (Boland et al., 1998). Per the NCI guidelines, when a tumor shows instability in two or more of the five markers, it is defined as MSI-H. However, this definition may vary by source and markers used (NCI, n.d.). When only a single marker shows instability, tumors may be classified as low-frequency MSI (MSI-L) and tumors lacking any instability are often classified as microsatellite stable (MSS) (Boland et al., 1998).

Microsatellite instability has been identified in many cancer types, with the highest prevalence in uterine corpus endometrial carcinoma, colon adenocarcinoma, stomach adenocarcinoma, and rectal adenocarcinoma. In studies by Bonneville et al. (2017) and Zhao et al. (2019), MSI was undetectable (or at the borderline of detection) in 12 out of 39 cancer types (Bonneville et al., 2017; Zhao et al., 2019).

Proprietary Testing

Caris MI Tumor Seek

Caris Life Sciences has developed MI Tumor Seek™, an NGS-based tumor profiling service that combines WES analysis of DNA for mutations, copy number alterations, insertions/deletions, and genomic signatures (MSI, TMB, and LOH) with Whole Transcriptome Sequencing (WTS) analysis for RNA fusions and variant transcripts. WES covers about 23,000 genes with 200-500x depth of coverage, while WTS covers about

23,000 genes with 60 million reads/sample. DNA and RNA are isolated from formalin-fixed paraffin-embedded (FFPE) tumor tissue "with a minimum of 20% malignant origin for DNA and 10% malignant origin for RNA. Needle biopsy is also acceptable (4-6 cores)" (Caris Life Sciences, 2024).

FoundationOne CDx™

FoundationOne CDx™ is a single-site assay that is "a next generation sequencing based in vitro diagnostic device for detection of substitutions, insertion and deletion alterations (indels) and copy number alterations (CNAs) in 324 genes and select gene rearrangements, as well as genomic signatures including microsatellite instability (MSI) and TMB using DNA isolated from formalin-fixed paraffin-embedded (FFPE) tumor tissue specimens." It is intended for use by health care professionals as a companion diagnostic to identify patients with solid malignant neoplasms who may benefit from treatment with targeted ICIs (FDA, 2017c).

FoundationOne Liquid CDx

The FoundationOne Liquid CDx assay uses circulating cell-free DNA (cfDNA) that is isolated from plasma from patients with solid malignant neoplasms. The assay uses a "single DNA extraction method to obtain cfDNA from plasma from whole blood. Extracted cfDNA undergoes whole-genome shotgun library construction and hybridization-based capture of 324 cancer-related genes. All coding exons of 309 genes are targeted; select intronic or non-coding regions are targeted in BRCA1 and BRCA2 … Hybrid-capture selected libraries are sequenced with deep coverage using the NovaSeq® 6000 platform. Sequence data are processed using a custom analysis pipeline designed to detect genomic alterations, including base substitutions and indels in 311 genes, and copy number variants and genomic rearrangements in BRCA1 and BRCA2. A subset of targeted regions in 75 genes is baited for increased sensitivity" (FDA, 2020b).

Guardant360® TissueNext

Guardant Health offers Guardant360® CDx, a liquid biopsy that provides comprehensive genomic results from a simple blood draw. This test "uses targeted high throughput hybridization-based capture technology for detection of single nucleotide variants (SNVs), insertions and deletions (indels) in 55 genes, copy number amplifications (CNAs) in two (2) genes, and fusions in four (4) genes. Guardant360® CDx utilizes circulating cell-free DNA (cfDNA) from plasma of peripheral whole blood." It is an FDA-approved liquid biopsy that can be used for tumor mutation profiling across all solid cancers and as a companion diagnostic to identify NSCLC patients who may benefit from Tagrisso® (10ealth10inib), RYBREVANT™ (amivantamab-vmjw), or LUMAKRAS™ (sotorasib). To compliment Guardant360 CDx, Guardant Health also

offers Guardant360® TissueNext. Guardant360 TissueNext assesses TMB either from an FFPE tumor specimen or from a blood sample initially processed with Guardant360® CDx. If an actionable biomarker is found in a Guardant360® CDx sample, it is then processed with the Guardant360® TissueNext assay (FDA, 2021; Guardant, 2024a, 2024b).

MSK-IMPACT

The MSK-IMPACT assay is a single-site assay performed at Memorial Sloan Kettering Cancer Center (MSKCC) and is designed to compare two samples from a single patient—a normal specimen and a specimen from a solid malignant neoplasm—allowing the assay to detect tumor gene alterations in a broad multi gene panel (FDA, 2017a). MSK-IMPACT analyzes 505 genes chosen for their critical role in the development and behavior of tumors. To "take full advantage of MSK-IMPACT, MSK doctors and researchers developed a knowledge base called OncoKB®. This system includes information about the clinical and biological effects of more than 4,000 genomic changes. That information is based on public databases, scientific literature, and clinical guidelines" (MSKCC, 2024). The assay is intended to provide information on both somatic mutations and microsatellite instability and is not conclusive or prescriptive for labeled use of any specific therapeutic product (FDA, 2017a).

QIAseq TMB

Qiagen offers QIAseq Tumor Mutational Burden Panels. These new panels collectively create a comprehensive profile of TMB and MSI status by "achieving high analytical sensitivity, with lower false and negative rates, while still maintaining >95% correlation with whole exome datasets." The QIAseq TMB Panel covers 486 genes and can be boosted to add 27 MSI markers, with sample preparation coming from FFPE of solid tumors, patient's plasma/serum, fresh or frozen tissue, or from cell lines in a research setting. This assay has been shown to correlate well with WES and established TMB panels. It uses enzymatic fragmentation for easy workflow, employs robust analysis modules, and incorporates unique molecular indices to correct for polymerase chain reaction (PCR) and sequencing errors (Qiagen, 2024).

TruSight Oncology 500

Illumina offers the TruSight Oncology 500 (formerly Illumina TSO500), a NGS assay that enables in house CGP of tumor samples, supports the identification of relevant DNA and RNA variants implicated in various solid tumor types, and accurately measure current immune-oncology biomarkers: MSI and TMB. This assay assesses both DNA (523 genes) and RNA (55 genes) for assessment of all variant types in addition to MSI and TMB. The TruSight Oncology 500 assay is intended for multiple solid tumor types and detects CNVs, gene fusions, insertions-deletions, single nucleotide variants, and

transcript variants. It provides stealth-oncology biomarker coverage, including biomarkers of TMB and MSI, and is inclusive of human leukocyte antigen (HLA) regions, DNA polymerase epsilon catalytic subunit isoform b (POLE1), and DNA polymerase delta catalytic subunit (POLD1) (Illumina, 2024).

Analytical Validity

Wu et al. (2019) noted that targeted NGS panels often use correlation (R^2) between panel- and WES- based TMB to validate TMB estimation, which can be distorted by cases where a tumor within a certain cancer type has a relatively ultra-high TMB. Thus, the authors proposed using accuracy (the proportion of cases correctly identified as TMB-high or TMB-low using panel based TMB) as a more robust indicator of panel performance, suggesting that accuracy and cancer type individualization are key factors to consider when designing panels for TMB estimation. The authors examined the TMB estimation from five available NGS panels for TMB determination (F1CDx, MSK-IMPACT, Illumina TSO500 [now TruSight Oncology 500], Oncomine TML, QIAseq TMB) to compare correlation to accuracy. F1CDx seemed to accurately assess TMB ($R^2 \geq 0.75$) in at least 24 out of 33 cancer types. However, when the cutoff point for high TMB was defined as the top 20% in each cancer type, the accuracy within these 24 cancer types ranged largely (56-99%), with only seven cancer types having satisfactory accuracy. These results indicate that F1CDx-based TMB estimation is only reliable in certain cancer types (cervical squamous cell carcinoma and endocervical adenocarcinoma, colon adenocarcinoma, head and neck squamous cell carcinoma, lung adenocarcinoma, skin cutaneous melanoma, stomach adenocarcinoma, and uterine corpus endometrial carcinoma). In the other 17 cancer types, correlation overestimated TMB status misclassifying a considerable number of TMB-low patients as TMB-high. This overestimation by correlation occurs because correlation is vulnerable to distortion by the common presence of cases with relatively ultra-high TMB within each cancer type. When removing cases with these relatively ultra-high TMB (top five percent within a particular cancer type), a dramatic decline in correlation between F1CDx- and WES-based TMB was observed in half of the 24 cancer types. In contrast, removing the top five percent of cases in each cancer type did not, in general, affect the accuracy within these 24 cancer types. Accuracy was also superior to correlation in the other four NGS panels examined. The authors conclude that the five available NGS panels can assess TMB accurately only in the seven cancer types aforementioned and note that for relatively ultra-high TMB, correlation is an unreliable evaluation of panel based TMB estimation performance in most cancer types. Instead, they find that accuracy is a superior index in this situation. They conclude that individualized panels by cancer type might be a better strategy to guarantee the most robust TMB estimation and provide better power in detecting the predictive function of TMB in these cancer types (Wu et al., 2019).

J. Willis et al. (2019) aimed to evaluate the validity of cell-free (cf) DNA to detect microsatellite instability (MSI). The authors validated the Guardant360 MSI detection with 1145 cf-DNA samples and further investigated the landscape of cf-DNA based MSI across 28459 plasma samples. Circulating tumor (ct, used as a proxy for cf-DNA) MSI assessment was compared to current standard of care tissue testing (a combination of immunohistochemistry, PCR, and NGS). The study included 949 patients that were considered unique and evaluable. The ctDNA method detected MSI-high values (82% accuracy) in 71 of 82 patients. A total of 863 of 867 patients reported as MSI-stable (99.5% accuracy) for a total of 98.4% accuracy amongst all MSI-reported groups. The positive predictive value was found to be 95%. Finally, the authors examined the clinical outcomes of 16 patients with MSI-H gastric cancer that were treated with immunotherapy. The authors found that 10 of 16 patients achieved "complete or partial remission with sustained clinical benefit" after being treated with immunotherapy (J. Willis et al., 2019).

Georgiadis et al. (2019) aimed to validate a noninvasive approach for detection of MSI and TMB. The authors used "a hybrid-capture–based 98-kb pan-cancer gene panel, including targeted microsatellite regions" as well as a "novel peak-finding algorithm…established to identify rare MSI frameshift alleles in cell-free DNA." The authors evaluated 163 healthy patients with this assay, identifying a specificity of 99.4% (one false positive, which was considered a lower bound by the authors). The authors also evaluated 23 MSI-H cases (from patients with metastatic cancers) and six MSI-stable cases with the algorithm. Using cf-DNA, the algorithm detected MSI in 18 of the 23 MSI-H samples (78.3%) and correctly identified all six of the MSI-stable cases. Further, this approach was also applied to TMB (using a cutoff of 51 mutations/Mbp), of which the algorithm correctly detected 10 of the 15 samples identified as TMB-high (67%) (Georgiadis et al., 2019).

Woodhouse et al. (2020) evaluated the analytical performance of FoundationOne Liquid CDx assay to detect genomic alterations in cancer patients. The assay was evaluated across more than 30 different cancer types in over 300 genes and greater than 30,000 gene variants. "Results demonstrated a 95% limit of detection of 0.40% variant allele fraction for select substitutions and insertions/deletions, 0.37% variant allele fraction for select rearrangements, 21.7% tumor fraction (Marabelle, Le, et al.) for copy number amplifications, and 30.4% TF for copy number losses. The false positive variant rate was 0.013% (approximately one in 8,000). Reproducibility of variant calling was 99.59%" (Woodhouse et al., 2020). In comparison to in situ hybridization and immunohistochemistry, FoundationOne had an overall 96.3% positive percent agreement and >99.9% negative percent agreement. "These study results demonstrate that FoundationOne Liquid CDx accurately and reproducibly detects the major types of genomic alterations in addition to complex biomarkers such as microsatellite

instability, blood tumor mutational burden, and tumor fraction" (Woodhouse et al., 2020).

Using data from the phase III MYSTIC trial, Si et al. (2021) validated the use of blood TMB (bTMB) using circulating cell-free tumor DNA (ctDNA) through comparisons with TMB measurements from tumor tissue (tTMB). Patients with metastatic NSCLC were treated either with first-line durvalumab (anti–PD-L1 antibody) ± tremelimumab (anticytotoxic T-lymphocyte-associated antigen-4 antibody) or chemotherapy, then bTMB and tTMB were evaluated using the GuardantOMNI and the FoundationOne CDx assay, respectively. To identify the optimal bTMB cutoff, the authors used a Cox proportional hazards model and minimal p value cross-validation. In the majority of patients in the MYSTIC study, somatic mutations were detected in ctDNA extracted from plasma samples, which allowed for the subsequent calculation of bTMB. The authors found that the success rate for obtaining valid TMB scores was higher for bTMB (81%) than for tTMB (63%) and that with minimal p value cross-validation analysis, they suggest a bTMB ≥20 mutations per megabase (mut/Mb) as the optimal cutoff for clinical benefit with durvalumab + tremelimumab. Overall, their study demonstrated that use of bTMB from plasma samples was feasible and provided accurate and reproducible TMB detection using the GuardantOMNI ctDNA platform. They also state that using "the new bTMB algorithm and an optimal bTMB cutoff of ≥20 mut/Mb, high bTMB was predictive of clinical benefit with durvalumab + tremelimumab versus chemotherapy" (Si et al., 2021).

Clinical Utility and Validity

Overman et al. (2017) examined MSI-H/dMMR colorectal cancer individual response to nivolumab, a PD-1 ICI. In this phase two trial, the authors assessed adult individuals with histologically confirmed recurrent or mCRC locally assessed as dMMR/MSI-H who had progressed either while still on or after, or who had been intolerant of, at least one prior line of treatment, including fluoropyrimidine and oxaliplatin or irinotecan. The primary endpoint of this study was investigator-assessed ORR. This study ran from March 12, 2014 to March 16, 2016 and included 74 individuals, most of whom (54.1%), had received more than three prior therapies. Twelve months following initiation of nivolumab treatment, 31.1% (23) of the individuals had an investigator-assessed ORR, which 68.9% of the individuals had disease control for more than 12 weeks. The median duration of response was not reached, as all responders were alive and eight of them had responses greater than 12 months. Twenty-three of the individuals died during the study, though none of the deaths were considered treatment-related. The authors concluded that nivolumab provided durable responses and disease control in dMMR/MSI-H patients that had previously received other forms of treatment for their

colorectal cancer and they also note that nivolumab is a relevant treatment option for these patients (Overman et al., 2017).

Hellmann, Ciuleanu, et al. (2018) conducted an open-label, multipart, phase three trial to examine progression-free survival in non-small-cell lung cancer patients with a high TMB (TMB-H) that were being treated with nivolumab plus ipilimumab or with chemotherapy. TMB was determined by the FoundationOne CDx™ assay. Here, they found that progression-free survival in TMB-H patients was significantly longer with nivolumab plus ipilimumab (42.6%) compared with chemotherapy (13.2%). This discovery was found to be accurate irrespective of PD-L1 expression level and validated that a treatment of nivolumab and ipilimumab for NSCLC elicited a favorable outcome for select patients, as well as determining that tumor mutational burden was an important biomarker for patient selection when it comes to drug therapy (Hellmann, Ciuleanu, et al., 2018).

To examine the association between TMB and clinical response to ICIs in select cancer types, Samstein et al. (2019) analyzed the clinical and genomic data of 1,662 advanced cancer patients treated with ICI compared to 5,371 patients not treated with ICI. Tumors from these patients underwent targeted NGS with MSK-IMPACT. The authors found that among all patients, higher somatic TMB (highest 20% in each cancer type, consistent with many MSI-high colorectal tumors receiving ICI treatment) was associated with better overall survival. However, the TMB cutoffs associated with improved survival varied markedly between the different cancer types studied, suggesting that while TMB is associated with improved survival in patients receiving ICI across a variety of cancer types, there may not be a single, universal definition of high TMB (Samstein et al., 2019).

Ready et al. (2019) conducted an open-label phase II trial to evaluate the efficacy and safety of nivolumab plus low-dose ipilimumab as first-line treatment of advanced/metastatic NSCLC and assessed the treatment efficacy associated with PD-L1 expression and TMB. For this trial, "the primary end point was objective response rate (ORR) in patients with 1% or more and less than 1% tumor PD-L1 expression. Efficacy on the basis of TMB (FoundationOne CDx™ assay) was a secondary end point." They found that regardless of PD-L1 expression, ORRs were higher in TMB-H patients versus patients with tumors below the threshold for TMB-H status and progression-free survival was longer in patients with TMB-H. They concluded that "nivolumab plus low-dose ipilimumab was effective and tolerable as a first-line treatment of advanced/metastatic NSCLC" and a high TMB status was associated with both improved response and prolonged progression-free survival irrespective of PD-L1 status. This identifies TMB-H as a potentially relevant cutoff in the assessment of TMB as a biomarker for first-line nivolumab plus ipilimumab (Ready et al., 2019).

A comprehensive study by Singal et al. (2019) examined the electronic health records of 4064 individuals with NSCLC from 275 different oncology practices to explore the associations between tumor genomics and patient characteristics with clinical outcome. The authors note that 21.4% of these individuals had a mutation in *EGFR, ALK, or ROS1* and that patients with driver mutations who received targeted therapies had significantly improved overall survival times than individuals who did not receive targeted therapies (median of 18.6 versus 11.4 months, respectively). Moreover, a TMB of 20 or higher was associated with improved overall survival for patients on PD-L1-targeted therapy compared to patients with a TMB less than 20. TMBs measure the quality of a mutation in a tumor, suggesting whether a patient will benefit from immunology-based cancer therapies or not. The authors concluded that similar associations from previous research were replicated "between clinical and genomic characteristics, between driver mutations and response to targeted therapy, and between TMB and response to immunotherapy" (Singal et al., 2019).

Yarchoan et al. (2019) examined the relationship between the expression of PD-L1, a widely used biomarker for selecting patients for ICI, and TMB across the entire spectrum of ICI-responsive human cancers. They sought to use these predictive biomarkers to provide a broad definition to the immunologic subtypes of cancers and identify opportunities for the development of therapeutics. Their clinical cohort contained 9,887 unique clinical samples with paired CGP and PD-L1 expression obtained during standard clinical care. They found that 15.2% of samples had a positive expression of PD-L1 and that the highest occurrence of PD-L1 positivity occurred in thymic cancer and diffuse large B cell lymphoma, while there were no adenoid cystic or appendiceal samples with positive PD-L1. A total 3.6% of sample specimens were identified as having a high PD-L1 positivity (defined as greater than 50% of tumor cells staining positive). In addition, the median tumor mutational burden for all specimens was 3.48 mutations per megabase. One group of sampled tumors (16.4% of the cancers) had a TMB of greater than 10 mutations per megabase and 7.3% of tumors analyzed had a TMB of more than 20 mutations per megabase, indicating that the overall TMB profiles were comparable to prior cancer studies of a similar nature (including whole-exome studies) that estimated TMB biomarkers in solid tumors. This study found a relative independence of PD-L1 expression and TMB, and that the biomarkers were important indicators of patient response to ICI therapy. The study also defined which biomarkers may help identify future therapies through their ability to segment and profile different tumor types. In conclusion, they found that PD-L1 and TMB status may help determine whether the use of ICI therapy is indicated as well as pinpoint tumor types that would demonstrate a beneficial response to immune checkpoint inhibitor therapy (Yarchoan et al., 2019).

Alborelli et al. (2020) investigated the predictive power of TMB for patients treated with ICIs. Seventy-six NSCLC patients treated with ICIs were included and TMB was evaluated with the Oncomine™ Tumor Mutational Load (TML) sequencing assay. Patients were separated into cohorts of "durable clinical benefit" (DCB) or "no durable benefit" (NDB). TMB was found to be higher in the DCB cohort (median TMB of 8.5 mutations / Mb compared to six mutations / Mb in NDB). Sixty-four percent of patients in the highest one third of TMB were responders, compared to 33% and 29% in the middle and lowest thirds, respectively. TMB-H patients were also found to have higher progression-free survival and overall survival. Overall, the authors concluded that the TML panel was an effective tool to stratify patients for ICI treatment and suggested that "a combination of biomarkers might maximize the predictive precision for patient stratification." Further, the authors remarked that their data "supports TMB evaluation through targeted NGS in NSCLC patient samples as a tool to predict response to ICI therapy" (Alborelli et al., 2020).

Marabelle, Fakih, et al. (2020) prospectively explored the association of a high tumor mutational burden with outcomes in ten tumor-type-specific cohorts from the phase two KEYNOTE-158 study. The study assessed use of the anti–PD-1 monoclonal antibody pembrolizumab in patients with select, previously treated, advanced solid tumors. Patients for this study were from 81 academic facilities across 21 countries in Africa, the Americas, Asia, and Europe, were over 18 years of age, and had an established tumor of anal, biliary, cervical, endometrial, mesothelioma, neuroendocrine, salivary, small-cell lung, thyroid, or vulvar origin. In addition, patients showed continued tumor progression or an inability to tolerate standard therapy and continued measurable disease (based on the Response Evaluation Criteria in Solid Tumors). The treatment course for this study was pembrolizumab 200 mg intravenously every three weeks for up to thirty-five cycles, with tissue TMB assessed in formalin-fixed, paraffin-embedded tumor samples using the FoundationOne CDx assay. The authors report that 13% of the participants showed a high number of tumor mutations (≥ 10 mutations per megabase) while 87% of the participants had a TMB status lower than this threshold. From this study, they found that a high TMB status characterized a small group of patients who might have a beneficial response to pembrolizumab therapy; those with previously treated recurrent or advanced solid tumors. As such, tissue TMB may be both a "novel and useful predictive biomarker" for therapy indications (Marabelle, Fakih, et al., 2020).

Data from the KEYNOTE-158 study was also analyzed by to examine the efficacy of pembrolizumab as an ICI treatment for MSI-H.dMMR cancer. The authors examined the efficacy of pembrolizumab in patients with previously treated, advanced noncolorectal MSI-H/DMMR cancer from the phase II KEYNOTE-158 study. In the 233 enrolled patients, 27 tumor types were represented (endometrial, gastric,

cholangiocarcinoma, and pancreatic cancers were the most common). ORR was 34.3%, median PFS was 4.1 months, and median OS was 23.5 months. Adverse, treatment-related events occurred in 64.8% of patients (151) and 14.6% (34) patients had grade three to five treatment-related fatal adverse events. They report that pembrolizumab is clinically beneficial in patients with previously treated, unresectable or metastatic MSI-H/dMMR noncolorectal cancer and that toxicity of pembrolizumab monotherapy in these patients was consistent with previous data (Marabelle, Le, et al., 2020).

A study by Stahler et al. (2020) explored the ORR, PFS, and OS in the FIRE-3 clinical trial on metastatic colorectal cancer patients who were identified by the FoundationOne CDx panel to have SNVs, copy number alterations, TMB-H, or MSI-H tumors. Of the 752 patients in the FIRE-3 trial, 373 provided material for this specific analysis. They found that MSI-H (30%) and TMB-H (17.3%) tumors were enriched by *FBXW7* mutations a frequent SNV found in the analysis. The authors found that "*RAS, BRAF V600E* and *SMAD4* mutations were identified as poor prognostic biomarkers in patients of the FIRE-3 trial, whereas improved outcome was observed for *BRAF* non-V600E mutation. *SMAD4* mutation might provide predictive relevance for cetuximab efficacy. MSI-H tumours showed numerically lower ORR, OS and PFS" (Stahler et al., 2020).

While ICIs are highly effective in patients with MSI/dMMR metastatic colorectal cancer (mCRC), Cohen et al. (2020) predicted that the Response Evaluation Criteria in Solid Tumors (RECIST) 1.1 criteria was underestimating the response to ICIs due to the pseudoprogression phenomenon. Using data from the GERCOR NIPICOL phase II study, the authors aimed to evaluate the frequency of pseudoprogressions in patients with MSI/dMMR mCRC that were treated with nivolumab and ipilimumab. Nivolumab was given to MSI/dMMR mCRC patients previously treated with fluoropyrimidines, oxaliplatin, and irinotecan with/without targeted therapies. The primary endpoint of the study was disease control rate at 12 weeks according to RECIST 1.1 and iRECIST by central review. Fifty-seven patients were included in the study, with 48% having received ≥ three prior lines of chemotherapy, 18% with *BRAF* mutations, and 56% with Lynch syndrome-related cancer. Of these 57 patients, seven discontinued due to adverse events and one died due to a treatment-related adverse events (TRAE). The authors found that at 12 weeks, the disease control rate was 86% with RECIST 1.1 and 87.7% with iRECIST and two pseudoprogressions were observed (one at week 6, one at week 36). These two pseudoprogressions represented 18% of patients with disease progression per RECIST 1.1 criteria. The 12-month PFS rate was 72.9% with RECIST 1.1 and 76.5% with iRECIST and the 12-month OS rate was 84%. The ORR was 59.7% with both criteria. The authors concluded that pseudoprogression is rare in patients with MSI/dMMR mCRC who are treated with nivolumab and ipilimumab and that this combined ICI therapy confirms impressive disease control rate and survival outcomes in these MSI/dMMR patients (Cohen et al., 2020).

Andre et al. (2020) examined the efficacy of first-line pembrolizumab therapy as compared to first-line chemotherapy therapy for dMMR/MSI-H advanced or metastatic colorectal cancer. In this phase three, open-label clinical trial, 307 patients with metastatic MSI/dMMR colorectal cancer who had not received prior cancer treatment were randomly assigned to pembrolizumab or chemotherapy as a primary treatment and PFS and OS were assessed. Patients that received chemotherapy were able to cross over to pembrolizumab therapy if their disease progressed. The authors found that pembrolizumab treatment in MSI-H/dMMR colorectal cancer patients was superior to chemotherapy with respect to PFS. At the time of cutoff, 56 members of the pembrolizumab group and 69 chemotherapy group patients had died. At the time of the report, OS data were still evolving (they report that 66% of required events had occurred). An overall response (complete or partial) was observed in 43.8% of pembrolizumab patients as compared to only 33.1% of chemotherapy patients. Among those patients with an overall response, 83% of the pembrolizumab group, as compared to just 35% of the chemotherapy group, had an ongoing response at 24 months. TRAEs occurred in just 22% of pembrolizumab patients as compared to 66% of chemotherapy patients (including one death). The authors conclude that pembrolizumab is superior to chemotherapy as a first-line therapy in MSI-H/dMMR metastatic colorectal cancer, with fewer TRAE (Andre et al., 2020).

Wei et al. (2022) evaluated Illumina's TruSight Oncology 500 (TSO500) Assay for its ability to assess tumor mutational burden and the clinical utility of predicting response to pembrolizumab. Using samples collected from approximately 300 patients with "at least twelve different types of advanced solid tumors enrolled in eight clinical trials of pembrolizumab monotherapy," and using FoundationOneCDx and WES as reference methods for TMB, the researchers found that the TSO500 was able to properly classify the status of high tumor mutational burden, a reproducible finding with subsequent use of the assay. The researchers also found that "similar to the validated and FDA-approved TMB cut-point of 10 mut/Mb assessed by FoundationOneCDx, the TSO500 TMB cut-point of 10 mut/Mb is predictive of response to pembrolizumab monotherapy." Ensuring the comparability of this assay to current technologies in the necessary settings may increase access to immunotherapy for patients with solid tumors and TMB-H (Wei et al., 2022).

Aggarwal et al. (2023) completed a clinical validation study of a TMB biomarker in the aim of assessing the association between TMB and clinical outcomes. The study included 674 patients with solid tumors from eight different cancer types. Patients were collected from 300 cancer sites between 2018 and 2022. All patients were sequenced with Tempus xT and treated with ICIs. The authors studied the association between the TMB binary category, high or low, and overall survival. Overall, "high TMB (TMB-H) cancers (206 patients [30.6%]) were significantly associated with longer OS

than low TMB (TMB-L) cancers." Additionally, "an overall survival benefit was seen regardless of the type of ICI used." The authors concluded that "TMB-H cancers were significantly associated with improved clinical outcomes compared with TMB-L cancers" (Aggarwal et al., 2023).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN includes TMB and MSI testing in several of their guidelines for different types of cancers. Across these guidelines, TMB-high (TMB-H) is defined as tumors with a TMB value of ≥10 mutations/megabase.

The NCCN has clinical practice guidelines for NSCLC. In 2020 the NCCN deleted TMB as an emerging immune biomarker based on clinical trial data and other issues, though was previously considered potentially useful for selecting patients to be treated with nivolumab with or without ipilimumab. However, recent data showed that overall survival was improved with nivolumab/ipilimumab regardless of TMB status. They conclude that PD-L1 expression level is a more useful immune biomarker than TMB for deciding how to prescribe immunotherapy in NSCLC patients in some instances. For example, "Testing for PD-L1 expression levels is recommended before prescribing pembrolizumab monotherapy", but "is not required for prescribing subsequent therapy with atezolizumab or nivolumab", though it may still provide useful information. Moreover, the NCCN guidelines "do not recommend measurement of TMB levels before deciding whether to use nivolumab plus ipilmumab regimens or to use other ICIs, such as pembrolizumab" (NCCN, 2024l).

The NCCN clinical practice guidelines for cervical cancer advise that for stage IVB or distant metastases, "comprehensive molecular profiling as determined by an FDA-approved assay, or a validated test performed in a CLIA-certified laboratory" should be considered. They repeat this under their section for principles of pathology for squamous cell carcinoma, adenocarcinoma, and adenosquamous carcinoma, and add on that they recommend "PD-L1 testing for patients with recurrent, progressive, or metastatic disease". The NCCN also recommend "mismatch repair (MMR)/microsatellite instability (MSI) testing for patients with recurrent, progressive, or metastatic cervical carcinoma" and/or "*NTRK* gene fusion testing for patients with cervical sarcoma". For systemic cervical cancer therapy, the NCCN reports that pembrolizumab is a preferred regimen as a second-line or subsequent therapy for TMB-H, PD-L1–positive, or MSI-H/dMMR tumors that are recurrent or metastatic squamous cell carcinoma, adenocarcinoma, or adenosquamous carcinoma (NCCN, 2024g).

The NCCN clinical practice guidelines for breast cancer note that pembrolizumab is indicated for the treatment of patients with either unresectable or metastatic, MSI-high or mismatch repair-deficient (dMMR) solid tumors, or TMB-H breast tumors that have progressed following prior treatment and have no satisfactory alternative treatment options. TMB-H status is detected via NGS and MSI is detected via immunohistochemistry, NGS, or PCR. The NCCN finds using TMB and MSI to guide pembrolizumab treatment is associated with category 2A evidence (based upon lower-level evidence, there is uniform NCCN consensus that the intervention is appropriate). Dostarlimab-gxly is indicated for adult patients with MSI-H/dMMR unresectable or metastatic tumors and (category 2A) solid tumors or for TMB-H tumors that have progressed following prior treatment and with no satisfactory alternative treatment options. (NCCN, 2024f).

In their clinical practice guidelines for uterine neoplasms, the NCCN recommends that one should "Consider tumor mutational burden (TMB) testing through an FDA-approved assay, or a validated test performed in a CLIA-certified laboratory" as one of their principles of molecular analysis. The NCCN also notes the use of pembrolizumab for TMB-H or MSI-H/deficient DNA mismatch repair (dMMR) tumors as "useful in certain circumstances" as a biomarker-directed systemic therapy for uterine sarcoma and endometrial carcinoma. There, the NCCN also "recommends TMB-H testing if not previously done. Pembrolizumab is indicated for patients with unresectable or metastatic tumors with TMB-H [≥10 mutations/ megabase (mut/Mb)], as determined by an FDA-approved assay, or a validated test performed in a CLIA-certified laboratory, whose disease has progressed following prior treatment and who have no satisfactory alternative treatment options." In the molecular analysis of sarcoma, it is recommended that "Comprehensive genomic profiling in setting of metastatic disease as determined by an FDA-approved assay, or a validated test performed in a CLIA-certified laboratory, is informative for predicting rare pan-tumor targeted therapy opportunities and should include at least *NTRK*, MSI, and TMB"(NCCN, 2024t).

The NCCN guidelines for colon cancer state that "determination of tumor gene status for KRAS/NRAS and BRAF mutations, as well as HER2 amplifications and MSI/MMR status (if not previously done), are recommended for patients with mCRC." They note that "Testing may be carried out for individual genes or as part of an NGS panel, although no specific methodology is recommended." However, NGS panels do have an advantage in that they are "able to pick up rare and actionable genetic alterations, such as neurotrophic tyrosine receptor kinase (NTRK) and rearranged during transfection (RET) fusions and may be carried out using either a tissue or blood-based (eg, liquid) biopsy" (NCCN, 2024h). The NCCN advises that "As with other conditions in which stage IV disease is diagnosed, a tumor analysis (metastases or original primary) for KRAS/NRAS and BRAF mutations and HER2 amplifications, as well as MSI/MMR

testing if not previously done, should be performed to define whether targeted therapies can be considered among the potential options". In pedunculated or sessile colon polyps (adenoma) with invasive cancer, MSI/MMR testing can be part of the workup. Colon cancer appropriate for resection (non-metastatic) will "require a complete staging workup, including biopsy, pathologic tissue review, total colonoscopy, CBC, chemistry profile, CEA determination, and baseline CT scans of the chest, abdomen, and pelvis", while "Testing for MMR/MSI should be done at diagnosis to help with detection of Lynch syndrome and to inform treatment decision-making." When evaluating the recurrence of documented metachronous metastases by CT, MRI, and/or biopsy, dMMR and MSI-H can be considered endpoints for workups (NCCN, 2024h).

In the NCCN clinical practice guidelines for head and neck cancer note that in cancer that occurs in the oral-cavity, image-guided (ultrasound [US] or CT) needle biopsy of cystic neck nodes may offer better diagnostic yield than fine-needle aspiration (FNA) by palpation alone for initial diagnosis. For unresectable or metastatic disease where there is a plan for systemic therapy, a core biopsy would allow for ancillary immune-genomic testing." It is a requirement for cancer that occurs in the oropharynx be tested for tumor human papillomavirus (HPV) by p16 immunohistochemistry (IHC). Biopsy of primary site or FNA of the neck is recommended (NCCN, 2024w). For cancer that occurs in the Nasopharynx with nonkeratinizing or undifferentiated histology, it is recommended to test for EBV in tumor and blood. Common means for detecting EBV in pathologic specimens include ISH for EBV-encoded RNA or immunohistochemical staining for latent membrane protein (LMP). The EBV DNA load within the serum or plasma may be quantified using PCR targeting genomic sequences of the EBV DNA such as BamHI-W, Epstein-Barr virus nuclear antigen (EBNA), or LMP; these tests vary in their sensitivity. The EBV DNA load may reflect prognosis and change in response to therapy. Cancer that occurs in the salivary glands, "use NGS profiling and other appropriate biomarker testing to check status of androgen receptor (AR), HER2, NTRK, HRAS, PIK3CA, and tumor mutational burden (TMB) prior to treatment"(NCCN, 2024w).

In the NCCN clinical practice guidelines for esophageal and EGJ cancers, the panel outlines their principles of pathologic review and biomarker testing. There, they assert that "Immunohistochemistry/in situ hybridization/targeted PCR should be considered first for the identification of biomarkers, followed by NGS testing. If limited tissue is available, or the patient is unable to undergo a traditional biopsy, sequential testing of single biomarkers/limited molecular diagnostic panels will exhaust the sample. In these scenarios, or at the discretion of the treating physician, comprehensive genomic profiling via a validated NGS assay performed in a CLIA-approved laboratory should be considered". Their list of targeted biomarkers include HER2 overexpression/amplification, PD-L1 expression by immunohistochemistry,

microsatellite instability, tumor mutational burden, *NTRK* gene fusion, *RET* gene fusion, and *BRAF V600E* mutation (NCCN, 2024i). Furthermore, during workup for esophageal and esophagogastric junction cancers, "Universal testing for microsatellite instability (MSI) by PCR/next-generation sequencing (NGS) or MMR by IHC is recommended in all newly diagnosed patients". They also recommend "Programmed death ligand 1 (PD-L1) testing if advanced/ metastatic disease is documented/suspected", "HER2 testing if metastatic adenocarcinoma is documented/ suspected", and that "NGS should be considered". Universal testing for MSI by PCR/NGS or MMR by IHC is recommended in all newly diagnosed patients for biopsy specimen types, endoscopic resection, and esophagogastrectomy, without prior chemoradiation (if MSI and MMR has not been previously performed) (NCCN, 2024i). In their assessment of overexpression or amplification of HER2 in esophageal and EGJ cancers, the NCCN recommends that "The use of IHC/ISH should be considered first, followed by NGS testing as appropriate. Repeat biomarker testing may be considered at clinical or radiologic progression for patients with advanced/metastatic esophageal/EGJ adenocarcinoma" (NCCN, 2024i).

The NCCN clinical practice guidelines for occult primary (cancer of unknown primary [CUP]) note that "MSI/mismatch repair (MMR) testing is indicated for patients with CUP; however, it should be noted that the population of patients with MSI-high/MMR-deficient (MSI-H/dMMR) occult primary tumors is generally low." Moreover, they remark that determination of TMB by a validated and/or FDA-approved assay is a category 2B recommendation (2B: based on lower-level evidence, there is NCCN consensus that the intervention is appropriate) and a biopsy from a suspected metastatic malignancy should undergo TMB testing during the workup of the tumor. The NCCN also asserts that during workup "Gene sequencing to predict tissue of origin is not recommended" and "Molecular profiling of tumor tissue using next-generation sequencing (NGS) (or other technique to identify gene fusions) can be considered after an initial determination of histology has been made". Again, the NCCN cautions that "The population of patients with microsatellite instability-high/mismatch repair-deficient (MSI-H/dMMR) occult primary tumors is low. Use immunohistochemistry (IHC) for MMR or polymerase chain reaction (PCR) for MSI, which are different assays measuring the same biological effect" (NCCN, 2024m). For occult primary tumors, dostarlimab-gxly is recommended as "useful in certain circumstances" only in dMMR/MSI-H tumors, while pembrolizumab may be extended to tumors with either TMB-H or dMMR/MSI-H (NCCN, 2024m).

In the NCCN clinical practice guidelines for gastric cancer, universal testing, no matter the specimen type, for MSI by PCR/NGS or MMR by IHC is recommended in all newly diagnosed patients in the biopsy stage, endoscopic mucosal resection, gastrectomy without prior chemoradiation (if not previously performed). In the palliative

management of unresectable locally advanced, locally recurrent, or metastatic disease, "Perform HER2, programmed death ligand 1 (PD-L1), and microsatellite testing (if not done previously) if metastatic cancer is documented or suspected" and "NGS may be considered via a validated assay". Tumors should be interpreted as MSI-stable, MSI-low (1-29% of markers exhibit instability, one of the five NCI or mononucleotide markers exhibits instability), or MSI-H (≥30% of the markers exhibit instability, two or more of the five NCI or mononucleotide markers exhibit instability). They also state that "If limited tissue is available, or the patient is unable to undergo a traditional biopsy, sequential testing of single biomarkers/limited molecular diagnostic panels will exhaust the sample. In these scenarios, or at the discretion of the treating physician, comprehensive genomic profiling via a validated NGS assay performed in a CLIA-approved laboratory should be considered." Their list of targeted biomarkers includes HER2 overexpression/amplification, PD-L1 expression by immunohistochemistry, microsatellite instability, tumor mutational burden, *NTRK* gene fusion, *RET* gene fusion, and *BRAF V600E* mutation (NCCN, 2024j).

The NCCN clinical practice guidelines for hepatocellular carcinoma state that there is "no established role for microsatellite instability (MSI), mismatch repair (MMR), tumor mutational burden (TMB), or PD-L1 testing in [hepatocellular carcinoma] at this time". Immune checkpoint inhibition has shown clinical benefit leading to regulatory approvals in patients with HCC without selection for MSI, MMR, TMB, or PD-L1 status. Regarding therapies, the panel recommends nivolumab + ipilimumab (category 2B) as a first-line systemic therapy that is useful in certain circumstances and a subsequent-line systemic therapy if there is disease progression for individuals with TMB-H tumors. The NCCN also dostarlimab-gxly (category 2B) as a subsequent-line systemic therapy if there is disease progression for individuals with MSI-H/dMMR tumors (NCCN, 2024x).

The NCCN clinical practice guidelines for biliary tract cancers (BTCs) recommend germline testing and/or referral to a genetic councilor for patients with dMMR/MSI-H tumors or a family history suggestive of BRCA1/2 mutation" when presenting during intraoperative staging biopsy following an incidental finding of suspicious mass during surgery. Germline testing and/or referral to genetic counseling for patients with dMMR/MSI-H tumors or a family history suggestive of BRCA1/2 mutations should also be extended to situations where hepatobiliary surgery expertise is unavailable and postoperative workup is deemed unresectable, incidental finding on pathologic review with T1b or greater and/or T1a with positive margins deemed unresectable, unresectable mass on imaging, jaundice, metastatic disease, or isolated intrahepatic mass with unresectable or metastatic disease biopsy. The NCCN recommends that "Comprehensive molecular profiling is recommended for patients with unresectable or metastatic BTC who are candidates for systemic therapy". They also note that "Evidence remains insufficient for definitive recommendations regarding specific

criteria to guide genetic risk assessment in hepatobiliary cancers or for universal germline testing in these tumors" and, as such, "In BTCs, genetic counseling referral and potential germline testing should be considered in patients with any of the following characteristics: young age at diagnosis; a strong personal or family history of cancer; no known risk factors for liver disease; or presence of mutations identified during tumor testing that are suspected to be possible germline alterations. For patients who do harbor a known germline mutation associated with a cancer predisposing syndrome (ie, Lynch syndrome or hereditary breast and ovarian cancer syndrome), there is currently insufficient evidence to support screening for biliary tract malignancies" (NCCN, 2024d). The NCCN asserts that "testing for MSI or MMR deficiency is recommended in patients with unresectable or metastatic gallbladder cancer, intrahepatic CCA, or extrahepatic CCA" and that "Testing for TMB is recommended for patients with unresectable or metastatic gallbladder cancer, intrahepatic CCA, or extrahepatic CCA based upon clinical benefit observed across advanced solid tumors." They also outline the three possible tests to evaluate mismatch repair (MMR) protein deficiency or microsatellite status. First, an immunohistochemical staining for the *MLH1*, *MSH2*, *MSH6*, and *PMS2* gene products will establish protein retention or loss, followed by NGS to determine if there are inactivating mutations in the MMR genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*). Lastly, "microsatellite repeats of tumor DNA are examined by polymerase chain reaction (PCR)" and caution that "Tumor mutational burden (TMB) can be tested with a clinically validated NGS panel but has inherent platform variation" (NCCN, 2024d). In addition, the NCCN provides a helpful graphic to show their recommendations for molecular testing in unresectable or BTCs, captured below:

Recommended Molecular Testing	Anatomic Subsite		
	Gallbladder	Intrahepatic CCA	Extrahepatic CCA
***NTRK* gene fusion**	X	X	X
MSI-H/dMMR	X	X	X
TMB-H	X	X	X
***BRAF* V600E mutation**	X	X	X
***FGFR2* fusion or rearrangement**	–	X	X
***IDH1* mutation**	–	X	X
HER2 *(ERBB2)* overexpression and/or amplification	X	X	X
***RET* gene fusion**	X	X	X
***KRAS* G12C**	X	X	X

MSI-H: microsatellite instability-high
dMMR: mismatch repair deficient
TMB-H: tumor mutational burden-high

(NCCN, 2024d).

The NCCN clinical practice guidelines for neuroendocrine and adrenal tumors recommends that TMB and MSI testing should be considered as part of the workup for adrenocortical carcinoma. In the evaluation of poorly differentiated or large or small cell carcinomas or unknown primary, "Tumor biomarkers such as microsatellite instability (MSI), MMR, and TMB testing (by an FDA-approved test) should be considered as they can aid in assessing targeted therapy options". In well-differentiated grade three neuroendocrine tumors, "Tumor/somatic molecular profiling should be considered for patients with locoregional unresectable/metastatic disease who are candidates for anti-cancer therapy to identify actionable alterations. Testing on tumor tissue is preferred; however, cell-free DNA testing can be considered if tumor tissue testing is not feasible." The NCCN notes that "patients with ACC may also consider MSI, MMR, and TMB (by an FDA-approved test) testing" because some analyses suggest that "3% of patients with ACC have Lynch syndrome" (NCCN, 2024k).

The NCCN clinical practice guidelines for vulvar cancer state that "Mismatch repair (MMR), microsatellite instability (MSI), programmed death ligand 1 (PD-L1), neurotrophic tyrosine receptor kinase (*NTRK*) gene fusion, and tumor mutational burden (TMB) testing may also be considered for treatment planning purposes in patients with recurrent, progressive, or metastatic disease" (NCCN, 2024u).

The NCCN clinical practice guidelines for ovarian cancer identify TMB testing as a clinically indicated tumor molecular analysis in addition to NGS for *BRCA1/2* mutations and other somatic mutations. They also recommend using tumor molecular analysis "to identify potential benefit from targeted therapeutics that have tumor-specific or tumor-agnostic benefit including, but not limited to, HER2 status (by IHC), BRCA1/2, HRD status, microsatellite instability (MSI), mismatch repair (MMR), tumor mutational burden (TMB), *BRAF*, FRα (FOLR1), *RET*, and *NTRK* if prior testing did not include these markers" in patients with recurrent disease and rising CA-125, regardless of prior chemotherapy status if molecular testing was not done previously in epithelial ovarian cancer/fallopian tube cancer/primary peritoneal cancer. The NCCN guidelines also recommend tumor molecular testing with TMB and MSI if not previously done when following up or monitoring for the recurrence of low-grade serous carcinoma (NCCN, 2024n).

In the NCCN clinical practice guidelines for testicular cancer, the NCCN recommends TMB or MSI testing as a third-line therapy in nonseminoma if there is progression after high-dose chemotherapy or other third-line therapies. The guideline also notes that similar to many other cancers, pembrolizumab may be useful in certain circumstances as a third-line chemotherapy regimen for metastatic germ cell tumors when the tumor has a TMB-H or MSI-H status, regardless of prior high-dose chemotherapy status (NCCN, 2024r).

In the NCCN clinical practice guidelines for pancreatic adenocarcinoma, it is stated that "Tumor/somatic molecular profiling is recommended for patients with locally advanced/metastatic disease who are candidates for anti-cancer therapy to identify uncommon mutations. Consider specifically testing for potentially actionable somatic findings including, but not limited to: fusions (*ALK*, *NRG1*, *NTRK*, *ROS1*, *FGFR2*, and *RET*), mutations (*BRAF*, *BRCA1/2*, *KRAS*, and *PALB2*), amplifications (*HER2*), microsatellite instability (MSI), mismatch repair deficiency (dMMR), or tumor mutational burden (TMB) via an FDA-approved and/or validated next-generation sequencing (NGS)-based assay. RNA sequencing assays are preferred for detecting RNA fusions because gene fusions are better detected by RNA-based NGS. Testing on tumor tissue is preferred; however, cell-free DNA testing can be considered if tumor tissue testing is not feasible". This is true for locally advanced disease where adenocarcinoma is confirmed, in metastatic disease when tumor tissue is available, and in tumors with recurrence after resection (NCCN, 2024b).

In the NCCN clinical practice guidelines for penile cancer, pembrolizumab is recommended as a subsequent-line systemic therapy for metastatic/recurrent disease in MSI-H/dMMR tumors that have progressed following prior treatment and that have no satisfactory alternative treatment options (NCCN, 2024c).

The NCCN clinical practice guidelines for prostate cancer recommend that in CRPC, tumor testing for microsatellite instability (MSI-H) or DMMR and HRRm should be considered when CRPC imaging studies are positive for metastases, if the testing has not been previously performed. It also recommends tumor testing for MSI-H or dMMR among patients with metastatic CRPC and "may be considered in patients with regional or castration-sensitive metastatic prostate cancer", and that "TMB testing may be considered in patients with metastatic castration-resistant prostate cancer." The NCCN also provides tumor testing recommendations based on risk groups. These recommendations include

1. "Tumor testing for somatic homologous recombination gene mutations (eg, BRCA1, BRCA2, ATM, PALB2, FANCA, RAD51D, CHEK2, CDK12) can be considered in patients with regional (N1) prostate cancer and is recommended for those with metastatic disease."
2. "Tumor testing for MSI or dMMR can be considered in patients with regional or metastatic castration-naïve prostate cancer and is recommended in the metastatic CRPC setting."
3. "Tumor mutational burden (TMB) testing may be considered in patients with metastatic CRPC."
4. "Multigene molecular testing can be considered for patients with low-, intermediate-, and high-risk prostate cancer and life expectancy ≥10 years."
5. "The Decipher molecular assay is recommended to inform adjuvant treatment if adverse features are found post-radical prostatectomy, and can be considered as part of counseling for risk stratification in patients with PSA resistance/recurrence after radical prostatectomy" (NCCN, 2024o).

The NCCN advises that "If MSI testing is performed, testing using an NGS assay validated for prostate cancer is preferred" and states that "If MSI-H or dMMR is found, the patient should be referred for genetic counseling to assess for the possibility of Lynch syndrome" (NCCN, 2024o).

The NCCN clincal practice guidelines for rectal cancer state that universal MMR or MSI testing is recommended in all newly diagnosed patients with rectal cancer, noting that IHC for MMR and DNA analysis for MSI are different assays and measure different biological effects caused by deficient MMR function (NCCN, 2024p). The NCCN cautions that "The presence of a BRAF V600E mutation in the setting of MLH1 absence would preclude the diagnosis of Lynch syndrome (LS) in the vast majority of patients. However, approximately one percent of cancers with BRAF V600E mutations (and loss of *MLH1*) are LS. Caution should be exercised in excluding patients with a strong family history from germline screening in the case of BRAF V600E mutations." The further explain that "One of two different initial tests can be performed on CRC specimens to

identify individuals who might have Lynch syndrome: 1) immunohistochemical analysis for MMR protein expression, which is often diminished because of mutation; or 2) analysis for microsatellite instability (MSI), which results from MMR deficiency and is detected as changes in the length of repetitive DNA elements in tumor tissue caused by the insertion or deletion of repeated units". They also remind clinicians that "MMR or MSI testing should be performed only in CLIA-approved laboratories" and that "testing for MSI may be accomplished by polymerase chain reaction (PCR) or a validated NGS panel, the latter especially in patients with metastatic disease who require genotyping of *RAS* and *BRAF*". In the management of malignant polyps, "All patients with a malignant polyp should undergo MMR or MSI testing at diagnosis". Similarly, "All patients with rectal cancer should undergo MMR or MSI testing at diagnosis to aid in the diagnosis of Lynch syndrome and for clinical trial availability, especially related to checkpoint inhibitors as neoadjuvant therapy" (NCCN, 2024p). MMR and MSI testing is also recommended as part of the initial workup in pedunculated polyps or sessile polyps (adenoma) with invasive cancer and in rectal cancers with and without suspected or proven distant metastases (if not previously done in the latter). Notably, during pathologic review, "It has not been established if molecular markers (other than MSI-H/dMMR) are useful in treatment determination (predictive markers) and prognosis" (NCCN, 2024p).

The NCCN clinical practice guidelines for small bowel adenocarcinoma recommend MSI testing as a workup when the tumor is in the duodenum or the jejunum/ileum, as well as in metastatic and/or recurrent tumors such as metastatic adenocarcinoma. Some general principles of pathologic review include the following:

- "Universal MMR or MSI testing is recommended in all newly diagnosed patients with SBA"
- "Patients with stage II dMMR/MSI-H may have improved survival compared to patients with proficient MMR (pMMR)/microsatellite stable (MSS); however, this has not been confirmed in the SBA population and is extrapolated from colorectal cancer data"
- "MMR or MSI testing should be performed only in Clinical Laboratory Improvement Amendments (CLIA)-certified laboratories"
- "Testing for MSI may be performed by validated next-generation sequencing (NGS) panels" (NCCN, 2024q).

The NCCN clinical practice guidelines for thyroid carcinoma suggest that treatment of structurally persistent/recurrent locoregional or distant metastatic disease not amenable to RAI therapy, "somatic testing to identify actionable mutations (including *ALK*, *NTRK*, *BRAF*, and *RET* gene fusions), mismatch repair deficiency (dMMR), microsatellite instability (MSI), and tumor mutational burden (TMB)" should be

considered for advanced, progressive, or threatening disease. Wh en FNA or core biopsy finds that it is anaplastic thyroid carcinoma, molecular testing is recommended as diagnostic molecular testing for actionable mutations, which they propound as including "BRAF, NTRK, ALK, RET, MSI, dMMR, and tumor mutational burden. BRAF IHC testing is recommended due to faster turnaround compared to genetic testing." This extends to the aggressive therapy approach for stage IVC (NCCN, 2024s).

The NCCN clinical practice guidelines for bone cancer recommend considering TMB or MSI testing as determined by a validated and/or FDA-approved assay to inform the use of treatment options in patients with metastatic chondrosarcoma, chordoma, Metastatic Ewing sarcoma, and metastatic osteosarcoma at presentation (NCCN, 2024e).

The NCCN clinical practice guidelines for ampullary adenocarcinoma suggest that if adenocarcinoma is found to be metastatic, then "Tumor/somatic molecular profiling is recommended for patients with locally advanced/metastatic disease who are candidates for anti-cancer therapy to identify uncommon mutations", and recommend that clinicians "Consider specifically testing for potentially actionable somatic findings including, but not limited to: fusions (*ALK*, *NRG1*, *NTRK*, *ROS1*, *FGFR2*, and *RET*), mutations (*BRAF*, *BRCA1/2*, *KRAS*, and *PALB2*), amplifications (HER2), microsatellite instability (MSI), mismatch repair deficiency (dMMR), or tumor mutational burden (TMB) via an FDA-approved and/or validated next-generation sequencing (NGS)-based assay." The NCCN panel also explains that "RNA sequencing assays are preferred for detecting RNA fusions because gene fusions are better detected by RNA-based NGS"; regardless, "Testing on tumor tissue is preferred; however, cell-free DNA testing can be considered if tumor tissue testing is not feasible" (NCCN, 2024a).

The NCCN clinical practice guidelines for anal carcinoma note that "microsatellite instability (MSI)/mismatch repair (MMR) testing is not required" during second-line treatment of metastatic anal cancer because "MSI is uncommon in anal cancer; [however], anal cancers may be responsive to PD-1/PD-L1 inhibitors because they often have high PD-L1 expression and/or a high tumor mutational load despite being microsatellite stable (MSS) " (NCCN, 2024v).

The NCCN clinical practice guidelines for hepatocellular carcinoma note that "There is no established role for microsatellite instability (MSI), mismatch repair (MMR), tumor mutational burden (TMB), or programmed death ligand 1 (PD-L1) testing in HCC at this time. Immune checkpoint inhibition has shown clinical benefit leading to regulatory approvals in patients with HCC without selection for MSI, MMR, TMB, or PD-L1 status" (NCCN, 2024x).

The NCCN clinical practice guidelines for pediatric central nervous system cancers mention TMB in terms of palliative systemic therapy for recurrent or progressive disease, noting that "targeted therapy based on the molecular composition of the tumor is recommended for patients with good performance status" including "checkpoint blockade for high tumor mutational burden (TMB) or personal or family history of cMMRD; RAF and MEK inhibition for tumors with BRAF V600E mutation, and TRK inhibitors for tumors with NTRK gene fusion" (NCCN, 2024y).

The NCCN clinical practice guidelines for soft tissue sarcoma recommends pembrolizumab as useful in certain circumstances as a subsequent line of therapy for advanced/metastatic disease for MSI-H or dMMR tumors (regardless of soft tissue sarcoma sub-type). The NCCN also recommends pembrolizumab or nivolumab ± ipilimumab as useful in certain circumstances as a subsequent line of therapy for advanced/metastatic disease for TMB-H (≥10 mutations/megabase [mut/Mb]) regardless of soft tissue sarcoma sub-type (NCCN, 2024z).

European Society for Medical Oncology (ESMO)

The ESMO has published clinical recommendations for MSI testing based on consensus decisions from the ESMO Translational Research and Precision Medicine Working Group. The recommended first action to assess MSI/dMMR, decided by a consensus with a strong agreement, is the use of immunohistochemistry for the mismatch repair proteins MLH1, MSH2, MSH6, and PMS2. The second method of MSI/dMMR testing, also with a consensus of strong agreement, is the use of PCR-based assessment of microsatellite alterations using five microsatellite markers (including at least BAT-25 and BAT-26). Based on a consensus with a very strong agreement, the ESMO notes that NGS coupling MSI and TMB analysis may represent "a decisive tool for selecting patients for immunotherapy, for common or rare cancers not belonging to the spectrum of Lynch syndrome." They note that the relationships between MSI, TMB, and PD-1/PD-L1 expression are both complex and different based on the type of tumor being assessed. They also note that the most important cancer types where MSI testing should be carried out using IHC to assess MSI-PCR or NGS are endometrial, intestinal (colorectal and small bowel), esophageal (adenocarcinomas and not squamous cell carcinoma), gastric, glioblastoma, and ovarian cancers (Luchini et al., 2019).

The ESMO has published clinical recommendations for the use of tumor multigene NGS in non-small cell lung cancer, cholangiocarcinoma, prostate, and ovarian cancers. They recommend to "test TMB in well- and moderately-differentiated neuroendocrine tumours (NETs), cervical, salivary, thyroid and vulvar cancers. . . as TMB-high predicted response to pembrolizumab in these cancers." They advise that a large panel of genes could be ordered but that the benefit for the patient and the cost for the public health

care system should be taken into consideration. Patient-specific recommendations are summarized in the table below (Mosele et al., 2020).

Tumour Types	General recommendations for daily practice	Special considerations for patients
Lung adenocarcinoma	Tumour multigene NGS to assess level I alterations. Larger panels can be used only on the basis of specific agreements with payers taking into account the overall cost of the strategy (drug included[a]) and if they report accurate ranking of alterations. NGS can either be done on RNA or DNA, if it includes level I fusions in the panel.	Using large panels of genes could lead to few clinically meaningful responders, not detected by small panels or standard testings. In this context and outside the diseases where large panels of genes are recommended, ESMO acknowledges that a patient and a doctor could decide together to order a large panel of genes, pending no extra cost for the public health care system, and if the patient is informed about the low likelihood of benefit.
Squamous cell lung cancers	No current indication for tumour multigene NGS	
Breast cancers	No current indication for tumour multigene NGS	
Colon cancers	Multigene tumour NGS can be an alternative option to PCR if it does not result in additional cost.	
Prostate cancers	Multigene tumour NGS to assess level I alterations. Larger panels can be used only on the basis of specific agreements with payers taking into account the overall cost of the strategy and if they report accurate ranking of alterations.	
Gastric cancers	No current indication for tumour multigene NGS	
Pancreatic cancers	No current indication for tumour multigene NGS	
Hepatocellular carcinoma	No current indication for tumour multigene NGS	
Cholangiocarcinoma	Multigene tumour NGS could be recommended to assess level I alterations. Larger panels can be used only on the basis of specific agreements with payers taking into account the overall cost of the strategy (drug includeda) and if they report accurate ranking of alterations. RNA-based NGS can be used.	
Others	Tumour multigene NGS can be used in ovarian cancers to	

	determine somatic BRCA1/2 mutations. In this latter case, larger panels can be used only on the basis of specific agreements with payers taking into account the overall cost of the strategy (drug includeda) and if they report accurate ranking of alterations. Large panel NGS can be used in carcinoma of unknown primary. It is recommended to determine TMB in cervical cancer, salivary cancer, thyroid cancers, well-to-moderately differentiated neuroendocrine tumours, vulvar cancer, pending drug access (and in TMB-high endometrial and SCL cancers if anti-PD1 antibody is not available otherwise).	

anti-PD1, anti-programmed cell death 1; DRUP, drug rediscovery protocol; ESMO, European Society for Medical Oncology; NGS, next-generation sequencing; SCL, small-cell lung cancer; TMB, tumour mutational burden.

[a] ESMO recommends using off-label drugs matched to genomics only if an access programme and a procedure of decision have been developed at the national or regional level, as illustrated by the DRUP programme.(Mosele et al., 2020)

College of American Pathologists (CAP)

In 2022, the College of American Pathologists issued an evidence-based clinical guideline on the use of mismatch repair and microsatellite instability testing for immune checkpoint inhibitor therapy. These recommendations include guidance for patients with Lynch syndrome, as well as for patients with colorectal, endometrial,

Guideline Statement	Strength of Recommendation
1. For patients with CRC being considered for immune checkpoint inhibitor therapy, pathologists should use MMR-IHC and/or MSI by PCR for the detection of DNA MMR defects. Although MMR-IHC or MSI by PCR are preferred, pathologists may use a validated MSI by NGS assay for the detection of DNA MMR defects. *Note:* MSI by NGS assay must be validated against MMR-IHC or MSI by PCR and must show equivalency.	Strong Recommendation
2. For patients with gastroesophageal and small bowel cancer being considered for immune checkpoint inhibitor therapy, pathologists should use MMR-IHC and/or MSI by PCR over MSI by NGS for the detection of DNA MMR defects. *Note:* This recommendation does not include esophageal squamous cell carcinoma.	Strong Recommendation
3. For patients with endometrial cancer being considered for immune checkpoint inhibitor therapy, pathologists should use MMR-IHC over MSI by PCR or NGS for the detection of DNA MMR defects.	Strong Recommendation
4. For patients with cancer types other than CRC, GEA, small bowel, and endometrial being considered for immune checkpoint inhibitor therapy, pathologists should test for DNA MMR, although the optimal approach for the detection of MMR defects has not been established. *Note:* Assays must be adequately validated for the specific cancer type being tested with careful consideration of performance characteristics of MMR-IHC and MSI by NGS or PCR for the detection of DNA MMR defects.	Conditional Recommendation
5. For all cancer patients being considered for immune checkpoint inhibitor therapy based upon defective MMR, pathologists should **NOT** use TMB as a surrogate for the detection of DNA MMR defects. If a tumor is identified as TMB-high, pathologists may perform IHC and/or MSI by PCR to determine if high TMB is secondary to MMR deficiency.	Strong Recommendation
6. For cancer patients being considered for immune checkpoint inhibitor therapy, if an MMR deficiency consistent with Lynch Syndrome is identified in the tumor, pathologists should communicate this finding with the treating physician.	Strong Recommendation

Abbreviations: CRC, colorectal cancer; DNA, deoxyribonucleic acid; GEA, gastroesophageal adenocarcinoma; IHC, immunohistochemistry; MMR, mismatch repair; MSI, microsatellite instability; NGS, next generation sequencing; PCR, polymerase chain reaction; TMB, tumor mutation burden

gastroesophageal, small bowel, and other types of cancers. Their summary of recommendations is captured below (CAP, 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state

coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

On November 30, 2017, the FDA approved FoundationOne CDx™ (Foundation Medicine, Inc.). This device is a next-generation sequencing based in vitro diagnostic device for detection of substitutions, insertion, and deletion alterations (indels), and copy number alterations (CNAs) in 324 genes and select gene rearrangements, as well as genomic signatures including microsatellite instability (MSI) and tumor mutational burden (TMB) using DNA isolated from formalin-fixed paraffin-embedded (FFPE) tumor tissue specimens. The test is intended as a companion diagnostic to identify patients who may benefit from treatment with the targeted therapies in accordance with the approved therapeutic product labeling. Additionally, F1CDx is intended to provide tumor mutation profiling to be used by qualified health care professionals in accordance with professional guidelines in oncology for patients with solid malignant neoplasms. The F1CDx assay is a single-site assay performed at Foundation Medicine, Inc. (FDA, 2017c).

On August 26, 2020, the FDA approved FoundationOne® Liquid CDx (Foundation Medicine, Inc.). This device is a qualitative next-generation sequencing based in vitro diagnostic test that uses targeted high throughput hybridization-based capture technology to detect and report substitutions, insertions, and deletions (indels) in 311 genes, including rearrangements and copy number losses only in BRCA1 and BRCA2, utilizing circulating cell-free DNA (cfDNA) isolated from plasma derived from anti-coagulated peripheral whole blood of cancer patients. This device is intended to provide tumor mutation profiling for substitutions and indels to be used by qualified health care professionals in accordance with professional guidelines in oncology for patients with solid malignant neoplasms (FDA, 2020b).

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81301	Microsatellite instability analysis (eg, hereditary non-polyposis colorectal cancer, Lynch syndrome) of markers for mismatch repair deficiency (eg, BAT25, BAT26), includes comparison of neoplastic and normal tissue, if performed
81457	Solid organ neoplasm, genomic sequence analysis panel, interrogation for sequence variants; DNA analysis, microsatellite instability
81458	Solid organ neoplasm, genomic sequence analysis panel, interrogation for sequence variants; DNA analysis, copy number variants and microsatellite instability
81459	Solid organ neoplasm, genomic sequence analysis panel, interrogation for sequence variants; DNA analysis or combined DNA and RNA analysis, copy number variants, microsatellite instability, tumor mutation burden, and rearrangements
81463	Solid organ neoplasm, genomic sequence analysis panel, cell-free nucleic acid (eg, plasma), interrogation for sequence variants; DNA analysis, copy number variants, and microsatellite instability
81464	Solid organ neoplasm, genomic sequence analysis panel, cell-free nucleic acid (eg, plasma), interrogation for sequence variants; DNA analysis or combined DNA and RNA analysis, copy number variants, microsatellite instability, tumor mutation burden, and rearrangements
81479	Unlisted molecular pathology procedure
0037U	Targeted genomic sequence analysis, solid organ neoplasm, DNA analysis of 324 genes, interrogation for sequence variants, gene copy number amplifications, gene rearrangements, microsatellite instability and tumor mutational burden Proprietary test: FoundationOne CDx™ (F1CDx) Lab/Manufacturer: Foundation Medicine, Inc
0048U	Oncology (solid organ neoplasia), DNA, targeted sequencing of protein-coding exons of 468 cancer-associated genes, including interrogation for somatic mutations and microsatellite instability, matched with normal specimens, utilizing formalin-fixed paraffin-embedded tumor tissue, report of clinically significant mutation(s) Proprietary test: MSK-IMPACT (Integrated Mutation Profiling of Actionable Cancer Targets) Lab/Manufacturer: Memorial Sloan Kettering Cancer Center
0211U	Oncology (pan-tumor), DNA and RNA by next-generation sequencing, utilizing formalin-fixed paraffin-embedded tissue, interpretative report for

	single nucleotide variants, copy number alterations, tumor mutational burden, and microsatellite instability, with therapy association Proprietary test: MI Cancer Seek™ - NGS Analysis Lab/Manufacturer: Caris MPI d/b/a Caris Life Sciences
0239U	Targeted genomic sequence analysis panel, solid organ neoplasm, cell-free DNA, analysis of 311 or more genes, interrogation for sequence variants, including substitutions, insertions, deletions, select rearrangements, and copy number variations Proprietary test: FoundationOne® Liquid CDx Lab/Manufacturer: Foundation Medicine, Inc
0242U	Targeted genomic sequence analysis panel, solid organ neoplasm, cell-free circulating DNA analysis of 55-74 genes, interrogation for sequence variants, gene copy number amplifications, and gene rearrangements Proprietary test: Guardant360® CDx Lab/Manufacturer: Guardant Health Inc
0244U	Oncology (solid organ), DNA, comprehensive genomic profiling, 257 genes, interrogation for single-nucleotide variants, insertions/deletions, copy number alterations, gene rearrangements, tumor-mutational burden and microsatellite instability, utilizing formalin-fixed paraffin-embedded tumor tissue Proprietary test: Oncotype MAP™ Pan-Cancer Tissue Test Lab/Manufacturer: Paradigm Diagnostics, Inc
0250U	Oncology (solid organ neoplasm), targeted genomic sequence DNA analysis of 505 genes, interrogation for somatic alterations (SNVs [single nucleotide variant], small insertions and deletions, one amplification, and four translocations), microsatellite instability and tumor-mutation burden Proprietary test: PGDx elio™ tissue complete Lab/Manufacturer: Personal Genome Diagnostics, Inc
0326U	Targeted genomic sequence analysis panel, solid organ neoplasm, cell-free circulating DNA analysis of 83 or more genes, interrogation for sequence variants, gene copy number amplifications, gene rearrangements, microsatellite instability and tumor mutational Proprietary test: Guardant360® Lab/Manufacturer: Guardant Health, Inc
0329U	Oncology (neoplasia), exome and transcriptome sequence analysis for sequence variants, gene copy number amplifications and deletions, gene rearrangements, microsatellite instability and tumor mutational burden utilizing DNA and RNA from tumor with DNA from normal blood or saliva for subtraction, report of clinically significant mutation(s) with therapy associations

	Proprietary test: Oncomap™ ExTra Lab/Manufacturer: Exact Sciences, Inc, Genomic Health Inc
0334U	Oncology (solid organ), targeted genomic sequence analysis, formalin-fixed paraffin-embedded (FFPE) tumor tissue, DNA analysis, 84 or more genes, interrogation for sequence variants, gene copy number amplifications, gene rearrangements, microsatellite instability and tumor mutational burden Proprietary test: Guardant360 TissueNext™ Lab/Manufacturer: Guardant Health, Inc
0379U	Targeted genomic sequence analysis panel, solid organ neoplasm, DNA (523 genes) and RNA (55 genes) by next-generation sequencing, interrogation for sequence variants, gene copy number amplifications, gene rearrangements, microsatellite instability, and tumor mutational burden Proprietary test: Solid Tumor Expanded Panel Lab/Manufacturer: Quest Diagnostics®
0391U	Oncology (solid tumor), DNA and RNA by next-generation sequencing, utilizing formalin-fixed paraffin-embedded (FFPE) tissue, 437 genes, interpretive report for single nucleotide variants, splicesite variants, insertions/deletions, copy number alterations, gene fusions, tumor mutational burden, and microsatellite instability, with algorithm quantifying immunotherapy response score Proprietary test: Strata Select™ Lab/Manufacturer: Strata Oncology, Inc.
0409U	Oncology (solid tumor), DNA (80 genes) and RNA (36 genes), by next-generation sequencing from plasma, including single nucleotide variants, insertions/deletions, copy number alterations, microsatellite instability, and fusions, report showing identified mutations with clinical actionability Proprietary Test: LiquidHALLMARK ® Lab/Manufacturer: Lucene Health, Inc.
0473U	Oncology (solid tumor), nextgeneration sequencing (NGS) of DNA from formalin-fixed paraffinembedded (FFPE) tissue with comparative sequence analysis from a matched normal specimen (blood or saliva), 648 genes, interrogation for sequence variants, insertion and deletion alterations, copy number variants, rearrangements, microsatellite instability, and tumor-mutation burden Proprietary test: xT CDx Lab/Manufacturer: Tempus AI, Inc
0487U	Oncology (solid tumor), cell-free circulating DNA, targeted genomic sequence analysis panel of 84 genes, interrogation for sequence variants, aneuploidycorrected gene copy number amplifications and losses, gene rearrangements, and microsatellite instability

	Proprietary test: Northstar SelectTM Lab/Manufacturer: BillionToOne Laboratory
0512U	Oncology (prostate), augmentative algorithmic analysis of digitized whole-slide imaging of histologic features for microsatellite instability (MSI) status, formalin-fixed paraffinembedded (FFPE) tissue, reported as increased or decreased probability of MSI-high (MSI-H) Proprietary test: Tempus p-MSI Lab/Manufacturer: Tempus AI, Inc
0513U	Oncology (prostate), augmentative algorithmic analysis of digitized whole-slide imaging of histologic features for microsatellite instability (MSI) and homologous recombination deficiency (HRD) status, formalinfixed paraffin-embedded (FFPE) tissue, reported as increased or decreased probability of each biomarker Proprietary test: Tempus p-Prostate Lab/Manufacturer: Tempus AI, Inc
0530U	Oncology (pan-solid tumor), ctDNA, utilizing plasma, nextgeneration sequencing (NGS) of 77 genes, 8 fusions, microsatellite instability, and tumor mutation burden, interpretative report for single nucleotide variants, copynumber alterations, with therapy association Proprietary test: LiquidHALLMARK® Lab/Manufacturer: Lucence Health, Inc, Lucence Health, Inc

Minimal Residual Disease (MRD)

Policy Number: AHS –M2175 – Minimal Residual Disease (MRD)	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Minimal residual disease, also called measurable residual disease or MRD, refers to the subclinical levels of residual diseases, such as acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML), and multiple myeloma (MM) (Horton & Steuber, 2023; Rajkumar, 2023; Stock & Estrov, 2022a, 2022b). MRD is a postdiagnosis, prognostic indicator that can be used for risk stratification and to guide therapeutic options when used alongside other clinical and molecular data (Schuurhuis et al., 2018). Many different techniques have been developed to detect residual disease. However, PCR-based techniques, multicolor flow cytometry, and deep sequencing-based MRD generally provide the best sensitivity, specificity, reproducibility, and applicability compared to other techniques such as fluorescence in situ hybridization (FISH), Southern blotting, or cell culture (Stock & Estrov, 2022b).

II. Related Policies

Policy Number	Policy Title
AHS-F2019	Flow Cytometry
AHS-G2054	Liquid Biopsy
AHS-M2182	Genomic Testing for Hematopoietic Neoplasms

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with multiple myeloma (MM), chronic lymphocytic leukemia (CLL), or small lymphocytic lymphoma (SLL), minimal residual disease (MRD) testing by

multiparameter flow cytometry **or** next-generation sequencing (NGS) **MEETS COVERAGE CRITERIA**.

2) For individuals with acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL), MRD testing by multiparameter flow cytometry, PCR-based techniques, **or** NGS **MEETS COVERAGE CRITERIA**.

3) For individuals with a diagnosis of human papilloma virus (HPV)-positive oropharyngeal squamous cell carcinoma (OPSCC) who are being monitored for disease recurrence (at least three months after completion of initial definitive therapy), blood-based detection of tumor tissue modified viral (TTMV)-HPV DNA fragments (i.e., NavDx®) **MEETS COVERAGE CRITERIA** once every three months.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

4) For all situations not addressed above (e.g., MRD testing for all other solid tumors), MRD testing by multiparameter flow cytometry, PCR, or NGS **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ABL	*Abelson tyrosine kinase gene*
AL	Acute leukemia
ALL	Acute lymphoblastic leukemia
ALL	Pediatric acute lymphoblastic leukemia
AML	Acute myeloid leukemia
AML1	*Acute myeloid leukemia 1 protein gene*
ASCO	American Society of Clinical Oncology
ASCT	Autologous Stem Cell Transplantation
ASH	American Society of Hematology
B-ALL	B-cell acute lymphoblastic leukemia
BCL1	*B-cell lymphoma 1 gene*
BCL2	*B-cell lymphoma 2 gene*
BCP	B-cell precursor
BCR	Break point cluster gene
BM	Bone marrow
BMA	Bone marrow aspirate

BMR	Bone marrow relapse
BRAF	Proto-oncogene B-Raf/v-Raf murine sarcoma viral oncogene homolog B
CA	Cytogenetic abnormalities
CAP	College of American Pathologists
CAR	Post-chimeric antigen receptor
CBF	Core binding factor
CBFB-MYH11	*Cord binding factor subunit beta-myosin 11 fusion gene*
CCO	Cancer Care Ontario
CD19	Cluster of differentiation 19
CD20	Cluster of differentiation 20
CD43	Cluster of differentiation 43
CD49b	Cluster of differentiation 49b
CD5	Cluster of differentiation 5
CD81	Cluster of differentiation 81
2-CldA	Cladribine
CLIA	Clinical Laboratory Improvement Amendments
CLL	Chronic lymphocytic leukemia
CMS	Centers for Medicare and Medicaid Services
CR	Complete response/complete remission
CT	Computed Tomography
ctDNA	Circulating tumor deoxyribonucleic acid
CV	Coefficients of variance
DCF	Pentostatin
DFCI	Dana Farber Cancer Institute
DFS	Disease Free Survival
DJ	Diversity and joining segment rearrangement
DNA	Deoxyribonucleic acid
E2A	Transcription factor E2-alpha gene
EFS	Event free survival
ELN	European LeukemiaNet
EMN	European Myeloma Network
EOCT	End of combination therapy
ERIC	European Research Initiative on chronic lymphocytic leukemia
ESMO	European Society for Medical Oncology
EWS	Ewing sarcoma

FC	Flow cytometry
FCR	Fludarabine cyclophosphamide and rituximab
FDA	Food and Drug Administration
FISH	Fluorescence in situ hybridization
FUM3	Follow up month 3
gDNA	Genomic deoxyribonucleic acid
HPV	Human papillomavirus
HR-NB	High-risk neuroblastoma
HSCT	Haematopoietic stem cell transplantation
HTS	High-throughput sequencing
IgH	Immunoglobulin heavy chain
IGH	*Immunoglobulin heavy chain gene*
IgK	Immunoglobulin K
IgL	Immunoglobulin L
IHC	Immunohistochemistry
IMWG	International Myeloma Working Group
iwCLL	International Workshop on Chronic Lymphocytic Leukemia
J	Joining
KIT	KIT proto-oncogene receptor tyrosine kinase
LDTs	Laboratory developed tests
MFC/mFC	Multicolor flow cytometry
MFC	Mutliparameter flow cytometry
MM	Multiple myeloma
mpFC	Multi parametic flow cytometry
MRD	Minimal residual disease
MRD	Measurable residual disease
NCCN	National Comprehensive Cancer Network
NDMM	Newly diagnosed multiple myeloma
NGF	Next-generation flow cytometry
NGS	Next generation sequencing
NGS-MRD	Next-generation sequencing-minimal residual disease
non-TBI	Non-total body irradiation
NPV	Negative Predictive Value
NPM1mut	*Nucleophosmin 1 gene mutant allele*
OS	Overall survival
OPSCC	Oropharyngeal squamous cell carcinoma

PBX1	*Pre-B-cell leukemia transcription factor 1 gene*
PCR	Polymerase chain reaction
PET-CT	Positron emission tomography -computed tomography
PFS	Progression-free survival
PML-RARA	*Promyelocytic leukemia-retinoic acid receptor alpha fusion gene*
PPV	Positive predictive value
QALYs	Quality adjusted life years
RQ-PCR/RT-qPCR	Real-time quantitative polymerase chain reaction
RRMM	Relapsed refractory multiple myeloma
RT-PCR	Reverse transcriptase polymerase chain reaction
RUNX1-RUNX1T1	*Runt-related transcription factor 1- RUNX1 partner transcriptional co-repressor 1 gene*
sCR	Stringent complete remission
SR	Standard risk
T-ALL	T-cell acute lymphocytic leukemia
TBI	Total body irradiation
TCR	T cell receptor
TEL	*Translocation-Ets-leukemia virus gene*
TRG	*T cell receptor gamma locus gene*
TTMV	tumor tissue modified viral
uMRD	Undetectable minimal residual disease
VDJ	Variable-diversity-joining
VGPR	Very good partial response
WGS	Whole genome sequencing

V. Scientific Background

The goal of treating cancer has traditionally been "complete remission" (or response), defined as "absence of visible tumor" based on techniques, such as imaging and histological examination of tissue (Luskin et al., 2018). However, some cancer cells may remain undetected due to a lack of sensitivity of conventional methods, leading to relapse. This subclinical amount of cancer cells is referred to as minimal residual disease or MRD (Bai et al., 2018). While many techniques have been developed to determine MRD, multicolor flow cytometry and PCR-based, including next generation sequencing (NGS), MRD techniques are the most commonly used (Rai & Stilgenbauer, 2024; Stock & Estrov, 2022b).

Multicolor flow cytometry (MFC), also known as multiparameter flow cytometry, can be used to identify MRD by measuring for the aberrant expression of antigens on cancer cells. MFC uses lasers of different colors to simultaneously determine specific immunophenotypic features of the cells within a sample. "Classic flow cytometry techniques using four to six colors have limited sensitivity and specificity for MRD detection. Current flow cytometry techniques use six to eight colors to assess MRD with a sensitivity which is approximately 10^{-4}, or about 0.5 to 1 log lower than that of polymerase chain reaction" (PCR) (Stock & Estrov, 2022b).

Polymerase chain reaction-based MRD techniques, including NGS, amplify sequences of DNA unique to the cancerous cell. These techniques have amazing sensitivity. In fact, real-time quantitative PCR can be used to detect a single cancerous cell from 10^4 – 10^5 cells (Brüggemann et al., 2006; Stock & Estrov, 2022b). The targets of amplification can include T cell receptor (TCR) gene rearrangements, the immunoglobulin heavy chain (IgH), or even fusion-gene transcripts (Del Giudice et al., 2019; Stock & Estrov, 2022b; van der Velden et al., 2003). Reverse transcriptase PCR-based MRD can also be used to detect cancer-related transcripts, including *E2A/PBX1, TEL/AML1,* and *BCR/ABL* (Lee et al., 2003; Madzo et al., 2003; Stock & Estrov, 2022b).

Proprietary Testing

ClonoSEQ (Adaptive Biotechnologies, Seattle, WA) is a commercially available NGS-based assay intended to assess MRD in certain types of cancer, such as MM and ALL. This test identifies rearrangements in certain receptor gene sequences, representing the level of MRD in a patient. This test typically uses genomic DNA extracted from bone marrow but may use circulating tumor DNA (ctDNA) (Herrera et al., 2016). After testing, a report is provided which includes each nucleotide sequence identified for tracking residual disease, the amount of each identified marker (per million cells), and whether MRD is determined to be present in the sample (Adaptive Biotechnologies, 2024).

Signatera™ is an MRD assay that uses ctDNA to attempt to inform the likelihood of cancer relapse earlier than standard of care tools. Whole-exome sequencing of an individual's tumor tissue is first performed, allowing the identification of clonal somatic mutations which are expected to be present in all cells for the individual's specific tumor. The test is customized to an individual through selection of 16 clonal, single nucleotide variants (SNVs). After customization, a blood sample may be obtained from the individual, from which the 16 SNVs may be amplified and detected. An individual is considered MRD-positive when at least two SNVs from the set of 16 are detected. According to the test makers, "a positive Signatera™ result predicts relapse with overall positive predictive value more than 98%" (Natera, 2024).

NavDx is a blood test developed by Naveris that detects trace amounts of HPV-associated tumor DNA in the bloodstream, specifically targeting residual disease or early recurrence of HPV-driven oropharyngeal cancers. It detects and analyzes the tumor tissue modified viral (TTMV)-HPV DNA fragments released by dying cancer cells to provide a TTMV-Score. The test indicates cancer activity before it is visible through imaging or other diagnostics (NavDx, 2024).

Analytical Validity

The EuroFlow Consortium has reported on the analytical validity of the use of an 8-color mFC for MRD. Theunissen et al. (2017) reported on the use of this methodology for B-cell precursor (BCP) ALL in a multicenter study (319 patients). Using samples containing more than four million cells, they note concordant results in 93% of samples, and "[m]ost discordances were clarified upon high-throughput sequencing of antigen-receptor rearrangements and blind multicenter reanalysis of flow cytometric data, resulting in an unprecedented concordance of 98% (97% for samples with MRD < 0.01%). In conclusion, the fully standardized EuroFlow BCP-ALL MRD strategy is applicable in >98% of patients with sensitivities at least similar to RQ-PCR ($\leq 10^{-5}$), if sufficient cells (>4 × 10^6, preferably more) are evaluated" (Theunissen et al., 2017). Another study reports the use of next-generation flow cytometry (NGF) using an "optimized 2-tube 8-color antibody panel" in five cycles to further increase the sensitivity. The authors report "a higher sensitivity for NGF-MRD vs conventional 8-color flow-MRD -MRD-positive rate of 47 vs 34% (P=0.003). Thus, 25% of patients classified as MRD-negative by conventional 8-color flow were MRD-positive by NGF, translating into a significantly longer progression-free survival for MRD-negative vs MRD-positive CR [complete response] patients by NGF (75% progression-free survival not reached vs 7 months; P=0.02)." Another study using a single-tube 10-fluorochrome analysis NGF method of MRD in myeloma reports a five-fold increase over the target minimum of 5 X 10^6 white blood cells per acquisition (Royston et al., 2016).

The FDA included an assessment of the analytical validity of ClonoSEQ in their approval summary of a *de novo* request evaluation. A total of 23 patients with MM, 21 patients with ALL, and 22 patients with other lymphoid malignancies were included. The study tested three different volumes of DNA: 500ng, 2µg, and 20 µg. Six MRD levels were tested for each sample, corresponding to the following amounts of malignant cells: 2.14, 6.13, 21.44, 61.26, 214.40, and 612.56. The authors found the coefficients of variance (%CV) to range from 72% at 2.14 cells to 21% at 612.56 cells. The authors noted that this precision trend was predictable, as ClonoSEQ is dependent on the number of cells evaluated instead of the actual MRD frequency. Regarding DNA extraction reproducibility, all samples were found to pass the "pre-established acceptance criteria of ± 30% MRD frequency." Regarding precision of the

nucleotide/base cells, the authors created a set of "baseline calibrating clonotype nucleotide sequences." From this set, replicates of each sample used to create the calibration sequence were created and the disagreement rate was identified. Out of 442.5 million nucleotides, ClonoSEQ was found to have a disagreement rate of 3.5 parts per million. The FDA notes a Phred Score of >30 is considered a "high-quality base call for NGS applications"; ClonoSEQ had a Phred Score of 44.5. When compared to multiparametic flow cytometry (mpFC), both ClonoSEQ and mpFC were tested at five dilutions (from $5x10^{-7}$ to $1x10^{-2}$)s and both techniques were found to be of similar accuracy at frequencies above 1×10^{-4} (FDA, 2018).

In 2020, the FDA made a substantially equivalent decision on ClonoSEQ, providing in their summary an assessment with further analytical validity. Here, they looked at patients with CLL, measuring MRD levels from gDNA samples extracted from either bone marrow (22 patients) or blood samples (15 patients). The study tested six MRD levels in three different volumes of DNA: 500ng, 2µg, and 20 µg. In bone marrow samples, precision ranged from 59% CV at 2.14 cells to 20% CV at 612.56 cells. In blood samples, precision ranged from 53% CV at 3.10 cells to 19% CV at 765.70 cells. The authors note that "like BMA [bone marrow aspirate], the precision of the clonoSEQ assay in CLL blood is largely dependent on the number of malignant cells that are being evaluated by the assay." From these data and those presented in the 2018 *de novo* approval document, the indications for use were developed. The authors report that "the clonoSEQ Assay measures minimal residual disease (MRD) to monitor changes in burden of disease during and after treatment. The test is indicated for use by qualified healthcare professionals in accordance with professional guidelines for clinical decision-making and in conjunction with other clinicopathological features" (FDA, 2020).

Othman Al-Sawaf et al. (2020) analyzed the clonal growth patterns of patients treated with venetoclax-obinutuzumab therapy within the CLL14 trial. In this case, MRD was analyzed using NGS via the adaptive clonoSEQ assay with cutoffs of 10^{-4}, 10^{-5}, and 10^{-6}; "the limit-of-quantification of the clonoSEQ assay is less than 10^{-6}." A total of 432 patients with untreated CLL were either treated with chlorambucil or venetoclax, in combination with 8binutuzumab for the first six cycles. Using samples from peripheral blood (PB) collected every three to six months until nine years from last patient enrollment, the researchers found that two months post-treatment completion, among patients treated with venetoclax and obinutuzmab, 40% had uMRD levels $<10^{-6}$, 26% had uMRD levels that were $\geq 10^{-6}$ and $<10^{-5}$, 8% had uMRD levels $\geq 10^{-5}$ and $<10^{-4}$, 5% had uMRD levels $\geq 10^{-4}$ and $<10^{-2}$, and 3% had uMRD levels $\geq 10^{-2}$. In comparison, among patients treated with chlorambucil and obinutuzmab, 7% had uMRD levels $<10^{-6}$, 13% had uMRD levels $\geq 10^{-6}$ and $<10^{-5}$, 14% had uMRD levels $\geq 10^{-5}$ and $<10^{-4}$, 21% had uMRD levels $\geq 10^{-4}$ and $<10^{-2}$, and 26% had uMRD levels $\geq 10^{-2}$. Furthermore, "In a

PFS landmark analysis after [end of treatment], patients in the [venetoclax-obinutuzumab] arm with MRD levels ≤ 10^{-5} had a 2-year PFS after [end of treatment] of approximately 93%, while patients with detectable MRD >10^{-2} had a 2-year PFS of [approximately] 37%." The average growth rate among patients treated with venetoclax-obinutuzumab was lower compared to the contrasting arm, and thus had a larger MRD doubling time. Because the clonal growth rate was lower, the study, using NGS, indicated "more effective MRD eradication and clonal growth modulation" (Othman Al-Sawaf et al., 2020; O. Al-Sawaf et al., 2020).

Nguyen Hoang et al. (2024) studied the analytical validity and clinical utilization of K-4CARE™, a comprehensive genomic profiling assay that integrates ctDNA tracking for residual cancer surveillance. K-4CARE™ is proposed to be a more time-efficient and tissue-efficient method than single or small gene panel testing. The assay tests for 473 cancer-relevant genes with a total length of 1.7 Mb. The authors rested the assay with 155 samples from 10 cancer types. "For detection of somatic SNVs and Indels, gene fusion and amplification, the assay had sensitivity of >99%, 94% and >99% respectively, and specificity of >99%." Furthermore, "when CGP-informed mutations were used to personalize ctDNA tracking, the detection rate of ctDNA in liquid biopsy was 79%, and clinical utility in cancer surveillance was demonstrated in 2 case studies." The authors concluded that the K-4CARE™ assay is "comprehensive and reliable" as a biomarker test for targeted therapy and immunotherapy. The authors also state that "integration of ctDNA tracking helps clinicians to further monitor treatment response and ultimately provide well-rounded care to cancer patients" (Nguyen Hoang et al., 2024).

Gunning et al. (2023) investigated the DNA stability and the ability to detect TTMV-HPV DNA analytes from patient samples stored in Streck collection tubes over a seven day interval. The ESR1 gene was chosen as the analyte for DNA stability analysis; DNA recovery was reported as the average, minimum, and maximum detected ESR1 per mL of plasma isolated. TTMV-HPV analyte detection was accomplished by measuring the TTMV-HPV DNA percent positivity rate, tracked daily. Percent positivity for TTMV-HPV DNA remained consistently between 26.2% - 32.5% from days one to seven. The average ESR1 values trended upward and more than doubled between days 1-6, which may be due to an increase in cellular lysis and DNA release within the sample over time. The LODs (limit of detection) for TTMV-HPV16, 18, 31, 33 and 35 DNA were reported to be: 0.56, 1.31, 0.63, 1.10 and 0.57 copies per microliter (copies/µL); LOQs (limit of quantitation) were reported as <1.20, 3.56, 4.11, 4.00, and 3.50 copies/ µL. The analytical specificity of this study was reported to be between 0 and 0.32 copies/µL for the five high-risk HPV subtypes. The authors investigated "the ability of the NavDx test to obtain a response that is directly proportional to the concentration of analyte standard." It was determined that all five HPV serotypes demonstrated linearity down

to the limit of quantitation. The coefficients of determination (R2) equaled one for all serotypes at all timepoints. Intra-assay and inter-assay precision were investigated through determination of % CVs (coefficients of variation) of the measured concentrations of each HPV serotype:

Dilution *	%CVs of Mean Effective Concentration (Copies/µL)									
	Intra-Assay					Inter-Assay				
	TTMV-HPV16	TTMV-HPV18	TTMV-HPV31	TTMV-HPV33	TTMV-HPV35	TTMV-HPV16	TTMV-HPV18	TTMV-HPV31	TTMV-HPV33	TTMV-HPV35
1:1	2.1	2.7	2.2	3.0	1.4	2.9	2.4	1.9	2.5	1.9
1:4	2.1	2.1	1.0	1.5	3.5	3.3	3.6	2.6	4.3	3.8
1:20	3.3	2.7	3.0	5.4	1.2	4.7	2.9	6.3	4.9	3.0
1:40	2.0	6.2	8.0	11.5	1.1	4.6	5.4	7.5	8.4	6.4
1:100	12.2	10.1	9.0	5.3	7.1	7.5	11.9	10.8	10.8	5.8
1:200	13.3	13.8	7.2	13.9	4.7	9.0	20.0	16.5	13.1	11.2

Table 4. Intra-assay precision (repeatability) and inter-assay precision (within-lab on differing days), reflected by percent relative standard deviations of effective concentrations of the five TTMV-HPV DNA types measured at six concentrations in triplicate.

Table borrowed from Gunning et al. (2023).

Clinical Utility and Validity

The FDA *de novo* approval document for ClonoSEQ contains two clinical validation studies. The first study for MM in ClonoSEQ's *de novo* approval document (DFCI 10-106) included 323 patients. The authors intended "to assess the ability of clonoSEQ to predict progression-free survival (PFS) and disease-free survival (DFS)." At the time of first MRD measurement, ClonoSEQ was found to be predictive of PFS at the MRD threshold of 10^{-5}. Each 10-fold increase in MRD level was associated with a 70% increase in "event" rate across all MRD values (FDA, 2018).

A second clinical validation study described in the FDA's *de novo* approval document was for ALL (AALL0232, AALL0331). A total of 273 samples were included (210 MRD $\leq 10^{-4}$, [negative], 63 MRD > 10^{-4} [positive]). The authors report that clonoSEQ MRD-negativity status was found to predict event-free survival (EFS) at all ages. MRD-positivity status was also associated with a 2.74-fold higher event risk compared to MRD-negativity status. Across all MRD values, a 10-fold increase in clonoSEQ MRD measurement was associated with a 50% increase in event rate and MRD-negative patients were found to have longer EFS compared to patients with higher frequencies of malignancies (FDA, 2018).

The FDA's 2020 substantially equivalent approval document for ClonoSEQ analyzed two separate studies to "support that MRD as estimated with the clonoSEQ Assay is prognostic of patient outcomes in CLL…" The first study was for CLL (NCT02242942) and included 337 patients to evaluate the ability of ClonoSEQ to predict PFS. Samples were collected three months or later following treatment (FUM3) and MRD positivity

was defined as >1 x 10^{-5} [malignant cells]. Patients found to be MRD-positive had an "event risk" 6.64 times higher than the MRD-negative cohort. A 10-fold increase in MRD was also associated with a 2.35-fold increase in event risk. The authors also analyzed the results for other confounding factors and found "that the MRD level at FUM3 is a stronger predictor of PFS than age, sex, geographic region, Binet stage, or treatment arm of the clinical trial. Together, these results demonstrate the clinical validity of MRD measurement in CLL." This study also found that "patients with clonoSEQ MRD ≤ 10^{-6} or between 10^{-6} and 10^{-5} had longer PFS, followed by patients with MRD between 10^{-5} and 10^{-4} and patients with MRD ≥ 10^{-4} (log-rank P = 4.902 x 10-31, Figure 11). These data demonstrate that patients with MRD ≤ 10^{-5} have better outcomes than patients with MRD > 10^{-5}, and that increasing MRD levels above 10^{-5} are associated with an increased risk of progression within the follow-up time of this study" (FDA, 2020).

The second clinical validation described in FDA's 2020 substantially equivalent approval document was also for CLL (NCT00759798). This study was a "phase 2 clinical trial that evaluated six cycles of fludarabine, cyclophosphamide, and rituximab (FCR) in 111 front-line chronic lymphocytic leukemia (CLL) patients with clonoSEQ ID samples and a corresponding 137 clonoSEQ MRD samples also evaluated by 4-color flow cytometry at an MRD threshold of 10-4 (NCT00759798) and with pertinent co-variate data. Within this cohort of 111 patients with flow MRD results, bone marrow was available for 75 patients and blood was available for 62 patients, of which 26 patients provided both blood and bone marrow. Due to some missing clinical covariates, three patients that provided bone marrow only, were excluded from analyses requiring these covariates. There was an association between PFS and continuous clonoSEQ MRD measurement in both blood and bone marrow, after end of treatment, where PFS is defined as the time from start of treatment until death, disease progression, or last time of disease assessment (p = 9.66 x 10^{-4} for blood, p = 2.13 x 10^{-4} for bone marrow). Additionally, patients who were MRD negative at a threshold ≤ 10^{-5} had superior progression-free survival compared to patients with MRD > 10^{-5} (p = .02 for blood and p = 8.17 x 10^{-5} for bone marrow… Taken together these results support the use of the clonoSEQ assay in CLL patients" (FDA, 2020).

Hay et al. (2019) evaluated the impact of MRD negativity status on relapse rates of ALL patients that post-chimeric antigen receptor [CAR] T-cell therapy. Per flow cytometry, 45 of 53 patients achieved an MRD-negative status. At a median follow-up of 30.9 months, the authors found that EFS and overall survival (OS) were significantly better in patients achieving MRD-negativity than patients that did not (median EFS: 7.6 months vs 0.8 months; median OS: 20 months vs five months). The authors also identified that the cytometric absence of the *IGH* index malignant clone was associated with better EFS (Hay et al., 2019).

Herrera et al. (2016) evaluated "whether the presence of ctDNA [circulating tumor DNA, measured with next-generation sequencing] was associated with outcome after allogeneic haematopoietic stem cell transplantation (HSCT) in lymphoma patients." A total of 88 patients were included from a "phase 3 clinical trial of reduced-intensity conditioning HSCT in lymphoma." Patients with detectable ctDNA three months after HSCT were found to have inferior progression-free survival compared to patients without detectable ctDNA (58% vs 84%, 2-year PFS rate). Detectable ctDNA was confered a 10.8-times higher risk of relapse/progression and a 3.9-times higher risk of progression/death compared to the non-detectable ctDNA group. The authors concluded that "detectable ctDNA is associated with an increased risk of relapse/progression, but further validation studies are necessary to confirm these findings and determine the clinical utility of NGS-based minimal residual disease monitoring in lymphoma patients after HSCT" (Herrera et al., 2016).

Perrot et al. (2018) examined the prognostic value of MRD (measured with NGS) in MM cases. A total of 127 patients achieved MRD negativity (defined as "the absence of tumor plasma cell within 1 000 000 bone marrow cells ($<10^{-6}$) at least once during maintenance therapy. At the start of therapy, MRD was found to be a strong prognostic factor for both progression-free survival as well as overall survival (hazard ratio = .22 and .24 respectively). From a previous cohort, the authors identified 233 patients labeled as MRD-negative, of which 120 were confirmed as MRD-negative with NGS (52%)" (Perrot et al., 2018).

Friend et al. (2020) investigated the impact of NGS-MRD in predicting relapse in ALL patients. Total body irradiation (TBI)-based regimens were the standard of care for ALL patients requiring allogeneic HSCT, but this procedure has numerous harmful side effects. The authors hypothesized that identifying MRD-negative patients may help some individuals avoid exposure to this radiation. The authors examined outcomes of 57 patients that received TBI and non-TBI regimens and found that relapse rates were similar for both methods of treatment. However, NGS-MRD positivity prior to treatment was "highly" predictive of relapse (for up to three years post-transplant). Based on their data, the authors suggested "that the decision to use either a TBI or non-TBI regimens in ALL should depend on NGS-MRD status, with conditioning regimens based on TBI reserved for patients that cannot achieve NGS-MRD negativity prior to allogeneic HSCT" (Friend et al., 2020).

Thörn et al. (2011) performed a comparative analysis of MFC and real-time quantitative polymerase chain reaction (RT-qPCR)-based MRD in pediatric ALL. The study, consisting of 726 follow-up samples from 228 children, used an MRD threshold of 0.1% and reported at day 29 a 84% concordance between the two different methods. For B-cell precursor ALL, the authors note that MFC was better at discriminating higher risk

of bone marrow relapse (BMR), whereas RT-qPCR performed better for T-ALL. Regardless, the authors state, "MRD levels of ≥0.1%, detected by either method at day 29, could not predict isolated extramedullary relapse." They conclude that "both methods are valuable clinical tools for identifying childhood ALL cases with increased risk of BMR" (Thörn et al., 2011).

Wood et al. (2018) compared high-throughput sequencing (HTS) of *IGH* and *TRG* genes to flow cytometry (FC) to evaluate measurable residual disease detection at the end of induction chemotherapy in pediatric patients with newly diagnosed B-ALL [B-cell acute lymphoblastic leukemia]. A total of 619 paired pre-treatment and end of induction bone marrow samples were included. At an MRD threshold of 0.01%, both HTS and FC showed similar event-free survival (EFS) and OS for both MRD-positive and MRD-negative patients. However, HTS identified 55 more patients as "MRD-positive" compared to FC. These "discrepant" patients were found to have worse outcomes than FC MRD-negative patients. HTS was also found to identify 19.9% of "standard risk" (SR) without MRD at any detectable level with excellent EFS and OS (98.1% and 100% respectively). The authors suggested that "the higher analytic sensitivity and lower false-negative rate of HTS improves upon FC for MRD detection in pediatric B-ALL by identifying a novel subset of patients at end of induction who are essentially cured using current chemotherapy and identifying MRD at 0.01% in up to one-third of patients who are missed at the same threshold by FC" (Wood et al., 2018).

Rawstron et al. (2016) conducted a parallel analysis of MRD using both ClonoSEQ and multiparameter flow cytometry in CLL as part of the European Research Initiative on CLL (ERIC) study. The MFC approach used within the ERIC study is validated to the level of 10^{-5} and consists of six different markers—CD5, CD19, CD20, CD43, CD49b, and CD81. The ERIC study reports that the ClonoSEQ method "provides good linearity to a detection limit of one in a million (10^{-6})." The authors also note, "a parallel analysis of high-throughput sequencing using the ClonoSEQ assay showed good concordance with flow cytometry results at the 0.010% (10^{-4}) level, the MRD threshold defined in the 2008 International Workshop on CLL guidelines… The combination of both technologies would permit a highly sensitive approach to MRD detection while providing a reproducible and broadly accessible method to quantify residual disease and optimize treatment in CLL" (Rawstron et al., 2016).

Thompson et al. (2019) evaluated 62 patients with CLL that were considered negative for MRD by flow cytometry (sensitivity of 10^{-4}). Using ClonoSEQ, the authors found that 72.6% of these MRD-negative patients were MRD-positive by ClonoSEQ (a discordant result). Only 27.4% of patients were found to be negative by both methods. The authors also found that patients that were negative by both methods were found to have superior PFS compared to patients that were only negative by flow cytometry,

thereby suggesting that ClonoSEQ was a superior prognostic discriminator (Thompson et al., 2019).

Z. Wang et al. (2019) published a study on the applicability of multiparameter (multicolor) flow cytometry (MFC) for detecting MRD to predict relapse in patients with AML after allogeneic transplantation. The researchers determined MFC and MRD status using real-time quantitative polymerase chain reaction (RT-qPCR) from 158 bone marrow samples from 44 different individuals and compared the statuses between the two. They noted that "Strong concordance was found between MFC-based and RT-qPCR-based MRD status (κ = 0.868)." Moreover, for individuals in complete remission (CR), "the positive MRD status detected using MFC was correlated with a worse prognosis [HRs (*P* values) for relapse, event-free survival, and overall survival: 4.83 (<0.001), 2.23 (0.003), and 1.79 (0.049), respectively]; the prognosis was similar to patients with an active disease before HSCT [hematopoietic stem cell transplantation]" (Z. Wang et al., 2019).

Carlson et al. (2019) published a cost-effectiveness study of NGS-based MRD testing during maintenance treatment for MM. The authors compared use of MRD testing to no MRD testing. A Markov model with six health states was developed; "MRD positive or MRD negative, on or off treatment, relapsed, or dead." From there, the authors compared yearly NGS-MRD to no MRD testing over a lifetime horizon. Overall, the authors found that "MRD testing saved $1,156,600 over patients remaining lifetime." Health outcomes were found to slightly favor MRD testing (0.01 quality-adjusted life years [QALYs]) compared to no testing. The authors concluded that "NGS MRD testing is cost saving, with potential QALY gains due to avoidance of [treatment-related adverse events] compared with no testing for MM patients on maintenance therapy" (Carlson et al., 2019).

Medina et al. (2020) evaluated MRD three months after transplantation in 106 myeloma patients, noting that "detecting persistent minimal residual disease (MRD) allows the identification of patients with an increased risk of relapse and death." In this study, they compared the results of NGS with NGF, where they noted that "correlation between NGS and NGF was high (R2 = 0.905). The three-year PFS rates by NGS and NGF were longer for undetectable vs. positive patients (NGS: 88.7% vs. 56.6%; NGF: 91.4% vs. 50%; p < 0.001 for both comparisons), which resulted in a three-year overall survival (OS) advantage (NGS: 96.2% vs. 77.3%; NGF: 96.6% vs. 74.9%, p < 0.01 for both comparisons). In the Cox regression model, NGS and NGF negativity had similar results but favoring the latter in PFS (HR: 0.20, 95% CI: 0.09-0.45, p < 0.001) and OS (HR: 0.21, 95% CI: 0.06-0.75, p = 0.02). All these results reinforce the role of MRD detection by different strategies in patient prognosis and highlight the use of MRD as an endpoint for multiple myeloma treatment" (Medina et al., 2020).

Goicoechea et al. (2021) examined MRD as a possible endpoint marker in MM. They note that while patients with MM that carry standard- or high-risk cytogenetic abnormalities (CA) are achieving similar CR rates, high-risk patients have an inferior PFS. They note that this "questions the legitimacy of CR as a treatment endpoint..." Using NGF cytometry to evaluate MRD in MM patients, they compared standard- vs high-risk CAs (n=300 and 90, respectively) and identified mechanisms that determine MRD resistance in both patient subgroups (n=40). In patients achieving undetectable MRD with either standard- or high-risk CAs, the 36-month PFS rates were higher than 90%. In comparison, patients with persistent MRD had a median PFS of about three (standard-risk CA) and two (high-risk CA) years. They found that "further use of NGF to isolate MRD, followed by whole-exome sequencing of paired diagnostic and MRD tumor cells, revealed greater clonal selection in patients with standard-risk CAs, higher genomic instability with acquisition of new mutations in high-risk MM, and no unifying genetic event driving MRD resistance." Ultimately, their results support "undetectable MRD as a treatment endpoint for patients with MM who have high-risk CAs and proposes characterizing MRD clones to understand and overcome MRD resistance" (Goicoechea et al., 2021).

Subhash et al. (2022) investigated the "feasibility of using whole-genome sequencing (WGS) data to design tumour-specific polymerase chain reaction (PCR)-based MRD tests (WGS-MRD)" for children with cancers with high-risk of relapse, like ALL, high-risk neuroblastoma (HR-NB), and Ewing sarcoma (EWS). The significance of this study was that pediatric solid tumor MRD DNA-based assays currently remains experimental, and remains focused on mRNA, methylated DNA, or microRNA. Through their experimentation, the researchers found that "sensitive WGS-MRD assays were generated for each patient and allowed quantification of 1 tumour cell per 10^{-4} (0.01%)-10^{-5} (0.001%) mononuclear cells." They also found that WGS-MRD and Ig/TCR-MRD assays were concordant in ALL, and the WGS-MRD assays "showed good concordance between quantitative PCR and droplet digital PCR formats." The WGS-MRD assay clinical samples also correlated with disease course and was found to be more sensitive than RNA-based MRD assays. This demonstrated how WGS could aid the development of MRD assays for pediatric cancers as it has been done in adults (Subhash et al., 2022).

Kater et al. (2019) utilized the MURANO study to investigate the effects of a fixed duration treatment with venetoclax and ritixumab on MRD. The study itself demonstrated "significant progression-free survival (PFS) benefit for fixed-duration venetoclax-rituximab compared with bendamustine-rituximab in relapsed/refractory chronic lymphocytic leukemia." However, among patients who received venetoclax-rituximab, there was a "higher rate of PB [peripheral blood] undetectable MRD (uMRD; less than 10^{-4}) at EOCT [end of combination therapy] (62% v 13%) with superiority

sustained through month 24 (end of therapy)," which predicted longer PFS. At the end of the therapy treatment period, 70% of patients remained in uMRD and 98% without disease progression. This demonstrated the correlation between uMRD and PFS using PB MRD in the setting of venetoclax-combination treatment (Kater et al., 2019).

Kim et al. (2022) investigated the clinical utility of NGF-based MRD assessment in a heterogeneous population of patients with MM at the Samsung Medical Center in Korea and found that "sCR samples showed a lower MRD-positive rate (25%) than CR (43%) and VGPR (53%) samples, although the difference was not significant (P=0.051)." When evaluating survival analysis based on clinical response and MRD, "PFS in VGPR patients was lower than that in sCR/CR patients (P<0.001) …whereas PFS in VGPR patients was lower than that in sCR/CR patients (P<0.001)." Cytogenetic risk survival analysis yielded similar results: "There was no significant difference in PFS between patients with high-risk and standard-risk cytogenetics (P=0.222)" and "Further analysis according to MRD status also revealed no significant difference in PFS in patients with standard-risk cytogenetics (P=0.246)," though it is worth noting that "among patients with high-risk cytogenetics, MRD-positive patients showed lower PFS than MRD-negative patients (P=0.016)." Overall, the authors concluded that "Sustained MRD negativity was only observed in patients with sustained sCR, and their PFS was superior to that of patients who were not MRD-negative (P=0.035)," though by their own admission the study was limited by the sample size (n=12 over 18 months) (Kim et al., 2022).

There is a growing pool of literature investigating the use of ctDNA-based MRD detection in the clinical context of solid tumors. Some studies suggest that inclusion of MRD assessment may offer some improvement over standard of care; this has been reported for gastrointestinal malignancies (Zhang et al., 2021), skin cancer (Eroglu et al., 2023; Khaddour et al., 2022), lung cancer (Zhong et al., 2023), and especially colorectal cancer, where several reports demonstrate potential benefits of ctDNA measurement, which include response monitoring, prognosis, post-surgical surveillance, chemotherapeutic management, and informing recurrence risk (Hofste et al., 2023; Sato et al., 2023; Tie et al., 2019; Tie et al., 2016; Y. Wang et al., 2019).

Signatera™ has been clinically validated across several cancer types for recurrence monitoring. In the context of colorectal cancer, Loupakis et al. (2021) demonstrated that a two-timepoint analysis of ctDNA (a baseline measure plus last follow-up time point–either the time of radiologic progression or last evidence of radiologic disease's absence) improved the sensitivity of the assay. For patients who were ctDNA positive at both timepoints, the authors reported that the assay demonstrated a sensitivity of 91.4%, specificity of 93.3%, and positive predictive value (PPV) of 96.7%. Reinert et al. (2019) also investigated the validity of ctDNA for MRD detection for individuals with

stages I-III colorectal cancer and reported promising metrics; the test demonstrated a sensitivity of 88%, specificity of 98%, PPV of 93.3%, and negative predictive value (NPV) of 96.7%. However, Fakih et al. (2022) recently determined that Signatera™ may not "provide advantages as a surveillance strategy compared with standard imaging combined with CEA levels when performed per National Comprehensive Cancer Network guidelines," after a cohort study failed to demonstrate a sufficient ability (sensitivity) of the test to detect disease recurrence in individuals with resected colorectal cancer.

Coombes et al. (2019) described the ability of ctDNA to detect disease recurrence ahead of clinical or radiological approaches for individuals with breast cancer with a sensitivity of 89%, specificity of 100%, PPV of 100%, and NPV of 94%. Christensen et al. (2019) found that ctDNA accurately identified individuals diagnosed with advanced bladder cancer who eventually relapsed (sensitivity of 100% and specificity of 98%). For individuals with non-small cell lung cancer, Abbosh et al. (2017) reported that Signatera™ detected relapse with 93% sensitivity and 90% specificity.

While evidence supporting MRD analysis for solid tumors continues to emerge, a consensus on the clinical validity and utility of this approach has not yet been reached. Sullivan et al. (2023) cite several limitations of ctDNA-based approaches to the management of gastrointestinal cancer; O'Sullivan et al. (2023) argue that the utility of this technology in the context of non-small cell lung cancer is still investigational; Moding et al. (2021) cite a lack of prospective clinical trials confirming clinical utility of ctDNA MRD assessment in general; and, Jacome and Johnson (2023) argue that there is not yet consensus on how to apply the results of ctDNA-based testing in the management of colorectal cancer.

Faulkner et al. (2023) conducted a systematic review and meta-analysis to study the utility of ctDNA for detecting MRD in colorectal cancer. The review included 37 studies involving 3002 patients. The authors calculated hazard ratios and PFS based on ctDNA detection. Overall, there was a "poorer" PFS associated with ctDNA detection at the first liquid biopsy post-surgery, with a hazard ratio of 6.92. Further, "this effect was also seen in subgroup analysis by disease extent, adjuvant chemotherapy and assay type." The authors conclude that "ctDNA detection post-surgery is associated with a greater propensity to disease relapse and is an independent indicator of poor prognosis," but note that "prior to incorporation into clinical practice, consensus around timing of measurements and assay methodology are critical" (Faulkner et al., 2023).

Berger et al. (2022) evaluated the use of circulating tumor tissue modified viral (TTMV)-HPV DNA as a biomarker for detecting recurrence in patients with HPV-driven oropharyngeal squamous cell carcinoma (OPSCC). The authors conducted a

retrospective analysis of 1,076 patients from 108 U.S sites who were at least three months post-treatment and had undergone TTMV-HPV DNA testing (NavDx) during routine surveillance between February 2020 and June 2021. The results determined that 80 out of 1,076 (7.4%) tested positive for TTMV-HPV DNA. Among these, 21 patients had known recurrences at the time of the first positive test, while 59 did not, and 93% of the latter group subsequently developed confirmed recurrences. The overall positive predictive value for the TTMV-HPV DNA test was 95%, and the negative predictive value was also 95%. These findings suggest that TTMV-HPV DNA testing can serve as an effective surveillance tool, often identifying recurrences earlier than traditional clinical evaluations and imaging techniques, and may influence future surveillance strategies for HPV-related cancers (Berger et al., 2022).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN has published several relevant guidelines on management of MRD in hematologic malignancies.

Multiple Myeloma (MM)

For MM, MRD is considered an "important" prognostic factor. The NCCN recommends measuring MRD during follow-up/surveillance for symptomatic MM patients after response to primary therapy "as indicated for prognostication." Next-generation flow and next-generation sequencing (or both) are recommended for methodology and a sensitivity of 1 in 10^5 (or better) is recommended for accuracy. The NCCN recommends to "consider baseline clone identification and storage of aspirate sample for future minimal residual disease (MRD) testing by NGS." MRD is a required criterion listed within the IMWG MM response criteria. The NCCN notes that "for MRD there is no need for two consecutive assessments, but information on MRD after each treatment state is recommended (eg, after induction, high-dose therapy/Autologous stem cell transplant (ASCT), consolidation, maintenance). MRD tests should be initiated only at the time of suspected complete response." Sustained MRD-negative status is only confirmed when taken a minimum of one year apart, but "subsequent evaluations can be used to further specify the duration of negativity (eg, MRD-negative at 5 years)." The NCCN also notes that MRD is being used in post-hematopoietic stem cell transplantation treatment assessments (NCCN, 2024e).

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

The NCCN remarks that "undetectable MRD in the peripheral blood at the end of fixed duration treatment is an important predictor of efficacy." The NCCN recommends

performing MRD assessment with an assay at a sensitivity of 10^{-4} "according to the standardized European Research Initiative on CLL (ERIC) method or standardized NGS method." NCCN also stated that "allele-specific oligonucleotide polymerase chain reaction (ASO-PCR) and six-color flow cytometry (MRD flow) are the two validated methods used for the detection of MRD at the level of 10^{-4} to 10^{-5}. NGS-based assays have been shown to be more sensitive, thus allowing for the detection of MRD at the level of 10^{-6}" (NCCN, 2024c).

Acute Myeloid Leukemia (AML)

The NCCN recommends measuring MRD "upon completion of initial induction" and "before allogenic HCT." The NCCN also states, "Additional time points should be guided by the regimen used." NGS-based assays to detect mutated genes are not routinely used in AML, as the sensitivity of PCR-based assays and flow cytometry is superior to what is achieved by NGS. The NCCN states that "if using flow cytometry to assess MRD, it is recommended that a specific MRD assay is utilized, but, most importantly, that it is interpreted by an experienced hematopathologist" since there are differences between "diagnostic threshold assessments and MRD assessments." They also note that "some evidence suggest MRD testing may be more prognostic than *KIT* mutation status in CBF-AML, but this determination depends on the method used to assess MRD and the trend of detectable MRD." The NCCN further states that "Based on the techniques, the optimal sample for MRD assessment is either peripheral blood (NPM1 PCR-based techniques) or an early, dedicated pull of the BM aspirate (i.e., other PCR, flow cytometry, NGS). The quality of the sample is of paramount importance to have reliable evaluation" (NCCN, 2024b).

Acute Lymphoblastic Leukemia (ALL)/Pediatric Acute Lymphoblastic Leukemia

The NCCN states that MRD quantification is an "essential component of patient evaluation over the course of sequential ALL therapy," noting the prognostic significance of MRD. Techniques used to assess for MRD include: flow cytometry assays, real-time quantitative PCR assays, reverse transcriptase quantitative PCR assays, and NGS-based assays. NGS is recognized as one of the most sensitive methods at detection levels of 10^{-6}, as can some PCRs. An entire section within the ALL guidelines is devoted to MRD assessment. They note the timing of MRD assessment to be as follows:

- Upon completion of initial induction.
- End of consolidation.
- Additional time points should be guided by the regimen used and risk features.
- Serial monitoring frequency may be increased in patients with molecular relapse or persistent low-level disease burden.

- For some techniques, a baseline sample (i.e., prior to treatment) is needed to characterize the leukemic clone for subsequent MRD assessment.

The guidelines also recommend "For patients with negative MRD by flow cytometry but positive MRD by an FDA-approved NGS assay, consider repeat testing before consolidation is started to confirm MRD status" (NCCN, 2024a). Overall, MRD has a strong correlation with risks for relapse and is considered to have a high prognostic value. MRD has a role in identifying optimal treatments for patients, both adult and pediatric, with ALL (NCCN, 2024a, 2024f).

Hairy Cell Leukemia

The NCCN writes that, for a complete response (CR) with or without MRD, "if CR is achieved, an IHC [immunohistochemistry] assessment of the percentage of MRD will be useful to stratify patients based on level of CR (with or without evidence of MRD)". The NCCN notes that "it has been suggested that MRD monitoring as a component of response assessment should be incorporated in all clinical trials for relapsed HCL" but clarifies that "MRD assessment is not recommended (outside of clinical trials) as part of response evaluation" (NCCN, 2024d).

International Myeloma Working Group (IMWG)

The IMWG recommends assessing MRD response at a sensitivity of $1/10^5$ nucleated cells or better (Kumar et al., 2016).

European Myeloma Network (EMN)

Regarding NGS in assessment of MRD in MM, the EMN writes that "Results from next-generation sequencing are highly concordant with flow-based MRD detection, highly reproducible and reach a sensitivity of 10^{-6}" and that the primary restraints for NGS are "a lack of standardization and limited commercial availability" (Caers et al., 2018).

American Society of Clinical Oncology (ASCO) and Cancer Care Ontario (CCO)

These joint guidelines focus on treatment of MM. Their MRD-related recommendations are listed below:

- "There is insufficient evidence to make modifications to maintenance therapy based on depth of response, including MRD status"
- "MRD-negative status has been associated with improved outcomes, but it should not be used to guide treatment goals outside the context of a clinical trial"

- "There is insufficient evidence to support change in type and length of therapy based on depth of response as measured by conventional IMWG approaches or MRD"
- "There are not enough data to recommend risk-based versus response-based duration of treatment (such as MRD)" (Mikhael et al., 2019).

The ASCO also fully endorsed the "Initial Diagnostic Work-Up of Acute Leukemia" released jointly by the College of American Pathologists and the American Society of Hematology in 2018 (de Haas et al., 2018).

European LeukemiaNet (ELN) MRD Working Party

The ELN states, "Measurable residual disease (MRD; previously termed minimal residual disease) is an independent, postdiagnosis, prognostic indicator in acute myeloid leukemia (AML) that is important for risk stratification and treatment planning, in conjunction with other well-established clinical, cytogenetic, and molecular data assessed at diagnosis." The ELN remarks that quantitative PCR is applicable to approximately 40% of AML patients with "1 or more suitable abnormalities." However, NGS for MRD assessment may provide assessment to an additional 40%-50% of AML patients, as NGS can "theoretically, be applied to all leukemia-specific genetic aberrations." The ELN recommends a sensitivity of at least 1 / 103 cells, and states that NGS platforms will be used after careful validation (Schuurhuis et al., 2018).

International Workshop on Chronic Lymphocytic Leukemia (iwCLL)

The iwCLL published guidelines on CLL in 2018. In it, they consider MRD assessment to be a necessary component in identifying complete remission of CLL. The iwCLL also writes that eradication of leukemia is a "desired end point." They go on to state: "Use of sensitive multicolor flow cytometry, PCR, or next-generation sequencing can detect MRD in many patients who achieved a complete clinical response… Six-color flow cytometry (MRD flow), allele-specific oligonucleotide PCR, or high-throughput sequencing using the ClonoSEQ assay are reliably sensitive down to a level of <1 CLL cell in 10 000 leukocytes" (Hallek et al., 2018).

College of American Pathologists (CAP) and the American Society of Hematology (ASH)

This CAP/ASH joint guideline was published in 2017 and focuses on Initial Diagnostic Workup of Acute Leukemia (AL). The guideline strongly recommends that "For patients with suspected or confirmed AL, the pathologist or treating clinician should ensure that flow cytometry analysis or molecular characterization is comprehensive enough to

allow subsequent detection of MRD." The guideline also notes that MRD is a "powerful" predictor of adverse outcome in patients with AL (Arber et al., 2017).

This guideline was endorsed by the American Society of Clinical Oncology in 2018 (Arber et al., 2017).

European Society for Medical Oncology (ESMO)

Chronic Lymphocytic Leukaemia

The ESMO notes that "detection of MRD by multicolour flow cytometry or RT-PCR has a strong prognostic impact following CIT73,74 as well as venetoclax plus CD20-antibody combinations. A total of 75 patients with undetectable MRD after therapy show a longer response duration and survival. Additional clinical consequences of MRD positivity after therapy with respect to treatment escalation remain unclear… Therefore, MRD assessment is not generally recommended for monitoring after therapy outside clinical studies. This may change soon, as increasing efforts are made to determine whether therapy with targeted agents could be discontinued on the basis of MRD status" (B. Eichhorst et al., 2021). The guidelines are also endorsed by the European Hematology Association (Barbara Eichhorst et al., 2021).

Acute Lymphoblastic Leukaemia

The ESMO writes that "Quantification of MRD is a major and well-established risk factor and should be obtained whenever possible for all patients also outside of clinical trials…If MRD is measured by flow cytometry, a good MRD response is often defined as less than 10^{-3} , although MRD levels less than 10^{-4} can be achieved with the 8–12 colour flow cytometers" (Hoelzer et al., 2016).

Multiple Myeloma

The ESMO states, "One of the most significant improvements in the response criteria is the introduction of minimal residual disease (MRD) both in the bone marrow (BM) [using either next-generation sequencing or next-generation flow cytometry (NGF)] and outside the BM [using positron emission tomography-computed tomography (PET-CT); imaging MRD]. MRD negativity in the BM in patients who have achieved conventional complete response (CR) consistently correlates with prolonged progression-free survival (PFS) and overall survival (OS) in both newly diagnosed MM (NDMM) and relapsed/refractory MM (RRMM) patients." ESMO also notes that "MRD has been found to be a surrogate endpoint for PFS in patients receiving first-line treatment. Therefore, MRD may be used as an endpoint to accelerate drug development. The use of MRD to drive treatment decisions is under investigation" (Dimopoulos et al., 2021).

Acute Myeloid Leukaemia

The ESMO includes MRD status as part of the treatment algorithm for AML. They state, "Morphological enumeration of the blast percentage should be refined by immunophenotypic or molecular MRD assessment in patients with <10% blasts. ELN recommendations on MRD assessment in AML specify its clinical use and technical requirements. It is recommended to assess MRD by reverse transcriptase polymerase chain reaction (RT-PCR) for patients positive for *NPM1*^{mut}*, RUNX1-RUNX1T1, CBFB-MYH11* or *PML-RARA* fusion genes; ~40% of all AML patients. In the remaining patients, MRD should be assessed by MFC, which relies on antigens aberrantly expressed by leukaemic cells that can be found in >90% of AML patients. Many clinical studies have shown the strong prognostic impact of MRD, as measured by MFC, with levels 0.1% defined as positive" (Heuser et al., 2020).

Hairy Cell Leukaemia

Concerning hairy cell leukemia, ESMO notes, "Recently, monoclonal antibodies that detect the mutated BRAF protein have been developed and shown to be useful for the diagnosis and detection of minimal residual disease (MRD)." Within the section on response evaluation, ESMO states, "Immunophenotypic analysis of peripheral blood or bone marrow is not required but is useful to detect MRD… The eradication of MRD is generally not recommended in routine clinical practice. Assessment of response should be performed 4 – 6 months after treatment with 2-CldA and after 8 – 9 courses of DCF. Relapse is defined as any deterioration in blood counts related to the detection of hairy cells in peripheral blood and/or bone marrow" (Robak et al., 2015).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On August 5, 2020, the FDA approved ClonoSEQ, marketed by Adaptive Biotechnologies, as a substantially equivalent DNA-based test for minimal residual disease. It is "an in vitro diagnostic device that identifies and quantifies specific nucleic

acid sequences isolated from human specimens to estimate the percentage of cells that harbor the specific sequence pathology test." In its Decision Summary, the FDA states that the "The clonoSEQ Assay is an in vitro diagnostic that uses multiplex polymerase chain reaction (PCR) and next-generation sequencing (NGS) to identify and quantify rearranged IgH (VDJ), IgH (DJ), IgK and IgL receptor gene sequences, as well as translocated BCL1/IgH (J) and BCL2/IgH (J) sequences in DNA extracted from bone marrow from patients with B-cell acute lymphoblastic leukemia (ALL) or multiple myeloma (MM), and blood or bone marrow from patients with chronic lymphocytic leukemia (CLL). The clonoSEQ Assay measures MRD to monitor changes in burden of disease during and after treatment. The test is indicated for use by qualified healthcare professionals in accordance with professional guidelines for clinical decision-making and in conjunction with other clinicopathological-p features" (FDA, 2020).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
88184	Flow cytometry, cell surface, cytoplasmic, or nuclear marker, technical component only; first marker
88185	Flow cytometry, cell surface, cytoplasmic, or nuclear marker, technical component only; each additional marker (List separately in addition to code for first marker)
0171U	Targeted genomic sequence analysis panel, acute myeloid leukemia, myelodysplastic syndrome, and myeloproliferative neoplasms, DNA analysis, 23 genes, interrogation for sequence variants, rearrangements, and minimal residual disease, reported as presence/absence Proprietary test: MyMRD® NGS Panel Lab/Manufacturer: Laboratory for Personalized Molecular Medicine
0306U	Oncology (minimal residual disease [MRD]), next-generation targeted sequencing analysis, cell-free DNA, initial (baseline) assessment to determine a patient-specific panel for future comparisons to evaluate for MRD Proprietary test: Invitae PCM Tissue Profiling and MRD Baseline Assay Lab/Manufacturer: Invitae Corporation

0307U	Oncology (minimal residual disease [MRD]), next-generation targeted sequencing analysis of a patient-specific panel, cell-free DNA, subsequent assessment with comparison to previously analyzed patient specimens to evaluate for MRD Proprietary test: Invitae PCM MRD Monitoring Lab/Manufacturer: Invitae Corporation
0340U	Oncology (pan-cancer), analysis of minimal residual disease (MRD) from plasma, with assays personalized to each patient based on prior next-generation sequencing of the patient's tumor and germline DNA, reported as absence or presence of MRD, with disease-burden correlation, if appropriate Protietary test: Signatera™ Lab/Manufacturer: Natera, Inc
0356U	Oncology (oropharyngeal or anal), evaluation of 17 DNA biomarkers using droplet digital PCR (ddPCR), cell-free DNA, algorithm reported as a prognostic risk score for cancer recurrence Proprietary test: NavDx® Lab/Manufacturer: Naveris, Inc
0364U	Oncology (hematolymphoid neoplasm), genomic sequence analysis using multiplex (PCR) and next-generation sequencing with algorithm, quantification of dominant clonal sequence(s), reported as presence or absence of minimal residual disease (MRD) with quantitation of disease burden, when appropriate Proprietary test: clonoSEQ® Assay Lab/Manufacturer: Adaptive Biotechnologies
0422U	Oncology (pan-solid tumor), analysis of DNA biomarker response to anti-cancer therapy using cell-free circulating DNA, biomarker comparison to a previous baseline pre-treatment cell-free circulating DNA analysis using next-generation sequencing, algorithm reported as a quantitative change from baseline, including specific alterations, if appropriate. Proprietary test: Guardant360 Response™ Lab/Manufacturer: Guardant Health, Inc,
0467U	Oncology (bladder), DNA, nextgeneration sequencing (NGS) of 60 genes and whole genome aneuploidy, urine, algorithms reported as minimal residual disease (MRD) status positive or negative and quantitative disease burden Proprietary test: UroAmp MRD Lab/Manufacturer: Convergent Genomics, Inc

0470U	Oncology (oropharyngeal), detection of minimal residual disease by next-generation sequencing (NGS) based quantitative evaluation of 8 DNA targets, cell-free HPV 16 and 18 DNA from plasma Proprietary test: HPV-SEQ Test Lab/Manufacturer: Sysmex Inostics, Inc

Molecular Analysis for Gliomas

Policy Number: AHS – M2139 – Molecular Analysis for Gliomas	Prior Policy Name and Number, as applicable: • AHS – M2139 – Analysis of MGMT Promoter Methylation for Malignant Gliomas
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Glioma refers to tumors resulting from metaplastic transformation of glial tissue of the nervous system. Tumors have historically been classified by the retained histologic features of the three types of glial cells: astrocytes, oligodendrocytes, and ependymal cells. Tumors of each type can vary widely in aggressiveness, response to treatment, and prognosis (Louis et al., 2023).

Molecular genetic features were added to histopathologic appearance in the current WHO classification to yield more biologically homogeneous and narrowly defined diagnostic entities for greater diagnostic accuracy, improved patient management, more accurate determinations of prognosis, and better treatment response (Louis et al., 2016; Louis et al., 2021).

II. Related Policies

Policy Number	Policy Title
N/A	

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For the prognosis of gliomas, the following tests **MEET COVERAGE CRITERIA:**
   a) Array-based genomic copy number testing or fluorescence in situ hybridization (FISH) for the co-deletion of 1p and 19q.
   b) *ATRX* mutation testing via gene sequencing **or** loss of ATRX protein expression via immunohistochemistry.
   c) *BRAF* fusion and mutation testing, including *BRAF* V600E common variant.
   d) *IDH1* and *IDH2* testing.
   e) *MGMT* promoter methylation testing.
   f) *TERT* promotor mutation testing.
2) For the prognosis of diffuse midline gliomas, the following tests **MEET COVERAGE CRITERIA:**
   a) *H3-3A* and *HIST1H3B* gene sequencing.
   b) *H3-3A* mutation testing by immunohistochemistry using an H3-3A K27M histone antibody.
3) For the prognosis of ependymomas, *ZFTA* fusion testing using either RNA sequencing analysis (RNA-Seq) or FISH **MEETS COVERAGE CRITERIA**.
4) *ATRX* mutation co-testing using **both** immunohistochemistry and gene sequencing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AG	Anaplastic glioma
ATRX	*Alpha-Thalassemia/Mental Retardation Syndrome X-Linked* gene
BRAF	*B-Raf proto-oncogene*
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid
CNA	Copy number alterations
CNS	Central nervous system

CSF	Cerebrospinal fluid
ddPCR	Digital droplet polymerase chain reaction
DIPG	Diffuse intrinsic pontine gliomas
EANO	European Association of Neuro-Oncology
ELISA	Enzyme-linked immunoassay
ESMO	European Society for Medical Oncology
FISH	Fluorescence in situ hybridization
H3-3A	*H3.3 histone A* gene
H3F3A	Previous gene name of *H3.3 histone A*
H3FA	*H3 clustered histone 1* gene
IDH1	*Isocitrate Dehydrogenase 1* gene
IDH2	*Isocitrate Dehydrogenase 2* gene
LDTs	Laboratory-developed tests
MGMT	*O-6-Methylguanine-Dna Methyltransferase* gene
NCCN	National Comprehensive Cancer Network
NICE	National Institute for Health and Care Excellence
NFkB	Nuclear factor kappa B
NGS	Next-generation sequencing
NICE	National Institute for Health and Care Excellence
PCR	Polymerase chain reaction
PFA	Posterior fossa ependymoma group A
PFB	Posterior fossa ependymoma group B
RELA	*RELA proto-oncogene, NF-kB subunit*
RNA-Seq	Ribonucleic acid sequencing analysis
SNVs	Single nucleotide variants
sPD-L1	Soluble programmed cell death ligand 1
TERT	*Telomerase reverse transcriptase*
TMB	Tumor mutational burden
TP53	*Tumor protein 53*
WHO	World Health Organization
YAP1	*Yes1 associated transcriptional regulator* gene
ZFTA	*Zinc finger translocation associated* gene

V. Scientific Background

According to the American Cancer Society, an estimated 25,400 adults in the United States were diagnosed with malignant tumors of the brain and spinal cord in 2023.

Additionally, The American Cancer Society reported that there was an estimated 18,760 deaths from brain and spinal cord tumors in 2023. (American Cancer Society, 2024).

Studies over the past two decades have clarified the genetic basis of tumorigenesis in the common, and some rarer, brain tumor entities (Louis et al., 2016), and identified clinically relevant molecular genetic characterizations that complement standard histologic analysis providing additional diagnostic and prognostic information to improve diagnostic accuracy, influence treatment selection, and improve survival. Molecular and/or genetic characterization do not replace standard histologic assessment, but rather serve as a complimentary approach (NCCN, 2023).

Isocitrate dehydrogenase (IDH1/2) mutations

Metabolic enzymes, IDH one and two, oxidize isocitrate to alpha-ketoglutarate, and are important in the mitigation of cellular oxidative damage (Horbinski, 2013b). Mutations in genes encoding these enzymes leads to the aberrant production of D-2 hydroxyglutarate (Dang et al., 2009), an oncometabolite that causes epigenetic modifications in affected cells (Horbinski, 2013b).

The *IDH* mutations are a defining feature of WHO grade II and III astrocytomas and oligodendrogliomas (Louis et al., 2016). Their presence distinguishes lower grade gliomas from primary glioblastomas, which are *IDH* wild type. *IDH* mutations are commonly associated with O-6-methylguanine-DNA methyltransferase (*MGMT*) promoter methylation and are also associated with a relatively favorable prognosis (Brat et al., 2015; Eckel-Passow et al., 2015).

O-6-methylguanine-DNA methyltransferase (MGMT) methylation

The DNA repair enzyme, MGMT, reverses the DNA damage caused by alkylating agents, resulting in tumor resistance to temozolomide and nitrosourea-based chemotherapy. Methylation of the *MGMT* promoter silences *MGMT,* making the tumor more sensitive to treatment with alkylating agents (Esteller et al., 2000; Gusyatiner & Hegi, 2018).

The *MGMT* promoter methylation is strongly associated with *IDH* mutation and genome-wide epigenetic change (Eckel-Passow et al., 2015); it is also associated with longer survival in patients with glioblastoma who receive alkylating agents (Hegi et al., 2005; Zhao et al., 2016). *MGMT* promoter methylation is particularly useful in treatment decisions for elderly patients with high grade gliomas (Malmstrom et al., 2012; Wick et al., 2012; Wick et al., 2014).

Codeletion of chromosomes 1p and 19q

The codeletion of 1p and 19q represents an unbalanced translocation (1;19) (q10;p10) leading to the whole arm deletion of chromosome 1p and chromosome 19q (Jenkins et al., 2006). Codeletion of 1p and 19q is a defining feature of oligodendroglial tumors, is strongly associated with oligodendroglial histology, and helps to confirm the oligodendroglial character of tumors with equivocal or mixed histologic features (Brat et al., 2015; Burger et al., 2001; Eckel-Passow et al., 2015). Combined loss involving chromosomes 1p and 19q is significantly associated with both favorable therapeutic response and longer recurrence-free survival after chemotherapy (Cairncross et al., 1998).

Alpha-thalassemia/mental retardation syndrome X-linked (ATRX) mutations

Mutations in the chromatin regulator gene, *ATRX*, enable alternative lengthening of telomeres (Abedalthagafi et al., 2013). ATRX is a switch/sucrose helicase that assists with H3.3 chromatin deposition in telomeric regions. Disruption of this gene leads to the alternative lengthening of telomeres stated above and is thought to represent an early event in gliomagenesis (Batchelor & Louis, 2023).

The *ATRX* mutations in glioma are strongly associated with *IDH* and *TP53* mutations and are nearly always mutually exclusive with 1p19q codeletion (Reuss et al., 2015). ATRX deficiency, coupled with *IDH* mutation, is typical of astrocytoma (Brat et al., 2015).

Tumor protein 53 (TP53) mutation

Tumor protein 53 is essential for regulating cell division and preventing tumor formation (Parikh et al., 2014). Missense mutations in the *TP53* gene are present in the clear majority of IDH-mutant astrocytomas (Brat et al., 2015). Immunopositivity for mutant p53 is not entirely sensitive or specific for a *TP53* mutation, however, and loss of *ATRX* expression may be a more reliable marker of astrocytic differentiation (Louis et al., 2023).

Telomerase reverse transcriptase (TERT) mutations

Telomerase reverse transcriptase encodes the catalytic active site of telomerase, the enzyme responsible for maintaining telomere length in dividing cells. *TERT* mutations in the noncoding promoter region cause increased expression of the TERT protein and are one of the major mechanisms of telomerase activation in gliomas (Arita et al., 2013). *TERT* mutations are strongly associated with 1p19q codeletion and are found in most glioblastomas. A *TERT* mutation in combination with an *IDH* mutation and 1p19q codeletion is characteristic of oligodendroglioma. The absence of a *TERT* mutation, coupled with an *IDH* mutation, designates astrocytoma (Eckel-Passow et al., 2015). In

terms of survival, mutation in the *TERT* promoter is generally unfavorable in the absence of *IDH* mutation and favorable in the presence of *IDH* mutation and 1p/19q codeletion. *TERT* promoter mutation is associated with an older age of the patient at presentation, regardless of whether *IDH* mutation is present (Eckel-Passow et al., 2015).

Histone (H3FA) mutations

A lysine to methionine substitution in the *H3F3A* gene (*H3K27M*) is the most common histone mutation in brain tumors and inhibits the trimethylation of H3.3 histone (Sturm et al., 2012), arresting cells in a primitive state refractory to differentiation induction (Weinberg et al., 2017). *G34R/G34V* mutations in the *H3F3A* gene are more common in cortical gliomas in children (Schwartzentruber et al., 2012). *H3FA* mutations can be useful in the diagnosis of infiltrative glioma (Sturm et al., 2012). The *H3K27M* mutation is an adverse prognostic marker in children and adults (Meyronet et al., 2017). The *G34* mutation does not appear to have any prognostic significance once the diagnosis of a glioblastoma has been established (Sturm et al., 2012).

A similar mutation to *H3K27M* may also occur in the *HIST1H3B/C* gene, which encodes the histone H3.1 variant. However, the mutation at *HIST1H3B/C* is about one third as common as *H3F3A* and often confers a better prognosis than its *H3F3A* counterpart (Louis et al., 2023).

B-Raf proto-oncogene (BRAF) mutations

The serine-threonine protein kinase, BRAF, is involved in cell survival, proliferation, and differentiation (Davies et al., 2002). Activating mutations in *BRAF*, most often V600E, have been discovered in most pediatric and some adult gliomas (Chappe et al., 2013; Horbinski, 2013a), including approximately 80% of pleomorphic xanthoastrocytomas, 20% of gangliogliomas, 10% of pilocytic astrocytomas, and occasionally diffuse gliomas (Chi et al., 2013). Tandem duplication of chromosome 7q34 resulting in an activating fusion of the *BRAF* and *KIAA1549* genes occur in 60-80% of pilocytic astrocytoma (Jones et al., 2008).

The presence of a *BRAF* fusion is reliable evidence that the tumor is a pilocytic astrocytoma and predicts a better clinical outcome (Hawkins et al., 2011). A *BRAF* mutation is more complicated, as it can occur in a variety of tumors and requires integration with histology. Tumors with *BRAF* mutations may respond to BRAF inhibitors; however, in pediatric gliomas, *BRAF* V600E indicates poor prognosis when treated with current adjuvant therapy, especially in combination with a *CDKN2A* mutation (Lassaletta et al., 2017).

v-rel avian reticuloendotheliosis viral oncogene homolog A (RELA, p65, NFKB3) fusion

Fusion between the *C11orf95* and *RELA* genes defines approximately 70 percent of all childhood supratentorial ependymomas (Louis et al., 2023). These fusions are associated with increased NF-kappa-B (NFkB) signaling and poor outcome (Malgulwar et al., 2018). Normally, NFkB is an inactive transcription factor in the cytoplasm. When its inhibitor degrades, it activates transcription of certain genes, *RELA* among them (NCBI, 2011). New research supports the hypothesis that the status of *RELA* fusion and p53 overexpression are significantly associated with the prognosis of supratentorial extraventricular ependymomas (Wang et al., 2019).

New Tests

Assessment of gliomas is incredibly difficult, and new methods of molecular analyses for gliomas are consistently being developed. For example, Miller et al. (2019) devised a liquid-biopsy based method to evaluate cerebrospinal fluid from 42 (of 85) patients. The genomic profile developed from the cerebrospinal fluid (CSF) samples closely matched established profiles, such as the characteristic 1p/19q codeletion and *IDH1/2* mutations. The authors stated that the ability to monitor the glioma genome in real time could be useful in management of this condition (Miller et al., 2019). Other researchers report that "A cerebrospinal fluid ct-DNA liquid biopsy approach may virtually support all the stages of glioma management, from facilitating molecular diagnosis when surgery is not feasible, to monitoring tumor response, identifying early recurrence, tracking longitudinal genomic evolution, providing a new molecular characterization at recurrence and allowing patient selection for targeted therapies" (Simonelli et al., 2020).

Clinical Utility and Validity

Nikiforova et al. (2016) validated GlioSeq, a commercial next generation sequencing (NGS) panel of 30 genes, in 54 patients with CNS tumors against fluorescence in-situ hybridization (FISH), Sanger sequencing, and reverse transcription polymerase chain reaction (PCR). GlioSeq correctly identified 71/71 (100%) genetic alterations known to be present by conventional techniques. The assay sensitivity was three to five percent for mutant alleles of single nucleotide variants (SNVs), and one to five percent for gene fusions. Likewise, Zacher et al. (2017) developed an NGS panel of 20 genes that allowed for molecular classification of 121 gliomas. The researchers conclude that gene panel NGS is a promising diagnostic technique that may facilitate integrated histological and molecular glioma classification.

Ramkissoon et al. (2017) used OncoPanel and OncoCopy to identify targetable alterations in tumors for the establishment of best practices in routine clinical pediatric oncology. They analyzed 117 samples by OncoPanel and 146 by OncoCopy; further, 60 tumors were subjected to both methodologies. OncoPanel revealed clinically relevant

alterations in 56% of patients (44 cancer mutations and 20 rearrangements), including *BRAF* alterations that directed the use of targeted inhibitors. Rearrangements in *MYB-QKI, MYBL1, BRAF*, and *FGFR1* were also detected. Furthermore, while copy number profiles differed across histologies, the combined use of OncoPanel and OncoCopy identified subgroup-specific alterations in 89% (17/19) of medulloblastomas.

Ryall et al. (2016) evaluated the prognostic impact of H3K27M and MAPK pathway aberrations in 64 gliomas (44 low grade, 22 high grade). Tumors are designated as low-grade if the cells are well differentiated, are less aggressive overall, and suggest a better prognosis for the patient. Five low grade gliomas contained the *H3F3A/HIST1H3B K27M* (*H3K27M*) mutation, and 11 high grade gliomas contained the *H3K27M* mutation. Survival analysis evaluated the median survival at 9.12 years for wildtype H3 patients compared to 1.02 years for patients with the *H3K27M* mutation. MAPK pathway mutations (through *BRAF* or *FGFR1* mutation) were associated with long-term survival in absence of *H3K27M* mutations. Further, H3K27M status and high-grade histology were found to be the most significant independent predictors of poor overall survival with hazard ratios of 6.945 and 7.721 respectively. MAPK pathway activation was a predictor of "favourable patient outcome," but dependent on other factors (Ryall et al., 2016).

Houdova Megova et al. (2017) evaluated the prognostic value of the *IDH1/2* mutation in glioblastomas. A total of 37 *IDH* mutations were examined and studied. The authors found that *IDH1* mutations were positively associated with *MGMT* methylation (odds ratio [OR]: 3.08), 1p/19q co-loss (OR: 8.85), and negatively associated with *EGFR* amplification. IDH-mutant patients had an overall survival of 25 months compared to only nine months for IDH-wildtype gliomas (Houdova Megova et al., 2017).

Johnson et al. (2017) performed comprehensive genomic profiling of 282 pediatric gliomas: 157 high-grade and 125 low-grade. The investigators used a 315 gene panel and calculated the tumor mutational burden (TMB). In low grade gliomas, *BRAF* was the most frequent mutation found (48%), followed by *FGFR* missense (17.6%), *NF1* loss of function (8.8%), and *TP53* (5.6%). Rearrangements were found in 35% of low-grade gliomas. In high-grade gliomas, *TP53* was the most frequent mutation found (49%), followed by *H3F3A* (37.6%), *ATRX* (24.2%), *NF1* (22.2%), and *PDGFRA* (21.7%). *H3F3A* mutations were found to be the K28M variant. Approximately six percent of the high-grade gliomas were found have a TMB of >20 mutations/Mb ("hypermutated") (Johnson et al., 2017).

Back et al. (2020) studied the pattern of failure in anaplastic glioma (AG) patients with an *IDH1/2* mutation. A total of 156 patients participated in the study, with data collected from 2008 to 2014; the median follow-up time was 5.1 years. Of all 156

patients, 75% were found to have an *IDH1 or IDH2* mutation. The authors concluded that "patients with *IDH*-mutated AG have improved outcomes"; however, this population also had a greater number of distant relapses approximately two years after intensity-modulated radiation therapy compared to individuals with *IDH* wild type mutations (Back et al., 2020).

Ji et al. (2021) studied the clinical utility of comprehensive genomic profiling to detect CNS tumors in children and young adults using the OncoKids next-generation sequencing panel, chromosomal microarray analysis, and germline testing. NGS was performed on 222 samples and CMA was performed on 146 of the 222 samples. The OncoKids NGS panel identified diagnostic biomarkers in 138/222 samples (62%), prognostic information in 49/222 cases (22%), and targetable genomic alterations in 41/222 samples (18%). Additionally, CMA revealed prognostic copy number alterations (CNA) in 101/146 cases (69%). Further, germline cancer predisposition testing was performed in 57 of 212 patients which identified 20 patients which a confirmed germline pathogenic/likely pathogenic variant of genes *TP53, NF1, SMARCB1, NF2, MSH6, PMS2*, and a patient with Klinefelter syndrome. Overall, the authors conclude that there is "significant clinical utility of integrating genomic profiling into routine clinical testing for pediatric and young adult patients with CNS tumors" (Ji et al., 2021).

Muralidharan et al. (2021) studied the diagnostic utility of a novel digital droplet PCR (ddPCR) assay for detection of two TERT promoter mutations (*C228T* and *C250T*) and monitoring of gliomas. In comparison with the gold-standard tumor tissue-based detection of *TERT* mutations, the ddPCR assay had an overall sensitivity of 62.5% and a specificity of 90%. Longitudinal monitoring of five patients demonstrated that the peripheral *TERT* mutant allele frequency reflects the clinical course of the disease. *TERT* mutant alleles decreased after surgical intervention and pharmacotherapy but increased with tumor progression. The authors conclude that the ddPCR assay has feasibility in "detecting circulating cfDNA TERT promoter mutations in patients with glioma with clinically relevant sensitivity and specificity" (Muralidharan et al., 2021).

Cabezas-Camarero et al. (2021) studied the levels of soluble PD-L1 (sPD-L1) in patients with gliomas according to histologic grade and IDH mutation status, evaluating its predicted role and dynamic changes in sPD-L1. Plasma samples were obtained prior to and after radiotherapy/chemotherapy and were evaluated using ELISA. The authors compared 12 healthy controls with 57 patients with grade II to IV gliomas. They found that sPD-L1 levels were numerically higher in glioma patients as compared to the healthy control group. The authors found that elevated sPD-L1 levels pre- and post-treatment associated with a worse prognosis in IDH-MUT gliomas. Dynamics of SPDL1 and other immune-biomarkers should still be explored in gliomas (Cabezas-Camarero et al., 2021).

Rios et al. (2022) studied the health and economic impacts of using tumor molecular testing for guiding treatments for pediatric patients with low grade glioma. With their microsimulation for modeling health and cost outcomes for 100,000 simulated patients, they found that there was a statistically significant increase in life expectancy in those who received molecular testing for the BRAF mutation (40.08 vs 39.01 in those who did not receiving testing), and an increase of 0.38 quality-adjusted life-years (QALY) and $1384 reduction in costs due to likely avoidance of adverse events associated with radiation, like stroke and other neoplastic transformations. This study ultimately demonstrates that in this subset of patients, there could be long-term benefits in the treatment plans derived for childhood cancers, including the increased timely use of *BRAF*-specific biologic agents versus standard treatment with radiation (Rios et al., 2022).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN published Clinical Practice Guidelines in Oncology (2023) for Central Nervous System Cancers which recommend:

IDH1 and *IDH2* mutation

Recommendation: *IDH* mutation testing is required for the workup of glioma.

"The most common *IDH1* mutation (R132H) is reliably screened by mutation specific immunohistochemistry (IHC), which is recommended for all glioma patients. If the R132H immunostain result is negative, in the appropriate clinical context, sequencing of *IDH1* and *IDH2* is highly recommended to detect less common *IDH1* and *IDH2* mutations. Prior to age 55 years, sequencing of *IDH1* and *IDH2* is required if the R132H immunostain result is negative, or if the glioma is only grade 2 or 3 histologically. Standard sequencing methods include Sanger sequencing, pyrosequencing, and next-generation sequencing (NGS), and should be performed on formalin fixed, paraffin embedded tissue" (NCCN, 2023).

MGMT promoter methylation

Recommendation: *MGMT* promoter methylation is an essential part of molecular diagnostics for all high-grade gliomas (grade 3 and 4). The NCCN also notes that "*MGMT* promoter methylation is strongly associated with *IDH* mutations and genome-wide epigenetic changes (G-CIMP phenotype)" (NCCN, 2023).

"There are multiple ways to test for *MGMT* promoter methylation, including methylation-specific polymerase chain reaction (PCR), methylation-specific high-resolution melting, pyrosequencing, and droplet-digital PCR" (NCCN, 2023).

"MGMT promoter methylation testing is particularly useful in treatment decisions for older adult patients with high-grade gliomas (grades 3–4) " (NCCN, 2023).

Codeletion of 1p and 19q

Recommendation: 1p/19q testing is an essential part of molecular diagnostics for oligodendroglioma.

"The codeletion of 1p and 19q is detectable by array-based genomic copy number testing (preferable), or fluorescence in situ hybridization (FISH) … IDH-mutated gliomas that do NOT show loss of *ATRX* (for example, by IHC) should be strongly considered for 1p/19q testing, even if not clearly oligodendroglial by histology. Conversely, *IDH1* wild-type gliomas do not contain true whole-arm 1p/19q codeletion. Therefore, 1p/19q testing is unnecessary if a glioma is definitely *IDH*-wild-type, and a glioma should not be regarded as 1p19q-codeleted without an accompanying *IDH* mutation, regardless of the test results" (NCCN, 2023).

ATRX mutation

"Recommendation: *ATRX* mutation testing is required for the workup of glioma."

"*ATRX* mutations can be detected by IHC for wild-type *ATRX* (loss of wild type expression) and/or sequencing. ATRX mutations in glioma are strongly associated with *IDH* mutations and are nearly always mutually exclusive with 1p/19q codeletion. *ATRX* deficiency, coupled with IDH mutation and *TP53* mutation, is typical of astrocytoma. A lack of *ATRX* immunostaining in glioblastoma should trigger *IDH1/2* sequencing if *IDH1* R132H immunostaining is negative, due to frequent co-occurrence of *ATRX* and *IDH* mutations" (NCCN, 2023).

TERT mutation

"Recommendation: *TERT* promoter mutation testing is required for the workup of gliomas."

"*TERT* promoter mutations are nearly always present in 1p/19q codeleted oligodendroglioma and are found in most glioblastomas. *TERT* promoter mutation, in combination with *IDH* mutation and 1p/19q codeletion, is characteristic of oligodendroglioma. Absence of *TERT* promoter mutation, coupled with the presence of mutant *IDH*, strongly suggests astrocytoma"(NCCN, 2023).

H3F3A and *HIST1H3B* mutation

"Recommendation: *H3-3A* and *HIST1H3B* mutation testing is recommended in the appropriate clinical context."

"Diffuse midline gliomas should be screened for *H3-3A* mutations, specifically the H3K27M mutation. While sequencing is the gold standard, H3K27M-specific IHC, paired with H3K27 trimethylation immunostaining, is a reasonable alternative, especially when tissue is scarce. In these gliomas, H3K27M immunopositivity should be associated with loss of histone trimethylation immunostaining."

"Although a K27M histone antibody is available, it is not 100% specific and interpretation can be difficult for non-experts. Therefore, screening by *H3F3A* and *HIST1H3B* sequencing is a viable alternative and preferred approach, especially since it will also detect mutations in G34" (NCCN, 2023).

"Diagnostic value: Histone mutations most commonly occur in pediatric midline gliomas (e.g., diffuse intrinsic pontine gliomas [DIPG]), although midline gliomas in adults can also contain histone modifications. Their presence can be considered solid evidence of an infiltrative glioma, which is often helpful in small biopsies of midline lesions that may not be fully diagnostic with light microscopy or do not fully resemble infiltrative gliomas."

"Prognostic value: The *K27M* gliomas typically do not have MGMT promoter methylation, and the mutation is an adverse prognostic marker in children and adults. The *G34* mutation does not appear to have any prognostic significance once the diagnosis of a glioblastoma has been established" (NCCN, 2023).

BRAF mutation

"Recommendation: *BRAF* fusion and/or mutation testing is recommended in the appropriate clinical context."

"*BRAF* V600E is best detected by sequencing, and *BRAF* fusions can be detected with RNA-Seq or other PCR-based breakpoint methods that capture the main 16-9, 15-9, and 16-11 breakpoints between *BRAF* and its main fusion partner, *KIAA1549*. FISH is too unreliable to detect *BRAF* fusions" (NCCN, 2023).

"The presence of a *BRAF* fusion is reliable evidence that the tumor is a [pilocytic astrocytoma], provided the histology is compatible. *BRAF* V600E is more complicated, as it can occur in a variety of tumors over all four WHO grades and requires integration with histology."

"Tumors with *BRAF* fusions tend to be indolent, with occasional recurrence but only rare progression to lethality. *BRAF* V600E tumors show a much greater range of outcomes and need to be considered in context with other mutations and clinicopathologic findings (e.g., CDKN2A/B deletion). *BRAF* V600E tumors may respond to BRAF inhibitors, such as vemurafenib, but comprehensive clinical trials are still ongoing" (NCCN, 2023).

ZFTA fusion

"Testing for *ZFTA* and *YAP1* fusions is recommended in the appropriate clinical context. Ependymomas arising in the supratentorium often contain activating fusions of *ZFTA*. This leads to increased NF-kappa-B signaling and more aggressive behavior. This event is more common in children than in adults, and occurs only in the supratentorium, not the posterior fossa or spine" (NCCN,2022).

"*ZFTA* fusion can be detected with RNA sequencing or a break-apart FISH probe set… Detection of *ZFTA* fusion is not required for the diagnosis of ependymoma, as this entity is still diagnosed by light microscopy."

"*ZFTA* fusion-positive ependymomas are now a distinct entity in the WHO classification of CNS tumors, as this subset of ependymomas tends to be far more aggressive than other supratentorial ependymomas, including those with *YAP1* fusions. PFA vs. PFB via methylation profiling is reasonable for posterior fossa ependymoma" (NCCN, 2023).

Finally, the NCCN states there are no identified targeted agents with demonstrated efficacy in glioblastoma (NCCN, 2023).

National Institute for Health and Care Excellence (NICE)

NICE recommends the following molecular markers for investigation of gliomas: *IDH1/2* mutations, *ATRX* mutations, 1p/19q co-deletion, histone H3.3 K27M, *BRAF* mutation, and *MGMT* promoter methylation (for prognosis). NICE also notes that testing *IDH* wild type gliomas for *TERT* promoter mutations may be considered (NICE, 2021).

European Society for Medical Oncology (ESMO)

The ESMO has published clinical practice guidelines for the diagnosis, treatment, and follow-up of high-grade gliomas. They state that *MGMT* promoter methylation status, *IDH1/2* mutation status, and 1p/19q codeletions are "commonly determined" for assessment of gliomas (ESMO, 2014).

World Health Organization (WHO)

In 2016 and 2021, the WHO published guidelines on the classification of central nervous system tumors. These WHO guidelines, for the first time, incorporated molecular testing in the diagnosis of gliomas and medulloblastomas. The following key points were given by the WHO regarding molecular testing:

- "*IDH1* R132H, which accounts for approximately 90% of *IDH* mutations, can be detected immunohistochemically. If this testing is negative, sequencing of *IDH1* and *IDH2* is necessary to ensure that no other *IDH* mutations are present.
- Given the importance of *IDH* mutational status in the diagnosis or gliomas, at a minimum, it will be important that most institutions have the capacity to both stain tumor specimens for *IDH1* R132H by immunohistochemistry and, ideally, sequence those tumors that are negative for both *IDH1* and *IDH2* mutations" (Wen & Huse, 2016).
- "Because of the growing importance of molecular information in CNS tumor classification, diagnoses and diagnostic reports need to combine different data types into a single, 'integrated' diagnosis. To display the full range of diagnostic information available, the use of layered (or tiered) diagnostic reports is strongly encouraged. Such reports feature an integrated diagnosis at the top, followed by layers that display histological, molecular, and other key types of information" (Louis et al., 2021).
- Certain tumors (Diffuse astrocytoma, MYB- or MYBL1-altered; Angiocentric glioma; Polymorphous low-grade neuroepithelial tumor of the young; and Diffuse low-grade glioma, MAPK pathway-altered) "require molecular characterization and the integration of histopathological and molecular information in a tiered diagnostic format as molecular work-up helps to characterize the lesion as one type or the other" (Louis et al., 2021).
- For other tumors such as Myxopapillary ependymoma and Subependymoma, "although these can be identified with methylome studies, molecular classification does not provide added clinicopathological utility for these two tumors" (Louis et al., 2021).
- "Several molecular biomarkers are also associated with classification and grading of meningiomas, including SMARCE1 (clear cell subtype), BAP1 (rhabdoid and papillary subtypes), and KLF4/TRAF7 (secretory subtype) mutations, TERT promoter mutation and/or homozygous deletion of CDKN2A/B62, H3K27me3 loss of nuclear expression (potentially worse prognosis), and methylome profiling (prognostic subtyping)" (Louis et al., 2021).

European Association of Neuro-Oncology (EANO)

In 2021, the EANO published guidelines regarding diagnosis and management of adult patients with diffuse gliomas. The following recommendations were made on molecular testing:

- "Patients with relevant germline variants or suspected hereditary cancer syndromes should receive genetic counselling and might subsequently be referred for molecular genetic testing.
- Immunohistochemistry for mutant *IDH1* R132H protein and nuclear expression of *ATRX* should be performed routinely in the diagnostic assessment of diffuse gliomas.
- If immunohistochemistry for *IDH1* R132H is negative, sequencing of *IDH1* codon 132 and *IDH2* codon 172 should be conducted in all WHO grade 2 and 3 diffuse astrocytic and oligodendroglial gliomas as well as in all glioblastomas of patients aged < 55 years to enable integrated diagnoses according to the WHO classification and to guide treatment decisions.
- 1p/19q codeletion status should be determined in all *IDH*-mutant gliomas with retained nuclear expression of *ATRX*.
- *MGMT* promoter methylation status should be determined in glioblastoma, notably in elderly or frail patients, to aid in decision-making for the use of temozolomide.
- *CDKN2A/B* homozygous deletions should be explored in *IDH*-mutant astrocytomas.
- Combined chromosome seven gain and chromosome 10 loss (+7/–10 signature), *EGFR* amplification and *TERT* promoter mutation should be tested in *IDH*-wild-type diffuse gliomas lacking microvascular proliferation and necrosis as histological features of WHO grade 4 to allow for a diagnosis of *IDH*-wild-type glioblastoma" (Weller et al., 2021).

In addition, EANO published a table to summarize the molecular markers used for the diagnosis and management of gliomas.

Table 1: Molecular Markers for the Diagnosis and Management of Gliomas (Weller et al., 2021)

Molecular Marker	**Diagnostic Roles**
IDH1 R132 or IDH2 R172 mutation	"Distinguishes diffuse gliomas with IDH mutation from IDH-wild-type glioblastomas and other IDH-wild-type gliomas
1p/19q codeletion	Distinguishes oligodendroglioma, IDH-mutant and 1p/19q-codeleted from astrocytoma, IDH-mutant

Loss of nuclear ATRX	Loss of nuclear ATRX in an IDH-mutant glioma is diagnostic for astrocytic lineage tumours
Histone H3 K27M mutation	Defining molecular feature of diffuse midline glioma, H3 K27M-mutant
Histone H3.3 G34R/V mutation	Defining molecular feature of diffuse hemispheric glioma, H3.3 G34-mutant
MGMT promoter methylation	None, but is a predictive biomarker of benefit from alkylating chemotherapy in patients with IDH-wild-type glioblastoma
Homozygous deletion of CDKN2A/CDKN2B	A marker of poor outcome and WHO grade 4 disease in IDH-mutant astrocytomas
EGFR amplification	EGFR amplification occurs in ~40–50% of glioblastoma, IDH wild type Molecular marker of glioblastoma, IDH wild type, WHO grade 4
TERT promotor mutation	TERT promoter mutation occurs in ~70% of glioblastoma, IDH wild type and >95% of oligodendroglioma, IDH-mutant and 1p/19q-codeleted Molecular marker of glioblastoma, IDH wild type, WHO grade 4
+7/–10 cytogenetic signature	Molecular marker of glioblastoma, IDH wild type, WHO grade 4
$BRAF^{V600E}$ mutation	Rare in adult diffuse gliomas but amenable to pharmacological intervention" (Weller et al., 2021).

College of American Pathologists

In 2022, The College of American Pathologists in Collaboration with the American Association of Neuropathologists, Association for Molecular Pathology, and Society for Neuro-Oncology published guidelines that suggests these following recommendations for molecular biomarker testing for the diagnosis of diffuse gliomas:

- "IDH mutational testing must be performed on all diffuse gliomas (DG) (Strong recommendation)"
- "ATRX status should be assessed in all IDH-mutant DG unless they show 1p/19q codeletion (Strong recommendation)"
- "TP53 status should be assessed in all IDH-mutant DGs unless they show 1p/19q codeletion (Conditional recommendation)"
- "1p/19q codeletion must be assessed in IDH-mutant DGs unless they show ATRX loss or *TP53* mutations (Strong recommendation)"

- "*CDKN2A/B* homozygous deletion testing should be performed on IDH-mutant astrocytomas (Conditional recommendation)"
- "*MGMT* promoter methylation testing should be performed on all glioblastoma (GBM), IDH-wild type (WT) (Strong recommendation)"
- "For IDH-mutant DG, *MGMT* promoter methylation testing may not be necessary (Conditional recommendation)"
- "*TERT* promoter mutation testing may be used to provide further support for the diagnosis of oligodendroglioma and IDH-WT GBM (Conditional recommendation)"
- "For histologic grade 2-3 DGs that are IDH-WT, testing should be performed for whole chromosome 7 gain/whole chromosome 10 loss, *EGFR* amplification, and *TERT* promoter mutation to establish the molecular diagnosis of GBM, IDH-WT, grade IV (Strong recommendation)"
- "H3 K27M testing must be performed in DGs that involve the midline in the appropriate clinical and pathologic setting (Strong recommendation)"
- "H3 G34 testing may be performed in pediatric and young adult patients with IDH-WT DG (Conditional recommendation)"
- "*BRAF* mutation testing (V600) may be performed in DGs that are IDH-WT and H3-WT (Conditional recommendation)"
- "*MYB/MYBL1* AND *FGFR1* testing may be performed in children and young adults with DGs that are histologic grade 2-3 and are IDH-WT and H3-WT (Conditional recommendation)" (Brat et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration

has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81120	IDH1 (isocitrate dehydrogenase 1 [NADP+], soluble) (eg, glioma), common variants (eg, R132H, R132C)
81121	IDH2 (isocitrate dehydrogenase 2 [NADP+], mitochondrial) (eg, glioma), common variants (eg, R140W, R172M)
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s);
81287	MGMT (O-6-methylguanine-DNA methyltransferase) (eg, glioblastoma multiforme) promoter methylation analysis
81345	TERT (telomerase reverse transcriptase) (eg, thyroid carcinoma, glioblastoma multiforme) gene analysis, targeted sequence analysis (eg, promoter region)
81479	Unlisted molecular pathology procedure ***H3F3A gene sequencing*** ***RELA Testing*** ***H3F3A testing using a K27M histone antibody***
88341	Immunohistochemistry or immunocytochemistry, per specimen; each additional single antibody stain procedure (List separately in addition to code for primary procedure)
88342	Immunohistochemistry or immunocytochemistry, per specimen; initial single antibody stain procedure
88374	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; each multiplex probe stain procedure
88377	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; each multiplex probe stain procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Molecular Diagnostics for Breast Cancer Prognosis

Policy Number: AHS – M2020 – Molecular Diagnostics for Breast Cancer Prognosis	Prior Policy Name and Number, as applicable: • Molecular Expression Testing for Breast Cancer Prognosis • Gene Expression Testing for Breast Cancer Prognosis
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Molecular diagnostics for breast cancer management is emerging as a useful tool to aid in disease prognosis or therapeutic efficacy on an individual level. Many of the currently available molecular tests are gene expression assays that measure the number of transcribed copies of specific mRNAs to assess the genes that are active in tumor tissue, which can be clinically useful for disease classification, diagnosis, and prognosis, as well as for tailoring treatment to underlying genetic determinants of pharmacologic response (Steiling & Christenson, 2023).

II. Related Policies

Policy Number	Policy Title
AHS-G2059	Epithelial Cell Cytology in Breast Cancer Risk Assessment
AHS-M2003	Genetic Testing for Breast, Ovarian, Pancreatic, and Prostate Cancers
AHS-M2126	Use Of Common Genetic Variants (Single Nucleotide Polymorphisms) To Predict Risk of Non-Familial Breast Cancer

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with newly diagnosed breast cancer, tumor testing for hormone receptor (estrogen receptor and progesterone receptor) expression and human

epidermal growth factor receptor 2 (HER2) overexpression **MEETS COVERAGE CRITERIA**.

2) For individuals who have been diagnosed with invasive breast cancer and who are being considered for adjuvant chemotherapy, use of the Oncotype DX 21-gene expression assay (see Note 1) **MEETS COVERAGE CRITERIA** when **all** of the following criteria are also met:
   a) Histology that is ductal/no special type (NST) (see Note 2), lobular, mixed or micropapillary.
   b) pT1, pT2, or pT3 cancer.
   c) Hormone receptor (HR) positive (either estrogen-receptor [ER] or progesterone-receptor [PR] positive) cancer.
   d) Human epidermal growth factor receptor two (HER2) negative cancer.
   e) Tumor is **one** of the following:
      i) pN0 tumor that is >0.5 cm in size.
      ii) pN1mi (≤2 mm axillary node metastases).
      iii) pN1 (1-3 positive nodes).

3) For individuals who have been diagnosed with pT1, pT2, or operable pT3, HR positive, HER2-negative, **and** node-negative or pN1 (1-3 positive nodes) breast cancer and who have been determined to be at high clinical risk per MINDACT categorization (see Note 3), use of the MammaPrint assay **MEETS COVERAGE CRITERIA**.

4) For individuals who have been diagnosed with T1 or T2, HR positive, HER2-negative, **and** node-negative or pN1 (1-3 positive nodes) breast cancer, use of the 12-gene (EndoPredict) assay **or** the 50-gene (Prosigna) assay **MEETS COVERAGE CRITERIA**.

5) For individuals who have been diagnosed with T1-T3, HR-positive, HER2-negative breast cancer, use of the Breast Cancer Index (BCI) test to determine the benefit of extended adjuvant endocrine therapy **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

6) In males, use of gene expression assays other than 21-gene RT-PCR-based assays **DO NOT MEET COVERAGE CRITERIA**.

7) Use of gene expression assays not mentioned above (e.g., Mammostrat, BluePrint®) **DOES NOT MEET COVERAGE CRITERIA**.

8) The use of Oncotype DX for ductal carcinoma in situ (DCIS) **DOES NOT MEET COVERAGE CRITERIA**.

9) For all other indications or in any other situation not mentioned above, use of gene expression assays **DOES NOT MEET COVERAGE CRITERIA**.

10) Use of protein profiling assays (e.g., DCISionRT®, BBDRisk Dx®) **DOES NOT MEET COVERAGE CRITERIA.**

NOTES:

Note 1: The assay should only be ordered on a tissue specimen obtained during surgical removal of the tumor and after subsequent pathology examination of the tumor has been completed and determined to meet the above criteria (i.e., the test should not be ordered on a preliminary core biopsy without surgical staging). For patients who have multiple primary tumors, a specimen from the tumor with the most aggressive histological characteristics should be submitted for testing. It is not necessary to conduct testing on each tumor; treatment is based on the most aggressive lesion.

Note 2: As per NCCN Clinical Practice Guidelines in Oncology (Breast Cancer), "According to WHO, carcinoma of no special type (NST) encompasses multiple patterns including medullary pattern, cancers with neuroendocrine expression, and other rare patterns" (NCCN, 2024).

Note 3: As per NCCN Clinical Practice Guidelines in Oncology (Breast Cancer), "High clinical risk in the MINDACT trial was defined for grade 1 tumors as >3 cm N0 or T2N1, for grade 2 tumors T2N0-1, and for grade 3 tumors T1c-2N0-1" (NCCN, 2024).

IV. Table of Terminology

Term	Definition
ABHD14A	*Abhydrolase domain containing 14A* gene
ACS	American Cancer Society
AI	Aromatase inhibitor
ASCO	American Society of Clinical Oncology
ATP6V0A4	*ATPase H+ transporting V0 subunit a4* gene
AUC	Areas under the curve
AZGP1	*Alpha-2-glycoprotein 1, zinc-binding* gene

BCI	Breast cancer index
BEND3	*BEN domain containing 3* gene
BIRC5	*Baculoviral IAP repeat containing 5* gene
BTG2	*BTG anti-proliferation factor 2* gene
BUB1B	*BUB1 mitotic checkpoint serine/threonine kinase B* gene
CDYL	*Chromodomain Y like* gene
CEF	Cyclophosphamide, epirubicin and fluorouracil
CENPA	*Centromere protein A*
CET	Chemoendocrine Therapy
CHAD	*Chondroadherin* gene
CHER-LOB	Chemotherapy, 4erceptin, and lapatinib in operable breast cancer
CMF	Cyclophosphamide, methotrexate and fluorouracil
CNB	Core needle biopsy
CTCs	Circulating tumour cells
CTS	Clinical treatment score
DCIS	Ductal carcinoma in situ
DHCR7	*7-dehydrocholesterol reductase* gene
DRFR	Distant recurrence free rate
EBC	Early HER2-negative breast cancer
EET	Extended Endocrine Therapy
EGAPP	Evaluation of Genomic Applications in Practice and Prevention
EGTM	European Group on Tumour Markers
ER	Estrogen receptor
ESMO	European Society for Medical Oncology
ET	Endocrine therapy
FDA	Food and Drug Association
FNAB	Fine-needle aspirate biopsy
HER2	Human epidermal growth factor receptor two
HER2DX	Model for predicting disease-free survival
HR	Hazard ratio
IDFS	Invasive disease-free survival
IDUA	*Alpha-L-iduronidase* gene
IHC4	Immunohistochemistry 4
IL6ST	*Interleukin 6 cytokine family signal transducer* gene
InvBE	Ipsilateral breast event
KIF18A	*Kinesin family member 18A* gene
LN	Lymph node
MFS	Metastasis free survival
MGI	Molecular grade index

MGP	*Matrix Gla protein* gene
MINDACT	Microarray in node negative disease may avoid chemotherapy
mRNAs	Messenger ribonucleic acid
MYL5	*Myosin light chain 5* gene
NaCT	Neoadjuvant chemotherapy
NCCN	National Comprehensive Cancer Network
NEK2	*NIMA related kinase 2* gene
NET	Neoadjuvant endocrine therapy
NICE	National Institute for Health and Care Excellence
NPI	Nottingham prognostic index
NST	No special type
PAI-1	Plasminogen Activator Inhibitor Type 1
PAM50	Prosigna assay looking at the activity of 50 genes
PMBC	Patients with pure mucinous breast cancer
PR	Progesterone Receptor
PREP	*Prolyl endopeptidase*
RACGAP1	*Rac GTPase activating protein 1* gene
RBBP8	*RB binding protein 8, endonuclease* gene
RCB	Residual cancer burden
ROR	Risk of recurrence
RRM2	*Ribonucleotide reductase regulatory subunit M2* gene
RS	Recurrence Score
RTN4IP1	*Reticulon 4 interacting protein 1* gene
RT-PCR	Reverse transcriptase/transcription polymerase chain reaction
S100PBP	*S100P binding protein* gene
STC2	*Stanniocalcin 2* gene
TAILORx	Trial assigning individualized options for treatment (Rx)
TotBE	Total breast event
TPRG1	*Tumor protein p63 regulated 1* gene
UBE2C	*Ubiquitin conjugating enzyme E2 C* gene
uPA	Urokinase plasminogen activator
WDR6	*WD repeat domain 6* gene

V. Scientific Background

Breast cancer is the most frequently diagnosed cancer and is the leading cause of cancer death globally in women. Approximately one in eight women will develop breast cancer in their lifetime (Siegel et al., 2019; Taghian & Merajver, 2024).

While adjuvant systemic therapy has reduced mortality from breast cancer (Darby et al., 2011; Davies et al., 2011; Forouzanfar et al., 2011; Peto et al., 2012), it is not without its risks and costs; therefore, reliable prognostic profiles for recurrence and clinically applicable predictive factors are of great value in the management of the disease (Foukakis & Bergh, 2022).

Several biology-based prognostic profiles have been developed, validated, and are in clinical use to predict breast cancer recurrence or response to chemotherapy. Among the most useful biomarkers for this purpose are the estrogen receptors (ER),progesterone receptors (PR), and the human epidermal growth factor receptor two (HER2). Tumors that express one or more of these proteins may have different sensitivities to certain cytotoxic chemotherapeutic agents, influencing the strategic management of the cancer. Moreover, many proprietary panels that aim to provide predictive and prognostic information about an individual's cancer are only suitable for use in tumors of a particular type (i.e., HER2-negative). Intensive research efforts are ongoing to refine the clinical utility and the indications for these predictive and prognostic profiles (Simon et al., 2009). In addition, as next generation sequencing of tumor genomes progresses, these profiles will be improved or replaced by the next generation of molecular profiles (Foukakis & Bergh, 2022).

Chen et al. (2018) examined the association of genomic methylation and the changes in the subsequent transcriptome. The authors observed how a chronic condition influenced epigenomic changes. A human volunteer provided peripheral blood samples over 36 months and the authors created 28 methylome datasets as well as 57 transcriptome datasets. During this period, the human volunteer experienced six viral infections and two elevated periods of fasting glucose and glycated hemoglobin A1c. The authors noted that the methylome changes correlated with the glucose level changes and that the gene expression levels varied greatly, often during the viral infections. The authors proposed that the DNA methylation was the primary gene expression mechanism for chronic conditions, as it was generally a stable epigenetic marker (Chen et al., 2018).

Rueda et al. (2019) presented a disease model that stratifies distinct stages and incorporated factors such as "locoregional recurrence, distant recurrence, breast-cancer-related death and death from other causes" (Rueda et al., 2019). This model integrated these features into an individual risk-of-recurrence prediction and was applied to 3240 patients, of which 1980 had molecular data. From this model, the authors identified four late-recurring "integrative subtypes, comprising about one quarter (26%) of tumours that are both positive for ER and negative for human epidermal growth factor receptor 2, each with characteristic tumour-driving alterations in genomic copy number and a high risk of recurrence (mean 47–62%) up to 20 years

after diagnosis." These four subtypes were enriched in copy number alterations, and these alterations were labeled the likely drivers of each subgroup. A triple negative subgroup, IntCluster 10, was found to be largely relapse-free after five years whereas the IntCluster4 ER negative subgroup was found to have a large risk of recurrence (Rueda et al., 2019).

Innovative ideas continue to spread as the field burgeons, not limiting its inspiration to etiology. Savci-Heijink et al. (2019) believe in the clinical value of identifying a gene expression profile in tumors that selects a subpopulation of patients that is more likely to develop visceral organ metastases due to their association with poor survival outcomes in breast cancers. The researchers analyzed the genetic profiles of 157 primary tumors from breast cancer patients who developed distant metastases and differentially expressed genes between the group of tumors with visceral metastasis and those without visceral metastases were noted. The results yielded fourteen differentially expressed genes (*WDR6, CDYL, ATP6V0A4, CHAD, IDUA, MYL5, PREP, RTN4IP1, BTG2, TPRG1, ABHD14A, KIF18A, S100PBP* and *BEND3*) between the tumors with visceral metastasis and those without visceral metastases. According to the data, five of the genes (*CDYL, ATP6V0A4, PREP, RTN4IP1* and *KIF18A*) were upregulated while the other genes were downregulated, creating a list of biomarkers and genetic signatures of interest that may result in earlier diagnosis and treatment (Savci-Heijink et al., 2019).

Proprietary Testing

OncoType DX

The Oncotype Dx 21-gene recurrence score (RS) is the best-validated prognostic assay and may identify patients who are most and least likely to derive benefit from adjuvant chemotherapy. The expression levels of 16 genes (plus five reference genes) are measured by quantitative reverse transcription polymerase chain reaction (RT-PCR). The sum of this calculation is known as the RS to optimize prediction of distant relapse despite tamoxifen therapy. At this time, it is indicated for individuals with node-negative, estrogen receptor (ER)-positive, human epidermal growth factor receptor 2 (HER2)-negative breast cancer to determine the prognosis in patients recommended to proceed with at least a five-year course of endocrine therapy. The optimal RS cutoff for omission of chemotherapy remains unclear given that the different studies have used different cutoffs (Mamounas et al., 2010; Paik et al., 2004; Paik et al., 2006; Sparano et al., 2015). However, it may be reasonable not to administer adjuvant chemotherapy for patients with node-negative, ER-positive breast cancer and an RS of <15 (Foukakis & Bergh, 2022).

Sparano et al. (2018) performed a prospective trial to assess the utility of the recurrence score based on the 21 gene breast cancer assay to predict chemotherapy in patients who have a midrange score. "Of the 9719 eligible patients with follow-up information, 6711 (69%) had a midrange recurrence score of 11 to 25 and were randomly assigned to receive either chemoendocrine therapy or endocrine therapy alone. The trial was designed to show noninferiority of endocrine therapy alone for invasive disease-free survival (defined as freedom from invasive disease recurrence, second primary cancer, or death)." They found that "Endocrine therapy was noninferior to chemoendocrine therapy in the analysis of invasive disease-free survival (hazard ratio for invasive disease recurrence, second primary cancer, or death [endocrine vs. chemoendocrine therapy], 1.08; 95% confidence interval, 0.94 to 1.24; P=0.26). At nine years, the two treatment groups had similar rates of invasive disease-free survival (83.3% in the endocrine-therapy group and 84.3% in the chemoendocrine-therapy group), freedom from disease recurrence at a distant site (94.5% and 95.0%) or at a distant or local-regional site (92.2% and 92.9%), and overall survival (93.9% and 93.8%). The chemotherapy benefit for invasive disease-free survival varied with the combination of recurrence score and age (P=0.004), with some benefit of chemotherapy found in women 50 years of age or younger with a recurrence score of 16 to 25." They concluded that "Adjuvant endocrine therapy and chemoendocrine therapy had similar efficacy in women with hormone-receptor-positive, HER2-negative, axillary node-negative breast cancer who had a midrange 21-gene recurrence score, although some benefit of chemotherapy was found in some women 50 years of age or younger" (Sparano et al., 2018).

In a prospective, randomized trial of endocrine therapy (ET) versus chemoendocrine therapy (CET), Kalinsky et al. (2021) attempted to gather support for the potential prognostic and predictive role of the RS for CT benefit in postmenopausal patients with one to three lymph node-positive breast cancer using Oncotype Dx in the RxPonder Trial. In the study, women with a RS less than 25 were randomized to receive ET or CET in 1:1 randomization using 3 stratification factors—RS (0-13 vs.14-25), menopausal status, and axillary nodal dissection vs. sentinel node biopsy—with the end goal of ascertaining whether the effect of CT on invasive disease-free survival (IDFS) was a function of RS. Of 9,383 patients screened in the study, 5,083 patients were randomized based on having met eligibility criteria and 5,018 participated in the trial. With a median follow-up period of 5.1 years, the authors observed 447 IDFS events. It was reported that in a model with CT, RS, and menopausal status (no interaction term), higher continuous RS was associated with worse IDFS (hazard ratio HR 1.06, 2-sided p<0) and that and CT was associated with an improvement in IDFS (HR 0.81, p=0.026). Moreover, a distinction exists between postmenopausal and premenopausal patients in their reception of chemoendocrine versus endocrine

therapy based on their RS: in postmenopausal patients (n=3350), the HR for CET vs. ET was not significant (HR=0.97, p=0.82, indicating no benefit from CT, whereas in premenopausal patients (N=1665, 33%), the HR (0.54) was statistically significant (p=0.0004), suggesting CT benefit. In other words, postmenopausal patients in this situation may be spared adjuvant chemotherapy, while premenopausal patients have much to benefit from the same. Therefore, the authors concluded that "the current data show that adjuvant therapy can be de-escalated to ET alone in postmenopausal pts with a RS < 25 and 1-3 +LN" (Kalinsky et al., 2021).

Lashen et al. (2023) studied the performance of Oncotype DX compared to conventional clinicopathological parameters. The study included 420 estrogen receptor-positive/HER2-negative breast cancer patients in the United Kingdom. All patients included in the study had undergone Oncotype DX testing. The authors found a significant association between a high Oncotype DX recurrence score and grade 3 tumors, as well as a significant association between low Oncotype DX recurrence score and special tumor types. Additionally, there was an inverse association between Oncotype DX recurrence score and the levels of estrogen receptor and progesterone receptor expression, and a positive linear relationship between Oncotype DX recurrence score and Ki67 labelling index. The authors state that "some tumour features such as tumour grade, type, PR status and Ki67 index can be used as surrogate markers in certain scenarios." The authors concluded that "Oncotype DX RS is correlated strongly with the conventional clinicopathological parameters" (Lashen et al., 2023).

EndoPredict

EndoPredict® (Myriad Genetic, Inc.) is a breast cancer prognostic test that assesses the expression of eight target genes as compared to three housekeeping (normalization) genes and one additional control gene to detect contamination by residual DNA. The results of this testing are combined to produce a clinical score to determine whether the breast cancer is at high- or low-risk of possible recurrence within ten years (Myriad, 2024a; Warf et al., 2017).

According to the Myriad EndoPredict® Technical Specifications (Effective Date: December 21, 2021), if the test is used on resected tissue, the 12-gene molecular score is then "combined with tumor size and lymph node status to generate an EPclin Risk Score associated recurrence risks and estimated absolute benefit of chemotherapy" whereas "the molecular score and its associated 10-year risk of distance recurrence…are provided" if the sample is a biopsy specimen (Myriad, 2021). The target genes in the EndoPredict® test include the following (Filipits et al., 2019; Warf et al., 2017):

- *BIRC5*
- *DHCR7*
- *UBE2C*
- *AZGP1*
- *IL6ST*
- *MGP*
- *RBBP8*
- *STC2*

Filipits et al. (2011) validated EP's 11 gene version (only missing the one gene to control for DNA contamination, HBB). The investigators combined these gene expression results with nodal status and tumor size into a risk score ("EPClin"). Two cohorts of 378 and 1324 samples were used in this study, and both cohorts demonstrated that the risk score produced was an independent predictor of distant recurrence. The investigators calculated that EPClin had superior prognostic power compared to solely clinicopathologic factors. EPClin was also found to result in a 4% rate of recurrence for both low-risk cohorts in each sample, a 28% recurrence rate in the "high risk" portion of the 378-item sample, and a 22% recurrence rate in the "high risk" portion of the 1324-item sample. The authors concluded that "the multigene EP risk score provided additional prognostic information to the risk of distant recurrence of breast cancer patients, independent from clinicopathologic parameters. The EPclin score outperformed all conventional clinicopathologic risk factors (Filipits et al., 2011; Myriad, 2024b).

Two studies by Sestak et al. (2018)have also shown the clinical validity and utility of EndoPredict® testing in women with node-positive breast cancer (Sestak et al., 2018; Sestak et al., 2019). One study consisted of both node-positive and node-negative women (n=3746) to compare the performance of EPclin for predicting distant recurrence in women who had either received endocrine therapy (ET) alone or ET with chemotherapy (ET+C). "In this comparative non-randomised analysis, the rate of increase in DR with EPclin score was significantly reduced in women who received ET + C versus ET alone. Our indirect comparisons suggest that a high EPclin score can predict chemotherapy benefit in women with ER-positive, HER2-negative disease" (Sestak et al., 2019). In the other study, the researchers compared the performance of six different prognostic signatures for ER-positive breast cancer in two different patient groups—node-negative and node-positive. The six tests include EndoPredict®, Breast Cancer Index (BCI), Clinical Treatment Score (CTS), IHC4, ROR, and RS. Within the node-positive cohort (n=277), the authors report the highest univariate hazard ratio (HR) for EPclin (1.69) compared to 1.39 for RS (Sestak et al., 2018).

Another study (n=1702) compared the use of EndoPredict® in node-positive and node-negative women treated with endocrine therapy only. This study assessed both the 10- and 15-year distant recurrence-free rate (DRFR). Similar to the node-negative individuals, the 10-year DRFR for patients with one to three positive nodes improved significantly higher than for the full cohort (95.6% versus 80.9%, respectively). "The molecular and EPclin scores were significant predictors of DRFR after adjusting for clinical variables, regardless of nodal status" (Filipits et al., 2019).

Evidence of EndoPredict's ability to produce a change in therapeutic management abound. For example, Villarreal-Garza et al. (2020) enrolled 99 premenopausal women with a median age of 43 and with hormone receptor-positive, HER2-negative, T1-T2, and N0-N1 breast cancer, and the cases were presented to a multidisciplinary tumor board. The researchers reported that a "change in chemotherapy or endocrine therapy regimen was suggested in 19% and 20% of cases" when EPclin results were made available. Moreover, it was reported that a significant difference could be "found in the median EPclin score between patients with a low- vs. high-intensity chemotherapy and endocrine therapy regimen recommendation ($p = 0.049$ and $p = 0.0001$, respectively)", which may have contributed to high final treatment adherence (93%) in premenopausal patients (Villarreal-Garza et al., 2020).

Dubsky et al. (2020) used hormone receptor (HR)-positive, HER2-negative samples from patients in the ABCSG-34 randomized phase II trial to generate a 12-gene molecular score with the goal of assessing EndoPredict's ability to predict response to neoadjuvant chemotherapy (NaCT) or neoadjuvant endocrine therapy (NET). The patients in the study were assigned to receive either NaCT or NET based on menopausal status, HR expression, grade and Ki67, and their responses to their assigned therapies were measured by using residual cancer burden (RCB). It was reported that the 12-gene molecular score significantly predicted treatment response for NaCT and NET, boasting areas under the curve (AUC) of 0.736 and 0.726 respectively. Based on these results, it was concluded that "Tumours with low MS were unlikely to benefit from NaCT, whereas a high MS predicted resistance to NET", further motivating the use of EndoPredict to provide personalized treatment to patients (Dubsky et al., 2020).

Breast Cancer Index

The Breast Cancer Index (BCI) is a combination of two profiles, the HOXB13-to-IL17BR expression ratio (H:I ratio) and the Molecular Grade Index (MGI). This combination is intended to report "Whether or not an additional five years of anti-estrogen therapy is likely to help reduce [the] risk of the cancer returning" and "[the] individual risk of recurrence after 5 years based on [the] original tumor biology." The five genes the MGI

examines are *BUB1B*, *CENPA*, *NEK2*, *RACGAP1*, and *RRM2* (Biotheranostics, 2023). Using genome-wide microarray analysis, three differentially expressed genes that were associated with an increased risk of progression among ER-positive patients treated with tamoxifen were: the antiapoptotic homeobox B13 (HOXB13, overexpressed in tamoxifen recurrent cases) and both interleukin 17B receptor (IL17BR) and EST AI240933 (both overexpressed in tamoxifen nonrecurrent cases) (Foukakis & Bergh, 2022).

The MGI was validated by separate 410-sample and 323-sample cohorts, and its interaction with the H:I ratio was evaluated. The authors found that "high MGI was associated with significantly worse outcome only in combination with high HOXB13:IL17BR, and likewise, high HOXB13:IL17BR was significantly associated with poor outcome only in combination with high MGI." The investigators concluded that "the combination of MGI and HOXB13:IL17BR outperforms either alone and identifies a subgroup (~30%) of early stage estrogen receptor–positive breast cancer patients with very poor outcome despite endocrine therapy (Ma et al., 2008).

The BCI has been recently demonstrated to be discerning in other respects. The IDEAL trial attempted to answer the pressing question of the optimal duration of extended endocrine therapy (EET), after completing five years of initial aromatase inhibitor (AI)–based adjuvant therapy (Liefers et al., 2020). The IDEAL trial assessed the ability of BCI (H/I) to predict endocrine benefit of 2.5 vs. five years of extended letrozole using available tumor specimen samples from 908 HR+ patients (73% lymph node-positive, disease free at 2.5 years), with 88% and 68% of which were receiving prior treatment with an aromatase inhibitor (AI) or chemotherapy, respectively. It was found that BCI by H/I status (High vs. Low) was "significantly predictive of response from extended letrozole in the overall (N = 908) and pN+ [lymph node-positive] (N = 664) cohorts", leading the researchers to exalt the BCI as an important genomic tool for future use (Liefers et al., 2020).

Predictor Analysis of Microarray 50

The Predictor Analysis of Microarray 50 (PAM50, by Prosigna) is a 50-gene test that characterizes an individual tumor by intrinsic subtype. It was designed to determine the intrinsic subtype of a cancer using only 50 prespecified genes. The four subtypes are "luminal A, luminal B, HER2-enriched, and basal-like" (Parker et al., 2009). Results from the PAM50 are used to generate the risk of recurrence (ROR) score, which can stratify patients with ER-positive disease into high, medium, and low subsets. The test can be performed on formalin-fixed, paraffin-embedded tissue with a high degree of analytical validity (Foukakis & Bergh, 2022; Nielsen et al., 2010).

This test was validated by Parker et al. (2009)The investigators developed this 50-gene set from 189 prototype samples and evaluated 761 patients for prognosis. The four discrete subtypes were found to be prognostically significant and predicted neoadjuvant chemotherapy efficacy with a negative predictive value for pathologic complete response (to a taxane and anthracycline regimen) of 97%. The authors concluded "diagnosis by intrinsic subtype adds significant prognostic and predictive information to standard parameters for patients with breast cancer" (Parker et al., 2009).

Recently, the intrinsic molecular subtype generated by the Prosigna assay has been demonstrated to be useful in guiding the inclusion and exclusion of an anthracycline to CMF-based chemotherapy. The DBCG89D trial randomized 980 high-risk early breast cancer patients to adjuvant CMF (cyclophosphamide, methotrexate and fluorouracil) or CEF (cyclophosphamide, epirubicin and fluorouracil), ultimately using the data from 686 tumor samples. Continuous ROR score was associated with distant recurrence for CMF and CEF (hazard ratios of 1.20 and 1.04, respectively), and distant recurrence was reported to be significantly longer in those patients with HER2-enriched tumors treated with CEF than with CMF. The results suggested that the benefit of CEF as compared to CMF correlate with an increasing ROR score, and so "patients with Her2-enriched breast cancer derived substantial benefit from anthracycline chemotherapy whereas anthracyclines are not an essential component of chemotherapy for patients with luminal subtypes", and, similarly, "A benefit from substituting methotrexate with epirubicin is observed among patients with Her2-enriched or Basal-like subtypes whereas there is a lack of such benefit among patients with a Luminal A or Luminal B subtypes" (Jensen et al., 2020). However, the authors admit that the results of the study may potentially be skewed by the retrospective evaluation's use of only a small subset of patients' data and the lack of optimal instrumentation and testing, since one-third of the patients were ER-positive but endocrine therapies were not employed (Jensen et al., 2020).

MammaPrint

MammaPrint is a 70-gene test that assesses the risk of recurrence within the first 5-10 years of diagnosis. The test reports risk in one of two categories, "low" and "high." MammaPrint's validation places "low" risk at a 1.3% chance (95% confidence interval: 0-3.1%) that cancer will recur in five years whereas those classified as "high" risk have a 11.7% chance for the cancer to recur in five years (95% confidence interval: 6.6%-16.8%) (Agendia, 2014, 2024b). Agendia offers other breast cancer assessments, such as BluePrint. BluePrint is an 80-gene molecular subtyping assay, which "analyzes the activity" of its genes. It is proposed to identify a tumor's molecular "subtype": luminal A/B, basal, or HER2. Each subtype has varying molecular characteristics (ER-positive or

negative, HER2-positive or negative, et al), which is proposed to help clinicians provide targeted treatment for a patient (Agendia, 2024a).

MammaPrint was validated by Cardoso et al. (2016)The authors determined the risk recurrence of 6693 patients. Of these 6693 patients, 1550 of them were found to have high clinical risk and low genomic risk, and the rate of survival without distant metastasis in this cohort was 94.7% among those not receiving chemotherapy. The difference in survival rate between these patients and those receiving chemotherapy was 1.5%. The authors estimated that "given these findings, approximately 46% of women with breast cancer who are at high clinical risk might not require chemotherapy" (Cardoso et al., 2016).

However, it may be possible that new prognostic assays are beginning to make their foray. Prat et al. (2020) derived a prognostic assay that integrates multiple data types for predicting survival outcome in patients with newly diagnosed HER2-positive breast cancer to aid treatment decisions for those with early-stage HER2-positive breast cancer, where escalation or de-escalation of systemic therapy is a point of contention. Using clinical-pathological data on stromal tumor-infiltrating lymphocytes, PAM50 subtypes, and expression of 55 genes obtained from patients who participated in the Short-HER phase 3 trial, Prat et al. (2020) then evaluated their model based on a combined dataset of 267 patients with early-stage HER2-positive breast cancer treated with different neoadjuvant and adjuvant anti-HER2-based combinations and from four other studies (PAMELA, CHER-LOB, Hospital Clinic, and Padova) with disease-free survival outcome data. The final model, named HER2DX, was comprised of data from 435 (35%) of 1254 patients for tumor size (T1 vs rest), nodal status (N0 vs rest), number of tumor-infiltrating lymphocytes (continuous variable), subtype (HER2-enriched and basal-like vs rest), and 13 genes. The authors exalt the analytical power of HER2DX by reporting that it was "significantly associated with disease-free survival as a continuous variable" and reported that the 5-year disease-free survival in the HER2DX low-risk group was 93.5% (89.0-98.3%) whereas the high-risk group reported 81.1% (71.5-92.1). The researchers assert that HER2DX "identifies patients with early-stage, HER2-positive breast cancer who might be candidates for escalated or de-escalated systemic treatment" and that "Future clinical validation of HER2DX seems warranted to establish its use in different scenarios, especially in the neoadjuvant setting" (Prat et al., 2020).

DCISionRT®

The DCISionRT test out of Prelude Corporation aims to provide patients with three results: 1) their overall score (continuous risk score and low vs elevated category, 2) their rate of recurrence over 10 years, and 3) their benefit from radiation. The intended demographic is females aged 26 and older who have been diagnosed with ductal

carcinoma in situ (DCIS) of the breast, and who have been treated with breast conserving surgery or a core biopsy (PreludeDx, 2024).

Recognizing that patients diagnosed with DCIS are at risk of recurrence (30%) within 10 years following breast conserving surgery and that election of RT is not always beneficial, the SweDCIS randomized clinical trials also investigated the validity of the DCISionRT biosignature, which combines an evaluation of protein expression (PR, HER2, Ki67, FOXA1, p16/INK4A, SIAH2, COX2) with clinicopathologic factors (age, tumor size, margin status, palpability) and mapped it along a continuous Decision Score (DS) on a scale of 1 to 10 with corresponding 10-year risks after breast conserving surgery with and without radiation therapy (Wärnberg et al., 2021). The authors found that "using the pre-specified DS threshold of 3.0 to define DS Low and Elevated Risk groups, approximately 50% of women were classified into the Elevated Risk group", which is significant as many women who would have been erroneously sorted into one risk group based on classical clinicopathology were found to be better reclassified into opposite risk groups based on their DS. Finally, in the DS Elevated Risk group, the addition of radiation therapy was found to reduce absolute 10-year rates for TotBE by 15.9%, and for InvBE by 9.4%, while the DS Low Risk Group boasted 10-year DCIS rates of 0.7% and 5.2%, and InvBE rates of 6.5% and 7.7%, with and without RT, respectively, indicating to the authors that "Radiotherapy benefit was statistically significant in patients with elevated DS but not in patients with low DS by DCISionRT", though it is also admitted that this evaluation may not reflect modern practice and modern risk profiles because the women participating in the trials were randomly assigned between 1987 and 2000 (Wärnberg et al., 2021).

Bremer et al. (2018) reported on the development and the cross-validation of the DCISionRT biosignature using archived tissue samples from Uppsala University Hospital and Västmanland County Hospital, Sweden (UUH), from 1986 and 2004 and samples from between 1999 and 2008 at the University of Massachusetts, Worcester (UMass), in collaboration with PreludeDx. The study population comprised 721 female patients diagnosed with a primary DCIS and treated with BCS identified from 2 study sites, with mean and median follow-ups of 10 years and 9 years, respectively. Here, the authors found the Decision Score reclassified greater than 50% of the low- and intermediate-grade patients as elevated risk, and 33% of patients that were grade III or had tumor size >2.5 cm were reclassified as low risk. Moreover, it was found that in the low clinicopathological risk group—defined to have tumor size less than 25 mm, low or intermediate grade, and nonpalpable and clear margins—DS reclassified 42% of these patients into the Elevated Risk Group (DS > 3.0). When a linear panel using weighted clinicopathologic and molecular factors to assess recurrence risk was constructed for comparison with the proprietary biosignature, it could not identify a clinically meaningful low-risk group. The researchers reported that "These reclassified patients

had substantial 10-year risks, 23% (95% CI: 7%–36%) IBC and 31% (95% CI: 14%–45%) IBE, when not treated with RT" and that while patients in the DS Low Group had similar outcomes regardless of whether they received RT, patients treated with RT and classified into the Elevated Risk Group received a 70% or greater risk reduction than those without RT (Bremer et al., 2018). As such, Bremer et al. (2018) claims that these "findings reflect the effectiveness of the biological signature to identify patients with favorable tumor biology and separate them from the Elevated Risk Group of patients that have the highest likelihood of recurrence."

These results corroborate other investigations into the utility of DCISionRT in guiding treatment management. The prospective, multi-institutional PREDICT study found that DCISionRT testing can lead to great changes in radiation therapy recommendations, such that of the 539 women participating in the study, 69% were initially slated RT pre-test (n = 374) by treating clinicians based on traditional clinicopathology and 46% were recommended to not receive RT post-test (*n* = 165). But of those initially recommended to not receive RT (n = 165), 35% were then recommended to receive RT post-test (n = 58). As such, the authors reported a significant overall change in the RT recommendation for 42% of women (n = 539, $p < 0.001$) and a net reduction in the RT recommendation by 20% (Shah et al., 2021). Furthermore, after DCISionRT testing, elevated versus low DCISionRT score (DS>3 vs. DS ≤ 3) was found to be the strongest factor for an RT recommendation (odds ratio of 43.1) compared against all other factors (age, grade, tumor size, margin status, patient preference). However, the authors acknowledge that there exist limitations to the study, namely that long-term clinical outcomes and satisfaction ratings from patients and physicians are unavailable for analysis and that data for RT recommendations are limited to post-surgery/pre-testing and post-surgery/post-testing time points (Shah et al., 2021). Thus, while the results seem promising, the real predictive power of the DCISionRT test is still uncertain. Additional information will be critical to evaluating the test's value and valence—whether positive or negative—in ultimately determining the benefit of adjuvant RT following BCS.

Dabbs et al. (2023) studied the analytical validity, performance assessment, and clinical performance validation and clinical utility for the DCISionRT test. The authors performed an analytical validation assessment on multiple DCIS molecular assays; the analytical validation test was conducted based on Clinical and Laboratory Standards Institute guidelines. "The analytic validation showed that the molecular assays that are part of DCISionRT test have high sensitivity, specificity, and accuracy/reproducibility (≥95%)." The authors concluded that the DCISionRT has high analytical validity (Dabbs et al., 2023).

BBDRisk Dx®

The BBDRisk Dx® test is "the first genomic risk test designed specifically for women diagnosed with breast masses that have one or more of the following: Atypical Ductal Hyperplasias (ADH), Atypical Lobular Hyperplasia (ALH), Usual Ductal Hyperplasias (UDH), Papilloma and Sclerosing Adenosis" (BBDRiskDx, 2023). The test assays four cancer biomarker oncoproteins—Matrix Metalloproteinase-1 (MMP-1), Carcinoembryonic Antigen-related Cell Adhesion Molecule 6 (CEACAM6), Hyaluronoglucosaminidase 1 (HYAL1), Highly Expressed in Cancer Protein 1 (HEC1)—requiring a sample of formalin fixed paraffin embedded (FFPE) tissue for the immunohistochemistry. The four-marker profile is then rendered to produce a Cancer Risk Score between the range of 0 and 10, classifying the patient into the 'Low Risk' Group (Risk Score =< 0.5), the 'Intermediate Risk' group (>0.5 but =<5.4), and the 'High Risk' group (>5.4). These scores help provide the patient with information about their chances of developing future breast cancer over 5 to 10 years—as compared with women with similar profiles—and guide physician discretion in proposing prophylactic endocrine treatments and or surgery (Silbiotech, 2021).

Poola et al. (2019) explored the effectiveness of the four-marker signature of MMP-1, CEACAM6, HYAL1, and HEC1 in identifying the benefit that high-risk patients presenting atypical and nonatypical hyperplasias would derive from preventive therapies. A total of 440 tissues were included in the study and categorized into two groups: a cancer group of 162 specimens that developed DCIS after a minimum of one year and a maximum of 13 years, and a cancer-free group of 278 specimens from subjects who did not have prior breast cancer and did not develop for a minimum of five years and a maximum of 19 years. A 'cancer risk score' (composite value between 0 and 10) was obtained by combining the multiple marker levels through using piecewise linear regression (Poola et al., 2019). From constructing box plots and density plots of the scores generated from the 440 samples, the authors found that in the risk scores of the cancer-free group peaked around 0.5, while the scores peaked around 9.0 for the cancer group, suggesting that the "risk signature segregates the cancer group from the cancer-free group of tissues." Moreover, analysis of the risk scores between atypical and nonatypical tissues for any differences using *t* test, yielded significantly higher values in the cancer group of atypical tissues ($P = 0.02$) than the nonatypical tissues but the authors did not find any significant differences in the cancer-free groups. Plots produced from Kaplan-Meier survival analysis demonstrated that "In the first 5 years, 53% of subjects in the high-risk group, 12% in the intermediate-risk group, and 1% in the low-risk group developed cancer", and 73% of atypical subjects in high-risk group developed cancer in the first five years, while in the nonatypical group the cancer rates were only 34%. Meanwhile, mapping cancer risk scores to percent cancer rates in five years, 10 years, 15 years, and beyond 15 years produced a direct and positive correlation (Poola et al., 2019).

Clinical Utility and Validity

Blok et al. (2018) performed a meta-analysis of the MammaPrint, OncotypeDX, PAM50/Prosigna and Endopredict assays. The authors investigated the evidence available on both the clinical utility and economic value of these assays. Most of the observed studies concluded that genomic profiling contributed to less chemotherapy use. However, the authors caution that "absolute numbers should be interpreted carefully, since some tests are less frequently studied than others" especially as "the clinical consensus on adjuvant chemotherapy is that we are most likely over-treating our patients, since we are not capable of identifying patients that will or will not benefit from chemotherapy using the current clinicopathological parameters." The authors note that Petkov et al. (2016) retrospectively matched OncoType DX use with SEER registry data for over 40000 patients and found that "patients with node negative, HR+, HER2- breast cancer which underwent testing (n = 40,134, 22.7% chemotherapy) had no lower chemotherapy use compared to patients that were not tested (n = 144,056, 22.2% chemotherapy)." The authors noted that 90% of the 44 economic analyses concluded that genomic testing was cost-effective; however, various biases are mentioned (publication bias, publications using overlapping samples, and more) (Blok et al., 2018).

Gustavsen et al. (2014) performed an economic analysis of the Breast Cancer Index and found that "Costs associated with adjuvant chemotherapy, toxicity, followup, endocrine therapy, and recurrence were modeled over 10 years. The models examined cost utility compared with standard practice when used at diagnosis and in patients disease-free at 5 years post diagnosis." The authors calculated BCI to save approximately $3803 per patient for the newly diagnosed population and $1803 per patient in the five years post diagnosis population. These savings were projected to come from "adjuvant chemotherapy use, extended endocrine therapy use, and endocrine therapy compliance" (Gustavsen et al., 2014).

Camp et al. (2019) investigated a new reinterpretative technique of the PAM50 assay. The authors reorganized the gene expression data provided by the assay into five "quantitative, orthogonal, multi-gene breast tumor traits" and stated that these "dimensions" better represented breast cancer pedigrees. They re-assessed the data of the GEICAM/9906 clinical trial with these dimensions. After reorganization, the authors concluded that dimensions "PC1 and PC5" were associated with disease-free survival, and low "PC3 and PC4" indicated response to paclitaxel. However, high PC3 or PC4 did not show survival advantage (Camp et al., 2019).

Wuerstlein et al. (2019) evaluated the clinical utility of MammaPrint and its intended adjunct test, BluePrint. Physicians were asked to provide initial therapy

recommendations (based on clinicopathological factors), then were provided results of MammaPrint/BluePrint risk stratifiers. Then the same physicians provided new treatment recommendations, and the subsequent treatment was recorded. The authors identified a switch in treatment in 29.1% of cases. Physician adherence to MammaPrint risk assessment was over 90% in both groups of risk (low and high). Even when physicians and risk stratifiers disagreed, the physicians tended to recommend treatments based on the risk stratifier. Overall, the authors concluded that "MammaPrint and BluePrint test results strongly impacted physicians' therapy decisions in luminal EBC with up to three involved lymph nodes" (Wuerstlein et al., 2019).

Toole et al. (2014) evaluated the similarities and differences in genetic profiles between primary breast cancers in patients with multiple primaries. The authors also evaluated whether obtaining genetic profiling scores (OncoType DX) on each primary affected chemotherapy decisions. In total, 22 patients had multiple tumor samples sent for analysis, and the authors found that six patients had their chemotherapy recommendations changed based on differing OncoType scores (between their samples). The authors also noted that scores tended to differ more between tumors appearing simultaneously on different breasts compared to multiple tumors on the same breast (Toole et al., 2014).

Martin et al. (2016) compared the use of EndoPredict® (EPclin) and PAM50 risk of recurrence (ROR) scores in node-positive breast cancer to predict distant metastasis-free survival (MFS). ROR scores can be based using subtype (ROR-S); subtype and proliferation (ROR-P); subtype and tumor size (ROR-T); and subtype, proliferation, and tumor size combined (ROR-PT). They found that "Predictors including clinical information showed superior prognostic performance compared to molecular scores alone (10-year MFS, low-risk group: ROR-T 88 %; ROR-PT 92 %; EPclin 100 %). The EPclin-based risk stratification achieved a significantly improved prediction of MFS compared to ROR-T, but not ROR-PT" (Martin et al., 2016).

Ding et al. (2019) used the 21-gene recurrence score for patients with pure mucinous breast cancer (PMBC). This multi-year study of 8048 female PMBC patients categorized the patients based on RS risk groups of low, intermediate, and high RS risk groups. They found the distribution to be 64.9%, 31.9%, and 3.2%, respectively. For PMBC patients, the authors note that PMBC patients do show significantly different 5-year survival rates based on ER status. They do conclude that RS can be used with PMBC patients…"age, progesterone receptor status, and grade could independently predict RS" (Ding et al., 2019). These data support the findings of a considerably smaller comparative study (n=35 PMBC patients and n=70 IDC patients) that show on average PMBC patients score lower than IDC patients (average RS 21.26 and 24.40,

respectively); however, they authors do conclude that "patients with high RS in the PMBC group might be recommended to receive adjuvant chemotherapy" since 8.57% of PMBC patients have RS scores within the highest risk stratification (W. Wang et al., 2018). Both studies contradict an earlier, smaller study (n=10 TC patients and n=33 MC patients) that reported no patients within the high-risk RS category (Turashvili et al., 2017).

Kizy et al. (2018) conducted a large retrospective study of various subtypes of T1-T2N0 estrogen receptor-positive breast cancer (n=83665) was published in 2018. Both mucinous and tubular histologies were included in the study. The authors note considerable differences in RS scores between the various histologies; for example, they found that 1.0% and 28.5% of tubular adenocarcinoma patients had RS scores in the high and intermediate ranges, respectively, whereas mucinous adenocarcinoma patients fared worse with 3.4% and 28.8%, respectively. It should be noted, however, that only 2.1% of the patients included in the study had been diagnosed with mucinous adenocarcinoma and 0.6% with tubular adenocarcinoma (J. Wang et al., 2018). Similarly, a study by Kizy et al also reports that 4% of tubular carcinoma patients were classified as high risk based on the Trial Assigning Individualized Options for Treatment RS criteria (Kizy et al., 2018).

Harnan et al. (2019) released an in-depth systemic review of the effectiveness and cost-effectiveness of Oncotype DX®, MammaPrint®, Prosigna®, EndoPredict®, and immunohistochemistry 4 (IHC4). For this review, the authors included a total of 153 studies, including the MINDACT RCT for MammaPrint. The authors note that a limitation of this systemic review, and of the current field in general, is that only one RCT has been completed to date. Their results include the following:

- "There is limited and varying evidence that oncotype DX and MammaPrint can predict benefit from chemotherapy."
- "The health economic analysis suggests that the incremental cost-effectiveness ratios for the tests versus current practice are broadly favourable for the following scenarios: (1) oncotype DX, for the LN0 subgroup with a Nottingham Prognostic Index (NPI) of > 3.4 and the one to three positive lymph nodes (LN1–3) subgroup (if a predictive benefit is assumed); (2) IHC4 plus clinical factors (IHC4+C), for all patient subgroups; (3) Prosigna, for the LN0 subgroup with a NPI of > 3.4 and the LN1–3 subgroup; (4) *EndoPredict Clinical, for the LN1–3 subgroup only* [emphasis added]; and (5) MammaPrint, for no subgroups" (Harnan et al., 2019).

Qi et al. (2021) examined the efficacy of the 21-gene assay (Oncotype DX) in core needle biopsies (CNB) as compared to breast cancer resection specimens (the gold standard for obtaining IHC or other molecular information, as they exhibit the most

abundant tumor characteristics). The 21-gene assay can be applied to a CNB and CNBs do have the advantage of having a more standardized fixation protocol as compared to resection specimens, which have many different protocols available and often have a greater time between loss of blood supply and the initiation of fixation due to the complexity of surgery. While CNBs are more reliable in determining hormone receptor status due to decreased loss of antigens from the fixation process that resection specimens undergo, CNBs cannot account for crush artefacts which can lead to inaccurate results because of tumor heterogeneity. CNBs are also less accurate than resection specimens in determining the histological characteristics of a tumor, such as tumor invasiveness and tumor grade. It's also important to note that intratumoral heterogeneity can lead to an underestimation of tumor genomic characteristics because of varying gene expression signations found within different regions of the same tumor.

Qi et al. (2021) utilized a paired CNB and resection specimen approach to assess the concordance of the Oncotype DX results between the CNB and resection samples. They found that determination of 21-gene assay results from CNBs are reliable, providing results which closely parallel those obtained from resection specimens. However, there is no clear data indicating that tumor grade can be determined using a CNB sample (Qi et al., 2021).

Sennerstam et al. (2017) conducted retrospective study looking at the long-term outcomes of patients with breast cancer diagnosed with fine-needle aspiration biopsy (FNAB) vs CNB in the 1970s and the 1990s (diagnosis using FNAB from 1971-1976 (n=354); diagnosed using CNB from 1991-1995 (n=1,729)) shows a potentially alarming trend. The authors treatment, mammography screening, tumor size, DNA ploidy, and patient age matched samples from the two decades to get two strictly matched samples representing FNAB (n=181) and CNB (n=203), which were selected for a 15-year follow-up study. When comparing the rates of distant metastasis in the strictly matched patient groups, they found that 5-15 years after diagnosis of the primary tumor, patients diagnosed via CNB had significantly higher rates of metastases as compared to those diagnosed via FNAB (Sennerstam et al., 2017).

VI. Guidelines and Recommendations

American Society of Clinical Oncology (ASCO)

In 2016, ASCO provided recommendations on appropriate use of breast tumor biomarker assay results to guide decisions on adjuvant systemic therapy for women with early-stage invasive breast cancer. ASCO recommends that "in addition to estrogen and progesterone receptors and human epidermal growth factor receptor 2,

the panel found sufficient evidence of clinical utility for the biomarker assays Oncotype DX, EndoPredict, PAM50, Breast Cancer Index, and urokinase plasminogen activator and plasminogen activator inhibitor type 1 in specific subgroups of breast cancer" (Harris et al., 2016).

ASCO also made the following recommendations:

- "If a patient has ER/PgR-positive, HER2-negative (node-negative) breast cancer, the clinician may use the 21-gene recurrence score to guide decisions on adjuvant systemic chemotherapy. Type: evidence based. Evidence quality: high. Strength of recommendation: strong.
- If a patient has ER/PgR-positive, HER2-negative (node-positive) breast cancer, the clinician should not use the 21-gene RS to guide decisions on adjuvant systemic chemotherapy. Type: evidence based. Evidence quality: intermediate. Strength of recommendation: moderate.
- If a patient has HER2-positive breast cancer or TN breast cancer, the clinician should not use the 21-gene RS to guide decisions on adjuvant systemic therapy. Type: informal consensus. Evidence quality: insufficient. Strength of recommendation: strong
- If a patient has ER/PgR-positive, HER2-negative (node-positive) breast cancer, the clinician should not use the Breast Cancer Index, the PAM50-ROR, the 12-gene risk score, or the 21-gene RS, (EndoPredict), to guide decisions on adjuvant systemic therapy.
- If a patient has ER/PgR-positive, HER2-negative (node-negative) breast cancer, the clinician may use urokinase plasminogen activator (uPA), plasminogen activator inhibitor type 1 (PAI-1), the Breast Cancer Index, the PAM50 risk of recurrence (ROR) score, the 12-gene risk score (EndoPredict), and the 21-gene recurrence score (Oncotype DX) to guide decisions on adjuvant systemic therapy. If the patient has had 5 years of endocrine therapy without evidence of recurrence, the clinician should not use multiparameter gene expression or protein assays (Oncotype DX, EndoPredict, PAM50, Breast Cancer Index, or IHC4) to guide decisions on extended endocrine therapy.
- If a patient has HER2-positive breast cancer or TN breast cancer, the clinician should not use uPA, IHC4, the 12-gene risk score (EndoPredict), PAI-1, the 21-gene RS (Oncotype DX), the five-protein assay (Mammostrat), the Breast Cancer Index or TILs to guide decisions on adjuvant systemic therapy. The clinician should not use circulating tumor cells (CTCs) to guide decisions on adjuvant systemic therapy.

- If a patient has HER2-positive breast cancer, the clinician should not use the PAM50-ROR to guide decisions on adjuvant systemic therapy. Type: informal consensus. Evidence quality: insufficient. Strength of recommendation: strong
- If a patient has TN breast cancer, the clinician should not use the PAM50-ROR to guide decisions on adjuvant systemic therapy. Type: informal consensus. Evidence quality: insufficient. Strength of recommendation: strong" (Harris et al., 2016).

In 2017 the ASCO (Krop et al., 2017), based on a review of the MINDACT study publication, revised their guidelines on *Use of Biomarkers to Guide Decisions on Adjuvant Systemic Therapy for Women With Early-Stage Invasive Breast Cancer* to state the following:

"***Recommendation 1.1.1 (update of Recommendation 1.7).***

If a patient has **ER/PgR–positive, HER2-negative, node-negative,** breast cancer, the MammaPrint assay may be used in those with **high clinical risk** per MINDACT categorization to inform decisions on withholding adjuvant systemic chemotherapy due to its ability to identify a good prognosis population with potentially limited chemotherapy benefit (Type: evidence based; Evidence quality: high; Strength of recommendation: strong).

Recommendation 1.1.2 (update of Recommendation 1.7).

If a patient has **ER/PgR–positive, HER2-negative, node-negative,** breast cancer, the MammaPrint assay **should not** be used in those with **low clinical risk** per MINDACT categorization to inform decisions on withholding adjuvant systemic chemotherapy as women in the low clinical risk category had excellent outcomes and did not appear to benefit from chemotherapy even with a genomic high-risk cancer (Type: evidence based; Evidence quality: high; Strength of recommendation: strong)."

Recommendation 1.2.2: (update of 2016 recommendation 1.7): If a patient has **ER/PgR–positive, HER2-negative, node-positive**, breast cancer, the MammaPrint assay should not be used in patients with one to three positive nodes and at low clinical risk per MINDACT categorization to inform decisions on withholding adjuvant systemic chemotherapy. There are insufficient data on the clinical utility of MammaPrint in this specific patient population (Type: informal consensus; Evidence quality: low; Strength of recommendation: moderate).

Recommendation 1.3: (update of 2016 recommendation 1.8): If a patient has **HER2-positive** breast cancer, the clinician should not use the MammaPrint assay to guide decisions on adjuvant systemic therapy. Additional studies are required to address the role of MammaPrint in patients with this tumor subtype who are also

receiving HER2-targeted therapy (Type: informal consensus; Evidence quality: low; Strength of recommendation: moderate).

Recommendation 1.4: (update of 2016 recommendation 1.9): If a patient has **ER/PgR negative and HER2-negative (triple negative)** breast cancer, the clinician should not use the MammaPrint assay to guide decisions on adjuvant systemic chemotherapy (Type: informal consensus; Evidence quality: insufficient; Strength of recommendation: strong)" (Krop et al., 2017).

ASCO published an update regarding the "Role of Patient and Disease Factors in Adjuvant Systemic Therapy Decision Making for Early-Stage, Operable Breast Cancer", which was released in response to the results of two phase III trials, MINDACT and TAILORx. The updated guidelines state that the clinical trials found evidence of clinical utility for both node-positive and node-negative patients, but only for patients determined to be at high clinical risk. Therefore, the Panel did not recommend use of MammaPrint for patients determined to be of low clinical risk (Henry et al., 2019).

In a focused update published in 2019, the ASCO addressed the use of Oncotype DX in the following recommendation:

"For patients with hormone receptor–positive, axillary node–negative breast cancer whose tumors have Oncotype DX recurrence scores of less than 26, there is little to no benefit from chemotherapy, especially for patients older than age 50 years. Clinicians may recommend endocrine therapy alone for women older than age 50 years. For patients 50 years of age or younger with recurrence scores of 16 to 25, clinicians may offer chemoendocrine therapy. Patients with recurrence scores greater than 30 should be considered candidates for chemoendocrine therapy. Based on informal consensus, the panel recommends that oncologists may offer chemoendocrine therapy to these patients with recurrence scores of 26 to 30" (Andre et al., 2019).

In 2022, the ASCO released a guideline update on biomarkers for adjuvant endocrine and chemotherapy in early-stage breast cancer. The ASCO recommends that

- "**Recommendation 1.1.** If a patient has node-negative breast cancer, the clinician may use the Oncotype DX test to guide decisions for adjuvant endocrine and chemotherapy (Type: evidence-based; Evidence quality: high; Strength of recommendation: strong).
- **Recommendation 1.2.** In the group of patients in Recommendation 1.1 with Oncotype DX recurrence score greater or equal to 26, the clinician should offer chemoendocrine therapy (Type: evidence-based; Evidence quality: high; Strength of recommendation: strong).

- **Recommendation 1.3.** In the group of patients in Recommendation 1.1 who are 50 years of age or younger with Oncotype DX recurrence score 16 to 25, the clinician may offer chemoendocrine therapy (Type: evidence-based; Evidence quality: intermediate; Strength of recommendation: moderate).
- **Recommendation 1.4.** If a patient is postmenopausal and has node-positive breast cancer with 1-3 positive nodes, the clinician may use the Oncotype DX test to guide decisions for adjuvant endocrine and chemotherapy (Type: evidence-based; Evidence quality: high; Strength of recommendation: strong).
- **Recommendation 1.5.** In the group of patients in Recommendation 1.4, the clinician should offer chemoendocrine therapy for those whose Oncotype DX recurrence score is ≥ 26 (Type: evidence-based; Evidence quality: high; Strength of recommendation: strong).
- **Recommendation 1.6.** If a patient is premenopausal and has node-positive breast cancer with 1-3 positive nodes, Oncotype DX test should not be offered to guide decisions for adjuvant systemic chemotherapy (Type: evidence-based; Evidence quality: high; Strength of recommendation: moderate).
- **Recommendation 1.7.** If a patient has node-positive breast cancer with ≥ 4 positive nodes, the evidence on the clinical utility of routine Oncotype DX to guide decisions for adjuvant endocrine and chemotherapy is insufficient to recommend its use (Type: informal consensus; Evidence quality: insufficient; Strength of recommendation: moderate)" (Andre et al., 2022).

American Cancer Society (ACS)

In 2017 the American Cancer Society (ACS) released a revision to the American Joint Cancer Committee's Eighth Edition Cancer Staging Manual. The revision suggests that

"For patients with hormone receptor-positive, HER2-negative, and lymph node-negative tumors, a21-gene (Oncotype Dx) recurrence score less than 11, regardless of T size, places the tumor into the same prognostic category as T1a-T1b N0 M0, and the tumor is staged using the AJCC prognostic stage group table as stage I.

For patients with hormone receptor-positive, HER2-negative, and lymph node-negative tumors, a Mammaprint low-risk score, regardless of T size, places the tumor into the same prognostic category as T1a-T1b N0 M0.

For patients with hormone receptor-positive, HER2-negative, and lymph node-negative tumors, a12-gene (EndoPredict) low-risk score, regardless of T size, places the tumor into the same prognostic category as T1a-T1b N0 M0.

For patients with hormone receptor-positive, HER2-negative, and lymph node-negative tumors, aPAM50 risk–of-recurrence score in the low range, regardless of T size, places the tumor into the same prognostic category as T1a-T1b N0 M0.

For patients with hormone receptor-positive, HER2-negative, and lymph node-negative tumors, a Breast Cancer Index in the low-risk range, regardless of T size, places the tumor into the same prognostic category as T1a-T1b N0 M0" (Giuliano et al., 2017).

National Comprehensive Cancer Network (NCCN)

The NCCN Clinical Practice Guidelines for Breast Cancer consider five gene expression assays for adjuvant systemic therapy. The five are comprised of the 21-gene Oncotype Dx, the 70-gene MammaPrint, the 50-gene PAM50 (Prosigna), the 12-gene EndoPredict, and the Breast Cancer Index (BCI). All five gene expression assays achieved the NCCN Category of Evidence and Consensus grade of 2A (consensus of appropriateness of intervention based on lower-level evidence) or higher, with Oncotype Dx achieving grade 1 (consensus based on higher-level evidence) for predictive and prognostic use, and MammaPrint achieving grade 1 for prognostic use in patients who are diagnosed as node-negative or with 1 to 3 positive nodes. It should be noted that NCCN identifies only the Oncotype Dx as suitable for prediction of chemotherapy benefit; NCCN states that "Other prognostic gene assays can provide prognostic information but the ability to predict chemotherapy benefit is unknown." BCI is identified as suitable for predicting benefit of extended adjuvant endocrine therapy (NCCN, 2024).

The NCCN Panel "notes that the multigene assays provide prognostic and therapy-predictive information that complements TNM and biomarker information." Below is the table from their recommendations and guidelines based on risk scores and nodal statuses of the multigene assays (NCCN, 2024):

GENE EXPRESSION ASSAYS FOR CONSIDERATION OF ADJUVANT SYSTEMIC THERAPY[a,b]

Assay	Recurrence Risk	Treatment Implications
21-gene (Oncotype Dx) (for postmenopausal patients with pN0 and pN1 [1–3 positive nodes])[c]	<26	Patients with T1b/c–2, pN0, HR-positive, HER2-negative tumors, with risk scores (RS) between 0–10 have a risk of distant recurrence of <4% and those with RS 11–25 derived no benefit from the addition of chemotherapy to endocrine therapy in the prospective TAILORx study.[1] Postmenopausal patients with pT1–3, pN1, HR-positive, HER2-negative, with RS <26 derived no benefit from the addition of chemotherapy to endocrine therapy in the prospective RxPONDER study.[2]
	≥26	In postmenopausal patients with pT1–3, HR-positive, HER2-negative, and pN0 and pN1 (1–3 positive nodes) tumors and an RS ≥26, the addition of chemotherapy to endocrine therapy is recommended.[1,2]
21-gene (Oncotype Dx) (for premenopausal patients: pN0)	≤15	Premenopausal patients with T1b/c –2, pN0, HR-positive, HER2-negative tumors with RS <16 derived no benefit from the addition of chemotherapy to endocrine therapy in the prospective TAILORx study.[1]
	16–25	In premenopausal patients with RS between 16–25, a small benefit from the addition of chemotherapy could not be ruled out, but it is unclear if the benefit was due to the ovarian suppression effect promoted by chemotherapy in premenopausal patients.[1,2] For this group, consider chemotherapy followed by endocrine therapy or alternatively, ovarian function suppression combined with either tamoxifen or an AI.
	≥26	In premenopausal patients with HR-positive, HER2-negative, and pN0 tumors and an RS ≥26, the addition of chemotherapy to endocrine therapy is recommended.[1]
21-gene (Oncotype Dx) (for premenopausal patients with 1–3 positive nodes)[c]	<26	In premenopausal patients with pT1–3 and pN1 (1–3 positive nodes) tumors and an RS <26, the addition of chemotherapy to endocrine therapy was associated with a lower rate of distant recurrence compared with endocrine monotherapy[2] but it is unclear if the benefit was due to the ovarian suppression effects promoted by chemotherapy. For this group of patients, consider chemotherapy followed by endocrine therapy or alternatively, ovarian function suppression combined with either tamoxifen or an AI.[2]
	≥26	In premenopausal patients with HR-positive, HER2-negative, pT1–3 and pN1 (1–3 positive nodes) tumors and an RS ≥26, the addition of chemotherapy to endocrine therapy is recommended.[2]

[a] Gene expression assays provide prognostic and therapy-predictive information that complements T,N,M and biomarker information. Use of these assays is not required for staging. The 21-gene assay (Oncotype Dx) is preferred by the NCCN Breast Cancer Panel for prognosis and prediction of chemotherapy benefit. Other prognostic gene expression assays can provide prognostic information but the ability to predict chemotherapy benefit is unknown.
[b] See Special Considerations for Breast Cancer in Males (Sex Assigned at Birth) (BINV-J).
[c] In the overall study population of the RxPONDER trial, 10.3% had high-grade disease and 9.2% had 3 involved nodes.

GENE EXPRESSION ASSAYS FOR CONSIDERATION OF ADJUVANT SYSTEMIC THERAPY[a,b]

Assay	Recurrence Risk	Treatment Implications
70-gene (MammaPrint) (for pN0 and 1–3 positive nodes)	High	Patients with high clinical risk and low genomic risk were randomly assigned to receive chemotherapy (n = 749) or not (n = 748); this was the intention-to-treat population. The 8-year estimates for distant metastasis-free survival in the intention-to-treat population were 92.0% (95% CI, 89.6–93.8) for chemotherapy versus 89.4% (86.8–91.5) for no chemotherapy (HR, 0.66; 95% CI, 0.48–0.92). An exploratory analysis confined to the subset of patients with HR-positive, HER2-negative disease (1358 [90.7%] of 1497 randomly assigned patients, of whom 676 received chemotherapy and 682 did not) shows different effects of chemotherapy administration on 8-year distant metastasis-free survival according to age: 93.6% (95% CI, 89.3–96.3) with chemotherapy versus 88.6% (83.5–92.3) without chemotherapy in 464 patients aged ≤50 years (absolute difference 5.0 percentage points [SE, 2.8; 95% CI, −0.5–10.4]) and 90.2% (86.8–92.7) versus 90.0% (86.6–92.6) in 894 females >50 years (absolute difference 0.2 percentage points [2.1, −4.0–4.4]). The 8-year distant metastasis-free survival in the exploratory analysis by nodal status in these patients was 91.7% (95% CI, 88.1–94.3) with chemotherapy and 89.2% (85.2–92.2) without chemotherapy in 699 node-negative patients (absolute difference 2.5 percentage points [SE, 2.3; 95% CI, −2.1 –7.2]) and 91.2% (87.2–94.0) versus 89.9% (85.8–92.8) for 658 patients with one to three positive nodes (absolute difference 1.3 percentage points [2.4, −3.5–6.1]).[3]
	Low[c]	
50-gene (Prosigna) (for pN0 and 1–3 positive nodes)	Node negative: Low (0–40), Intermediate (41–60), High (61–100)	For patients with T1 and T2 HR-positive, HER2-negative, pN0 tumors, a risk of recurrence score in the low range, regardless of T size, places the tumor into the same prognostic category as T1a–T1b,N0,M0.[4]
	Node positive: Low (0–40)	In patients with HR-positive, HER2-negative, pN+ tumors (1–3 positive lymph nodes) with low risk of recurrence score, treated with endocrine therapy alone, the distant recurrence risk was less than 3.5% at 10 years and no distant recurrence was seen at 10 years in the TransATAC study in a similar group.[5]
	Node positive: High (41–100)	
12-gene (EndoPredict) (pN0 and 1–3 positive nodes)	Low (≤3.3)	For patients with T1 and T2 HR-positive, HER2-negative, and pN0 tumors, a 12-gene low-risk score, regardless of T size, places the tumor into the same prognostic category as T1a–T1b,N0,M0.[6] In ABCSG 6/8, patients in the low-risk group had risk of distant recurrence of 4% at 10 years and in the TransATAC study, patients with 1–3 positive nodes in the low-risk group had a 5.6% risk of distant recurrence at 10 years.[6,7] The assay is prognostic in endocrine and chemo-endocrine treated patients.[7]
	High (>3.3)	

[a] Gene expression assays provide prognostic and therapy-predictive information that complements T,N,M and biomarker information. Use of these assays is not required for staging. The 21-gene assay (Oncotype Dx) is preferred by the NCCN Breast Cancer Panel for prognosis and prediction of chemotherapy benefit. Other prognostic gene expression assays can provide prognostic information but the ability to predict chemotherapy benefit is unknown.
[b] See Special Considerations for Breast Cancer in Males (Sex Assigned at Birth) (BINV-J).
[2] Postmenopausal patients with UltraLow risk in the Stockholm Tamoxifen trial had a 20-year breast cancer specific survival of 97% with 2-5 years of Tamoxifen (Esserman LJ, et al. JAMA Oncology 2017;3:1503-1510). Patients with an ultralow-risk in the MINDACT trial have shown 8-year breast cancer specific survival above 99%. (Lopes Cardozo JMN, et al. J Clin Oncol 2022;40:1335-1345).

GENE EXPRESSION ASSAYS FOR CONSIDERATION OF EXTENDED ADJUVANT SYSTEMIC THERAPY[a,b]

Assay	Recurrence Risk/ Predictive Result	Treatment Implications
Breast Cancer Index (BCI)	BCI (H/I) Low	• For patients with T1 and T2 HR-positive, HER2-negative, and pN0 tumors, a BCI (H/I) in the low-risk range (0–5), regardless of T size, places the tumor into the same prognostic category as T1a–T1b, N0, M0. • Patients with BCI (H/I) low demonstrated a lower risk of distant recurrence (compared to BCI [H/I] high) and no significant improvement in disease-free survival (DFS) or OS compared to the control arm in terms of extending endocrine therapy duration.[8]
	BCI (H/I) High	• For patients with T1 HR-positive, HER2-negative, and pN0 tumors, a BCI (H/I) high (5.1–10) demonstrated significant rates of late distant recurrence. • In secondary analyses of the MA.17, Trans-aTTom, and IDEAL trials, patients with HR-positive, T1–T3, pN0 or pN+ who had a BCI (H/I) high demonstrated significant improvements in DFS when adjuvant endocrine therapy was extended, compared to the control arm.[8-11] • In contrast, BCI (H/I) low patients derived no benefit from extended adjuvant therapy.[8]

[a] Gene expression assays provide prognostic and therapy-predictive information that complements T,N,M and biomarker information. Use of these assays is not required for staging. The 21-gene assay (Oncotype Dx) is preferred by the NCCN Breast Cancer Panel for prognosis and prediction of chemotherapy benefit. Other prognostic gene expression assays can provide prognostic information but the ability to predict chemotherapy benefit is unknown.
[b] See Special Considerations for Breast Cancer in Males (Sex Assigned at Birth) (BINV-J).

The NCCN also had the following to summarize about the assays mentioned above and their respective interpretations and/or rationales:

For Oncotype DX in Node-Negative, HR-positive, HER2-negative disease: "Among patients with T1b/c and T2, lymph node-negative, HR-positive, HER2-negative tumors with RS between 0-10, the risk of distant recurrence is low and these patients derive no incremental benefit from the addition of adjuvant chemotherapy to endocrine therapy. At the other end of the spectrum, patients with lymph node-negative, HR-positive, HER2-negative cancers with high RS (≥31) have a higher risk of distant recurrence and secondary analyses of prospective studies demonstrate a clear benefit from adjuvant chemotherapy."

Further, "for those with intermediate RS (11-25), the recently reported TAILORx trial of postmenopausal patients (n=6711) with lymph node-negative, HR-positive, HER-2 negative breast cancer, showed similar disease-free survival rates at 9-years in those who received adjuvant chemotherapy followed by endocrine therapy compared with endocrine therapy alone."

Based on secondary analyses of studies involving the use of Oncotype DX, the NCCN states that for individuals with node-positive, HR-positive, HER2-negative disease, "results suggest that in patients with limited nodal disease (1-3 positive lymph nodes) and a low RS, the absolute benefit from chemotherapy is likely to be very small." On the other hand, "There is a clear benefit from adjuvant chemotherapy in patients with node-positive, HR-positive, HER2-negative tumors, if the RS is high (≥31)." However, "The absolute benefit of chemotherapy in patients with limited lymph node involvement and a RS ≤25 remains to be determined."

For MammaPrint: The NCCN claims that the "data suggest that the additional benefit of adjuvant chemotherapy in patients with high-clinical risk/low genomic risk is likely

to be small" and that the data suggest that "the results of the 70-gene signature do not provide evidence for making recommendations regarding chemotherapy for patients at low clinical risk."

For PAM50: for "patients with T1 and T2, HR-positive, HER2-negative, lymph node-negative tumors, a ROR in the low range, regardless of tumor size, places the individual into the same prognostic category as T1a-T1b, N0, M0 tumors.

In patients with 1-3 lymph-node positive, HR-positive, HER2-negative disease with low-risk of recurrence score, the distant recurrence risk was less than 3.5% at 10 years with endocrine therapy alone."

For EndoPredict: "patients with HR-positive, HER-2 negative, and lymph-node node-negative disease with a low-risk score by the 12-gene assay had risk of distant recurrence of 4% at 10 years" and "patients with T1 and T2 HR-positive, HER2-negative, and lymph node-negative tumors, a 12-gene low risk score, regardless of T size, places the tumor into the same prognostic category as T1a-T1b, N0, M0." Citing another study, the NCCN states the following for EndoPredict: "patients with 1-3 positive nodes in the low-risk group had a 5.6% risk of distant recurrence at 10 years, suggesting that chemotherapy would be of limited benefit in these patients."

For the BCI: "For patients with T1 and T2 HR-positive, HER2-negative, and lymph node-negative tumors, a BCI in the low-risk range, regardless of T size, places the tumor into the same prognostic category as T1a-T1b, N0, M0. There are limited data as to the role of BCI in HR-positive, HER2-negative, and lymph node-positive breast cancer" (NCCN, 2024).

The NCCN **strongly recommends (Category 1)** considering the use of the 21-gene reverse transcriptase polymerase chain reaction (RT-PCR) assay for determining the use of adjuvant chemotherapy in premenopausal and postmenopausal patients with the following tumor characteristics:

- Hormone receptor-positive;
- HER2 [human epidermal growth factor receptor 2]-negative;
- Ductal/NST, lobular, mixed or micropapillary histology;
- pT1, pT2 or pT3 stage; and pN0;
- Tumor >0.5 cm.

The assay may also be considered for pre- and postmenopausal, node-positive (up to three positive nodes) individuals if such individuals are candidates for chemotherapy.

Within a section on special considerations for breast cancer in men, the NCCN states (Category 2A), "Data are limited regarding the use of molecular assays to assess prognosis and to predict benefit from chemotherapy in males with breast cancer. Available data suggest 21-gene assay recurrence score provides prognostic information in males with breast cancer" (NCCN, 2024).

NCCN also notes that ER status should be determined for DCIS patients, but do not mention any gene expression tests for evaluation (NCCN, 2024).

National Institute for Health and Care Excellence (NICE)

NICE released three new guidelines regarding gene expression tests, which are as follows:

1. "EndoPredict (EPclin score), Oncotype DX Breast Recurrence Score and Prosigna are recommended as options for guiding adjuvant chemotherapy decisions for people with oestrogen receptor (ER)-positive, human epidermal growth factor receptor 2 (HER2)-negative and lymph node (LN)-negative (including micrometastatic disease; see section 5.4) early breast cancer, only if:
    - they have an intermediate risk of distant recurrence using a validated tool such as PREDICT or the Nottingham Prognostic Index
    - information provided by the test would help them choose, with their clinician, whether or not to have adjuvant chemotherapy taking into account their preference
    - the companies provide the tests to the NHS with the discounts agreed in the access proposals and
    - clinicians and companies make timely, complete and linkable record-level test data available to the National Cancer Registration and Analysis Service as described in the data collection arrangements agreed with NICE (see section 5.29)."
2. "MammaPrint is not recommended for guiding adjuvant chemotherapy decisions for people with ER-positive, HER2-negative and LN-negative early breast cancer because it is not cost effective" (NICE, 2018).

European Society for Medical Oncology (ESMO)

ESMO notes that "In cases of uncertainty regarding indications for adjuvant chemotherapy (after consideration of other tests), gene expression assays, such as MammaPrint, Oncotype DX, Prosigna and EndoPredict, may be used, where available. These assays can determine the individual's recurrence risk as well as potentially

predict the benefit of chemotherapy." This point was unchanged in the 2019 update" (Cardoso et al., 2019; Senkus et al., 2015).

In a 2019 update, ESMO elaborates on gene expression profiles for breast cancer. They state that "Gene expression profiles, such as MammaPrint, Oncotype DX Recurrence Score, Prosigna and Endopredict, may be used to gain additional prognostic and/or predictive information to complement pathology assessment and to predict the benefit of adjuvant chemotherapy." They also remark that Prosigna, Endopredict, and Oncotype are intended for ER-positive early breast cancer only and that Mammaprint and OncoType are still being evaluated for clinical utility (Cardoso et al., 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

MammaPrint® received 510(k) clearance from the FDA on June 22, 2007. MammaPrint® is performed in Agendia laboratories and is FDA cleared for use in breast cancer patients who are under 61 years of age, with stage 1 or 2 breast cancer, tumor size ≤5 cm, and lymph node negative (FDA, 2007). MammaPrint® is a qualitative *in vitro* diagnostic test service which uses a 70 gene expression profile from fresh breast cancer tissue samples to assess a patient's risk for distant metastasis (up to 10 years in patients less than 61 years of age). It is indicated for use by physicians as a prognostic marker only, along with other clinicopathological factors. On December 11, 2009, the FDA approved modifications to the cleared device, adding five year prognostic information for breast cancer patients ≥61 years of age (FDA, 2009).

On January 23, 2015, the MammaPrint® FFPE received 510(k) clearance from the FDA. It is a qualitative *in vitro* diagnostic test, using the 70 gene expression profile obtained from FFPE breast cancer tissue samples to assess a patient's risk for distant metastasis within five years. Like the MammaPrint®, the MammaPrint® FFPE is performed for breast cancer patients who are under 61 years of age, with stage 1 or 2 breast cancer, tumor size ≤5 cm, and lymph node negative. It is indicated for use by physicians as a prognostic marker only, along with other clinicopathological factors (FDA, 2015).

The Prosigna™ Breast Cancer Prognostic Gene Signature Assay received 510(k) clearance from the FDA based on substantial equivalence to MammaPrint® on September 6, 2013. It is an *in vitro* diagnostic assay performed on the NanoString nCounter® Dx Analysis System and uses formalin-fixed, paraffin embedded breast tumor tissue that has previously been diagnosed as invasive breast carcinoma. This assay measures the RNA expression profile of 58 genes and weights the expression together with clinical variables to generate a risk category and numerical score, assessing a patient's risk of distant recurrence of disease (FDA, 2013).

On August 5, 2022, FDA approved Enhertu (fam-trastuzumab-deruxtecan-nxki) for the treatment of patients with unresectable or metastatic breast cancer that is also classified as HER2-low; establishing the first FDA-approved therapy for patients diagnosed with HER2-low breast cancer.

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
81518	Oncology (breast), mRNA, gene expression profiling by real-time RT-PCR of 11 genes (7 content and 4 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithms reported as percentage risk for metastatic recurrence and likelihood of benefit from extended endocrine therapy Proprietary test: Breast Cancer Index Lab/manufacturer: Biotheranostics, Inc
81519	Oncology (breast), mRNA, gene expression profiling by real-time RT-PCR of 21 genes, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as recurrence score Proprietary test: Oncotype DX® Lab/manufacturer: Genomic Health
81520	Oncology (breast), mrna gene expression profiling by hybrid capture of 58 genes (50 content and 8 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a recurrence risk score Proprietary test: Prosigna® Breast Cancer Assay Lab/manufacturer: NanoString Technologies, Inc.

CPT	Code Description
81521	Oncology (breast), mrna, microarray gene expression profiling of 70 content genes and 465 housekeeping genes, utilizing fresh frozen or formalin-fixed paraffin-embedded tissue, algorithm reported as index related to risk of distant metastasis Proprietary test: MammaPrint® Lab/Manufacturer: Agendia, Inc.
81522	Oncology (breast), mRNA, gene expression profiling by RT-PCR of 12 genes (8 content and 4 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as recurrence risk score Proprietary test: EndoPredict® Lab/Manufacturer: Myriad Genetic Laboratories, Inc.
81523	Oncology (breast), mRNA, next-generation sequencing gene expression profiling of 70 content genes and 31 housekeeping genes, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as index related to risk to distant metastasis Proprietary test: MammaPrint® Lab/Manufacturer: Agendia, Inc
81599	Unlisted multianalyte assay with algorithmic analysis
88360	Morphometric analysis, tumor immunohistochemistry (eg, Her-2/neu, estrogen receptor/progesterone receptor), quantitative or semiquantitative, per specimen, each single antibody stain procedure; manual
88361	Morphometric analysis, tumor immunohistochemistry (eg, Her-2/neu, estrogen receptor/progesterone receptor), quantitative or semiquantitative, per specimen, each single antibody stain procedure; using computer-assisted technology
88367	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; initial single probe stain procedure
88368	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; initial single probe stain procedure
88381	Microdissection (ie, sample preparation of microscopically identified target); manual
0045U	Oncology (breast ductal carcinoma in situ), mRNA, gene expression profiling by real-time RT-PCR of 12 genes (7 content and 5 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as recurrence score Proprietary test: Oncotype DX® Breast DCIS Score™ Lab/manufacturer: Genomic Health, Inc.

CPT	Code Description
0067U	Oncology (breast), immunohistochemistry, protein expression profiling of 4 biomarkers (matrix metalloproteinase-1 [MMP-1], carcinoembryonic antigen-related cell adhesion molecule 6 [CEACAM6], hyaluronoglucosaminidase [HYAL1], highly expressed in cancer protein [HEC1]), formalin-fixed paraffin-embedded precancerous breast tissue, algorithm reported as carcinoma risk score Proprietary test: BBDRisk Dx™ Lab/manufacturer: Silbiotech, Inc.
0153U	Oncology (breast), mRNA, gene expression profiling by next-generation sequencing of 101 genes, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a triple negative breast cancer clinical subtype(s) with information on immune cell involvement Proprietary test: Insight TNBCtype™ Lab/Manufacturer: Insight Molecular Labs
0295U	Oncology (breast ductal carcinoma in situ), protein expression profiling by immunohistochemistry of 7 proteins (COX2, FOXA1, HER2, Ki-67, p16, PR, SIAH2), with 4 clinicopathologic factors (size, age, margin status, palpability), utilizing formalin-fixed paraffin-embedded (FFPE) tissue, algorithm reported as a recurrence risk score Proprietary test: DCISionRT® Lab/Manufacturer: PreludeDx™/Prelude Corporation
S3854	Gene expression profiling panel for use in the management of breast cancer treatment

1) For the prognosis of gliomas, the following tests **MEET COVERAGE CRITERIA:**
   a) Array-based genomic copy number testing or fluorescence in situ hybridization (FISH) for the co-deletion of 1p and 19q.
   b) *ATRX* mutation testing via gene sequencing **or** loss of ATRX protein expression via immunohistochemistry.
   c) *BRAF* fusion and mutation testing, including *BRAF* V600E common variant.
   d) *IDH1* and *IDH2* testing.
   e) *MGMT* promoter methylation testing.
   f) *TERT* promotor mutation testing.
2) For the prognosis of diffuse midline gliomas, the following tests **MEET COVERAGE CRITERIA:**
   a) *H3-3A* and *HIST1H3B* gene sequencing.
   b) *H3-3A* mutation testing by immunohistochemistry using an H3-3A K27M histone antibody.
3) For the prognosis of ependymomas, *ZFTA* fusion testing using either RNA sequencing analysis (RNA-Seq) or FISH **MEETS COVERAGE CRITERIA**.
4) *ATRX* mutation co-testing using **both** immunohistochemistry and gene sequencing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AG	Anaplastic glioma
ATRX	*Alpha-Thalassemia/Mental Retardation Syndrome X-Linked* gene
BRAF	*B-Raf proto-oncogene*
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid
CNA	Copy number alterations
CNS	Central nervous system

CSF	Cerebrospinal fluid
ddPCR	Digital droplet polymerase chain reaction
DIPG	Diffuse intrinsic pontine gliomas
EANO	European Association of Neuro-Oncology
ELISA	Enzyme-linked immunoassay
ESMO	European Society for Medical Oncology
FISH	Fluorescence in situ hybridization
H3-3A	*H3.3 histone A* gene
H3F3A	Previous gene name of *H3.3 histone A*
H3FA	*H3 clustered histone 1* gene
IDH1	*Isocitrate Dehydrogenase 1* gene
IDH2	*Isocitrate Dehydrogenase 2* gene
LDTs	Laboratory-developed tests
MGMT	*O-6-Methylguanine-Dna Methyltransferase* gene
NCCN	National Comprehensive Cancer Network
NICE	National Institute for Health and Care Excellence
NFkB	Nuclear factor kappa B
NGS	Next-generation sequencing
NICE	National Institute for Health and Care Excellence
PCR	Polymerase chain reaction
PFA	Posterior fossa ependymoma group A
PFB	Posterior fossa ependymoma group B
RELA	*RELA proto-oncogene, NF-kB subunit*
RNA-Seq	Ribonucleic acid sequencing analysis
SNVs	Single nucleotide variants
sPD-L1	Soluble programmed cell death ligand 1
TERT	*Telomerase reverse transcriptase*
TMB	Tumor mutational burden
TP53	*Tumor protein 53*
WHO	World Health Organization
YAP1	*Yes1 associated transcriptional regulator* gene
ZFTA	*Zinc finger translocation associated* gene

V. Scientific Background

According to the American Cancer Society, an estimated 25,400 adults in the United States were diagnosed with malignant tumors of the brain and spinal cord in 2023.

Additionally, The American Cancer Society reported that there was an estimated 18,760 deaths from brain and spinal cord tumors in 2023. (American Cancer Society, 2024).

Studies over the past two decades have clarified the genetic basis of tumorigenesis in the common, and some rarer, brain tumor entities (Louis et al., 2016), and identified clinically relevant molecular genetic characterizations that complement standard histologic analysis providing additional diagnostic and prognostic information to improve diagnostic accuracy, influence treatment selection, and improve survival. Molecular and/or genetic characterization do not replace standard histologic assessment, but rather serve as a complimentary approach (NCCN, 2023).

Isocitrate dehydrogenase (IDH1/2) mutations

Metabolic enzymes, IDH one and two, oxidize isocitrate to alpha-ketoglutarate, and are important in the mitigation of cellular oxidative damage (Horbinski, 2013b). Mutations in genes encoding these enzymes leads to the aberrant production of D-2 hydroxyglutarate (Dang et al., 2009), an oncometabolite that causes epigenetic modifications in affected cells (Horbinski, 2013b).

The *IDH* mutations are a defining feature of WHO grade II and III astrocytomas and oligodendrogliomas (Louis et al., 2016). Their presence distinguishes lower grade gliomas from primary glioblastomas, which are *IDH* wild type. *IDH* mutations are commonly associated with O-6-methylguanine-DNA methyltransferase (*MGMT*) promoter methylation and are also associated with a relatively favorable prognosis (Brat et al., 2015; Eckel-Passow et al., 2015).

O-6-methylguanine-DNA methyltransferase (MGMT) methylation

The DNA repair enzyme, MGMT, reverses the DNA damage caused by alkylating agents, resulting in tumor resistance to temozolomide and nitrosourea-based chemotherapy. Methylation of the *MGMT* promoter silences *MGMT,* making the tumor more sensitive to treatment with alkylating agents (Esteller et al., 2000; Gusyatiner & Hegi, 2018).

The *MGMT* promoter methylation is strongly associated with *IDH* mutation and genome-wide epigenetic change (Eckel-Passow et al., 2015); it is also associated with longer survival in patients with glioblastoma who receive alkylating agents (Hegi et al., 2005; Zhao et al., 2016). *MGMT* promoter methylation is particularly useful in treatment decisions for elderly patients with high grade gliomas (Malmstrom et al., 2012; Wick et al., 2012; Wick et al., 2014).

Codeletion of chromosomes 1p and 19q

The codeletion of 1p and 19q represents an unbalanced translocation (1;19) (q10;p10) leading to the whole arm deletion of chromosome 1p and chromosome 19q (Jenkins et al., 2006). Codeletion of 1p and 19q is a defining feature of oligodendroglial tumors, is strongly associated with oligodendroglial histology, and helps to confirm the oligodendroglial character of tumors with equivocal or mixed histologic features (Brat et al., 2015; Burger et al., 2001; Eckel-Passow et al., 2015). Combined loss involving chromosomes 1p and 19q is significantly associated with both favorable therapeutic response and longer recurrence-free survival after chemotherapy (Cairncross et al., 1998).

Alpha-thalassemia/mental retardation syndrome X-linked (ATRX) mutations

Mutations in the chromatin regulator gene, *ATRX*, enable alternative lengthening of telomeres (Abedalthagafi et al., 2013). ATRX is a switch/sucrose helicase that assists with H3.3 chromatin deposition in telomeric regions. Disruption of this gene leads to the alternative lengthening of telomeres stated above and is thought to represent an early event in gliomagenesis (Batchelor & Louis, 2023).

The *ATRX* mutations in glioma are strongly associated with *IDH* and *TP53* mutations and are nearly always mutually exclusive with 1p19q codeletion (Reuss et al., 2015). ATRX deficiency, coupled with *IDH* mutation, is typical of astrocytoma (Brat et al., 2015).

Tumor protein 53 (TP53) mutation

Tumor protein 53 is essential for regulating cell division and preventing tumor formation (Parikh et al., 2014). Missense mutations in the *TP53* gene are present in the clear majority of IDH-mutant astrocytomas (Brat et al., 2015). Immunopositivity for mutant p53 is not entirely sensitive or specific for a *TP53* mutation, however, and loss of *ATRX* expression may be a more reliable marker of astrocytic differentiation (Louis et al., 2023).

Telomerase reverse transcriptase (TERT) mutations

Telomerase reverse transcriptase encodes the catalytic active site of telomerase, the enzyme responsible for maintaining telomere length in dividing cells. *TERT* mutations in the noncoding promoter region cause increased expression of the TERT protein and are one of the major mechanisms of telomerase activation in gliomas (Arita et al., 2013). *TERT* mutations are strongly associated with 1p19q codeletion and are found in most glioblastomas. A *TERT* mutation in combination with an *IDH* mutation and 1p19q codeletion is characteristic of oligodendroglioma. The absence of a *TERT* mutation, coupled with an *IDH* mutation, designates astrocytoma (Eckel-Passow et al., 2015). In

terms of survival, mutation in the *TERT* promoter is generally unfavorable in the absence of *IDH* mutation and favorable in the presence of *IDH* mutation and 1p/19q codeletion. *TERT* promoter mutation is associated with an older age of the patient at presentation, regardless of whether *IDH* mutation is present (Eckel-Passow et al., 2015).

Histone (H3FA) mutations

A lysine to methionine substitution in the *H3F3A* gene (*H3K27M*) is the most common histone mutation in brain tumors and inhibits the trimethylation of H3.3 histone (Sturm et al., 2012), arresting cells in a primitive state refractory to differentiation induction (Weinberg et al., 2017). *G34R/G34V* mutations in the *H3F3A* gene are more common in cortical gliomas in children (Schwartzentruber et al., 2012). *H3FA* mutations can be useful in the diagnosis of infiltrative glioma (Sturm et al., 2012). The *H3K27M* mutation is an adverse prognostic marker in children and adults (Meyronet et al., 2017). The *G34* mutation does not appear to have any prognostic significance once the diagnosis of a glioblastoma has been established (Sturm et al., 2012).

A similar mutation to *H3K27M* may also occur in the *HIST1H3B/C* gene, which encodes the histone H3.1 variant. However, the mutation at *HIST1H3B/C* is about one third as common as *H3F3A* and often confers a better prognosis than its *H3F3A* counterpart (Louis et al., 2023).

B-Raf proto-oncogene (BRAF) mutations

The serine-threonine protein kinase, BRAF, is involved in cell survival, proliferation, and differentiation (Davies et al., 2002). Activating mutations in *BRAF*, most often V600E, have been discovered in most pediatric and some adult gliomas (Chappe et al., 2013; Horbinski, 2013a), including approximately 80% of pleomorphic xanthoastrocytomas, 20% of gangliogliomas, 10% of pilocytic astrocytomas, and occasionally diffuse gliomas (Chi et al., 2013). Tandem duplication of chromosome 7q34 resulting in an activating fusion of the *BRAF* and *KIAA1549* genes occur in 60-80% of pilocytic astrocytoma (Jones et al., 2008).

The presence of a *BRAF* fusion is reliable evidence that the tumor is a pilocytic astrocytoma and predicts a better clinical outcome (Hawkins et al., 2011). A *BRAF* mutation is more complicated, as it can occur in a variety of tumors and requires integration with histology. Tumors with *BRAF* mutations may respond to BRAF inhibitors; however, in pediatric gliomas, *BRAF* V600E indicates poor prognosis when treated with current adjuvant therapy, especially in combination with a *CDKN2A* mutation (Lassaletta et al., 2017).

v-rel avian reticuloendotheliosis viral oncogene homolog A (RELA, p65, NFKB3) fusion

Fusion between the *C11orf95* and *RELA* genes defines approximately 70 percent of all childhood supratentorial ependymomas (Louis et al., 2023). These fusions are associated with increased NF-kappa-B (NFkB) signaling and poor outcome (Malgulwar et al., 2018). Normally, NFkB is an inactive transcription factor in the cytoplasm. When its inhibitor degrades, it activates transcription of certain genes, *RELA* among them (NCBI, 2011). New research supports the hypothesis that the status of *RELA* fusion and p53 overexpression are significantly associated with the prognosis of supratentorial extraventricular ependymomas (Wang et al., 2019).

New Tests

Assessment of gliomas is incredibly difficult, and new methods of molecular analyses for gliomas are consistently being developed. For example, Miller et al. (2019) devised a liquid-biopsy based method to evaluate cerebrospinal fluid from 42 (of 85) patients. The genomic profile developed from the cerebrospinal fluid (CSF) samples closely matched established profiles, such as the characteristic 1p/19q codeletion and *IDH1/2* mutations. The authors stated that the ability to monitor the glioma genome in real time could be useful in management of this condition (Miller et al., 2019). Other researchers report that "A cerebrospinal fluid ct-DNA liquid biopsy approach may virtually support all the stages of glioma management, from facilitating molecular diagnosis when surgery is not feasible, to monitoring tumor response, identifying early recurrence, tracking longitudinal genomic evolution, providing a new molecular characterization at recurrence and allowing patient selection for targeted therapies" (Simonelli et al., 2020).

Clinical Utility and Validity

Nikiforova et al. (2016) validated GlioSeq, a commercial next generation sequencing (NGS) panel of 30 genes, in 54 patients with CNS tumors against fluorescence in-situ hybridization (FISH), Sanger sequencing, and reverse transcription polymerase chain reaction (PCR). GlioSeq correctly identified 71/71 (100%) genetic alterations known to be present by conventional techniques. The assay sensitivity was three to five percent for mutant alleles of single nucleotide variants (SNVs), and one to five percent for gene fusions. Likewise, Zacher et al. (2017) developed an NGS panel of 20 genes that allowed for molecular classification of 121 gliomas. The researchers conclude that gene panel NGS is a promising diagnostic technique that may facilitate integrated histological and molecular glioma classification.

Ramkissoon et al. (2017) used OncoPanel and OncoCopy to identify targetable alterations in tumors for the establishment of best practices in routine clinical pediatric oncology. They analyzed 117 samples by OncoPanel and 146 by OncoCopy; further, 60 tumors were subjected to both methodologies. OncoPanel revealed clinically relevant

alterations in 56% of patients (44 cancer mutations and 20 rearrangements), including *BRAF* alterations that directed the use of targeted inhibitors. Rearrangements in *MYB-QKI, MYBL1, BRAF*, and *FGFR1* were also detected. Furthermore, while copy number profiles differed across histologies, the combined use of OncoPanel and OncoCopy identified subgroup-specific alterations in 89% (17/19) of medulloblastomas.

Ryall et al. (2016) evaluated the prognostic impact of H3K27M and MAPK pathway aberrations in 64 gliomas (44 low grade, 22 high grade). Tumors are designated as low-grade if the cells are well differentiated, are less aggressive overall, and suggest a better prognosis for the patient. Five low grade gliomas contained the *H3F3A/HIST1H3B K27M* (*H3K27M*) mutation, and 11 high grade gliomas contained the *H3K27M* mutation. Survival analysis evaluated the median survival at 9.12 years for wildtype H3 patients compared to 1.02 years for patients with the *H3K27M* mutation. MAPK pathway mutations (through *BRAF* or *FGFR1* mutation) were associated with long-term survival in absence of *H3K27M* mutations. Further, H3K27M status and high-grade histology were found to be the most significant independent predictors of poor overall survival with hazard ratios of 6.945 and 7.721 respectively. MAPK pathway activation was a predictor of "favourable patient outcome," but dependent on other factors (Ryall et al., 2016).

Houdova Megova et al. (2017) evaluated the prognostic value of the *IDH1/2* mutation in glioblastomas. A total of 37 *IDH* mutations were examined and studied. The authors found that *IDH1* mutations were positively associated with *MGMT* methylation (odds ratio [OR]: 3.08), 1p/19q co-loss (OR: 8.85), and negatively associated with *EGFR* amplification. IDH-mutant patients had an overall survival of 25 months compared to only nine months for IDH-wildtype gliomas (Houdova Megova et al., 2017).

Johnson et al. (2017) performed comprehensive genomic profiling of 282 pediatric gliomas: 157 high-grade and 125 low-grade. The investigators used a 315 gene panel and calculated the tumor mutational burden (TMB). In low grade gliomas, *BRAF* was the most frequent mutation found (48%), followed by *FGFR* missense (17.6%), *NF1* loss of function (8.8%), and *TP53* (5.6%). Rearrangements were found in 35% of low-grade gliomas. In high-grade gliomas, *TP53* was the most frequent mutation found (49%), followed by *H3F3A* (37.6%), *ATRX* (24.2%), *NF1* (22.2%), and *PDGFRA* (21.7%). *H3F3A* mutations were found to be the K28M variant. Approximately six percent of the high-grade gliomas were found have a TMB of >20 mutations/Mb ("hypermutated") (Johnson et al., 2017).

Back et al. (2020) studied the pattern of failure in anaplastic glioma (AG) patients with an *IDH1/2* mutation. A total of 156 patients participated in the study, with data collected from 2008 to 2014; the median follow-up time was 5.1 years. Of all 156

patients, 75% were found to have an *IDH1 or IDH2* mutation. The authors concluded that "patients with *IDH*-mutated AG have improved outcomes"; however, this population also had a greater number of distant relapses approximately two years after intensity-modulated radiation therapy compared to individuals with *IDH* wild type mutations (Back et al., 2020).

Ji et al. (2021) studied the clinical utility of comprehensive genomic profiling to detect CNS tumors in children and young adults using the OncoKids next-generation sequencing panel, chromosomal microarray analysis, and germline testing. NGS was performed on 222 samples and CMA was performed on 146 of the 222 samples. The OncoKids NGS panel identified diagnostic biomarkers in 138/222 samples (62%), prognostic information in 49/222 cases (22%), and targetable genomic alterations in 41/222 samples (18%). Additionally, CMA revealed prognostic copy number alterations (CNA) in 101/146 cases (69%). Further, germline cancer predisposition testing was performed in 57 of 212 patients which identified 20 patients which a confirmed germline pathogenic/likely pathogenic variant of genes *TP53, NF1, SMARCB1, NF2, MSH6, PMS2*, and a patient with Klinefelter syndrome. Overall, the authors conclude that there is "significant clinical utility of integrating genomic profiling into routine clinical testing for pediatric and young adult patients with CNS tumors" (Ji et al., 2021).

Muralidharan et al. (2021) studied the diagnostic utility of a novel digital droplet PCR (ddPCR) assay for detection of two TERT promoter mutations (*C228T* and *C250T*) and monitoring of gliomas. In comparison with the gold-standard tumor tissue-based detection of *TERT* mutations, the ddPCR assay had an overall sensitivity of 62.5% and a specificity of 90%. Longitudinal monitoring of five patients demonstrated that the peripheral *TERT* mutant allele frequency reflects the clinical course of the disease. *TERT* mutant alleles decreased after surgical intervention and pharmacotherapy but increased with tumor progression. The authors conclude that the ddPCR assay has feasibility in "detecting circulating cfDNA TERT promoter mutations in patients with glioma with clinically relevant sensitivity and specificity" (Muralidharan et al., 2021).

Cabezas-Camarero et al. (2021) studied the levels of soluble PD-L1 (sPD-L1) in patients with gliomas according to histologic grade and IDH mutation status, evaluating its predicted role and dynamic changes in sPD-L1. Plasma samples were obtained prior to and after radiotherapy/chemotherapy and were evaluated using ELISA. The authors compared 12 healthy controls with 57 patients with grade II to IV gliomas. They found that sPD-L1 levels were numerically higher in glioma patients as compared to the healthy control group. The authors found that elevated sPD-L1 levels pre- and post-treatment associated with a worse prognosis in IDH-MUT gliomas. Dynamics of SPDL1 and other immune-biomarkers should still be explored in gliomas (Cabezas-Camarero et al., 2021).

Rios et al. (2022) studied the health and economic impacts of using tumor molecular testing for guiding treatments for pediatric patients with low grade glioma. With their microsimulation for modeling health and cost outcomes for 100,000 simulated patients, they found that there was a statistically significant increase in life expectancy in those who received molecular testing for the BRAF mutation (40.08 vs 39.01 in those who did not receiving testing), and an increase of 0.38 quality-adjusted life-years (QALY) and $1384 reduction in costs due to likely avoidance of adverse events associated with radiation, like stroke and other neoplastic transformations. This study ultimately demonstrates that in this subset of patients, there could be long-term benefits in the treatment plans derived for childhood cancers, including the increased timely use of *BRAF*-specific biologic agents versus standard treatment with radiation (Rios et al., 2022).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN published Clinical Practice Guidelines in Oncology (2023) for Central Nervous System Cancers which recommend:

IDH1 and *IDH2* mutation

Recommendation: *IDH* mutation testing is required for the workup of glioma.

"The most common *IDH1* mutation (R132H) is reliably screened by mutation specific immunohistochemistry (IHC), which is recommended for all glioma patients. If the R132H immunostain result is negative, in the appropriate clinical context, sequencing of *IDH1* and *IDH2* is highly recommended to detect less common *IDH1* and *IDH2* mutations. Prior to age 55 years, sequencing of *IDH1* and *IDH2* is required if the R132H immunostain result is negative, or if the glioma is only grade 2 or 3 histologically. Standard sequencing methods include Sanger sequencing, pyrosequencing, and next-generation sequencing (NGS), and should be performed on formalin fixed, paraffin embedded tissue" (NCCN, 2023).

MGMT promoter methylation

Recommendation: *MGMT* promoter methylation is an essential part of molecular diagnostics for all high-grade gliomas (grade 3 and 4). The NCCN also notes that "*MGMT* promoter methylation is strongly associated with *IDH* mutations and genome-wide epigenetic changes (G-CIMP phenotype)" (NCCN, 2023).

"There are multiple ways to test for *MGMT* promoter methylation, including methylation-specific polymerase chain reaction (PCR), methylation-specific high-resolution melting, pyrosequencing, and droplet-digital PCR" (NCCN, 2023).

"MGMT promoter methylation testing is particularly useful in treatment decisions for older adult patients with high-grade gliomas (grades 3–4) " (NCCN, 2023).

Codeletion of 1p and 19q

Recommendation: 1p/19q testing is an essential part of molecular diagnostics for oligodendroglioma.

"The codeletion of 1p and 19q is detectable by array-based genomic copy number testing (preferable), or fluorescence in situ hybridization (FISH) … IDH-mutated gliomas that do NOT show loss of *ATRX* (for example, by IHC) should be strongly considered for 1p/19q testing, even if not clearly oligodendroglial by histology. Conversely, *IDH1* wild-type gliomas do not contain true whole-arm 1p/19q codeletion. Therefore, 1p/19q testing is unnecessary if a glioma is definitely *IDH*-wild-type, and a glioma should not be regarded as 1p19q-codeleted without an accompanying *IDH* mutation, regardless of the test results" (NCCN, 2023).

ATRX mutation

"Recommendation: *ATRX* mutation testing is required for the workup of glioma."

"*ATRX* mutations can be detected by IHC for wild-type *ATRX* (loss of wild type expression) and/or sequencing. ATRX mutations in glioma are strongly associated with *IDH* mutations and are nearly always mutually exclusive with 1p/19q codeletion. *ATRX* deficiency, coupled with IDH mutation and *TP53* mutation, is typical of astrocytoma. A lack of *ATRX* immunostaining in glioblastoma should trigger *IDH1/2* sequencing if *IDH1* R132H immunostaining is negative, due to frequent co-occurrence of *ATRX* and *IDH* mutations" (NCCN, 2023).

TERT mutation

"Recommendation: *TERT* promoter mutation testing is required for the workup of gliomas."

"*TERT* promoter mutations are nearly always present in 1p/19q codeleted oligodendroglioma and are found in most glioblastomas. *TERT* promoter mutation, in combination with *IDH* mutation and 1p/19q codeletion, is characteristic of oligodendroglioma. Absence of *TERT* promoter mutation, coupled with the presence of mutant *IDH*, strongly suggests astrocytoma"(NCCN, 2023).

H3F3A and *HIST1H3B* mutation

"Recommendation: *H3-3A* and *HIST1H3B* mutation testing is recommended in the appropriate clinical context."

"Diffuse midline gliomas should be screened for *H3-3A* mutations, specifically the H3K27M mutation. While sequencing is the gold standard, H3K27M-specific IHC, paired with H3K27 trimethylation immunostaining, is a reasonable alternative, especially when tissue is scarce. In these gliomas, H3K27M immunopositivity should be associated with loss of histone trimethylation immunostaining."

"Although a K27M histone antibody is available, it is not 100% specific and interpretation can be difficult for non-experts. Therefore, screening by *H3F3A* and *HIST1H3B* sequencing is a viable alternative and preferred approach, especially since it will also detect mutations in G34" (NCCN, 2023).

"Diagnostic value: Histone mutations most commonly occur in pediatric midline gliomas (e.g., diffuse intrinsic pontine gliomas [DIPG]), although midline gliomas in adults can also contain histone modifications. Their presence can be considered solid evidence of an infiltrative glioma, which is often helpful in small biopsies of midline lesions that may not be fully diagnostic with light microscopy or do not fully resemble infiltrative gliomas."

"Prognostic value: The *K27M* gliomas typically do not have MGMT promoter methylation, and the mutation is an adverse prognostic marker in children and adults. The *G34* mutation does not appear to have any prognostic significance once the diagnosis of a glioblastoma has been established" (NCCN, 2023).

BRAF mutation

"Recommendation: *BRAF* fusion and/or mutation testing is recommended in the appropriate clinical context."

"*BRAF* V600E is best detected by sequencing, and *BRAF* fusions can be detected with RNA-Seq or other PCR-based breakpoint methods that capture the main 16-9, 15-9, and 16-11 breakpoints between *BRAF* and its main fusion partner, *KIAA1549*. FISH is too unreliable to detect *BRAF* fusions" (NCCN, 2023).

"The presence of a *BRAF* fusion is reliable evidence that the tumor is a [pilocytic astrocytoma], provided the histology is compatible. *BRAF* V600E is more complicated, as it can occur in a variety of tumors over all four WHO grades and requires integration with histology."

"Tumors with *BRAF* fusions tend to be indolent, with occasional recurrence but only rare progression to lethality. *BRAF* V600E tumors show a much greater range of outcomes and need to be considered in context with other mutations and clinicopathologic findings (e.g., CDKN2A/B deletion). *BRAF* V600E tumors may respond to BRAF inhibitors, such as vemurafenib, but comprehensive clinical trials are still ongoing" (NCCN, 2023).

ZFTA fusion

"Testing for *ZFTA* and *YAP1* fusions is recommended in the appropriate clinical context. Ependymomas arising in the supratentorium often contain activating fusions of *ZFTA*. This leads to increased NF-kappa-B signaling and more aggressive behavior. This event is more common in children than in adults, and occurs only in the supratentorium, not the posterior fossa or spine" (NCCN,2022).

"*ZFTA* fusion can be detected with RNA sequencing or a break-apart FISH probe set… Detection of *ZFTA* fusion is not required for the diagnosis of ependymoma, as this entity is still diagnosed by light microscopy."

"*ZFTA* fusion-positive ependymomas are now a distinct entity in the WHO classification of CNS tumors, as this subset of ependymomas tends to be far more aggressive than other supratentorial ependymomas, including those with *YAP1* fusions. PFA vs. PFB via methylation profiling is reasonable for posterior fossa ependymoma" (NCCN, 2023).

Finally, the NCCN states there are no identified targeted agents with demonstrated efficacy in glioblastoma (NCCN, 2023).

National Institute for Health and Care Excellence (NICE)

NICE recommends the following molecular markers for investigation of gliomas: *IDH1/2* mutations, *ATRX* mutations, 1p/19q co-deletion, histone H3.3 K27M, *BRAF* mutation, and *MGMT* promoter methylation (for prognosis). NICE also notes that testing *IDH* wild type gliomas for *TERT* promoter mutations may be considered (NICE, 2021).

European Society for Medical Oncology (ESMO)

The ESMO has published clinical practice guidelines for the diagnosis, treatment, and follow-up of high-grade gliomas. They state that *MGMT* promoter methylation status, *IDH1/2* mutation status, and 1p/19q codeletions are "commonly determined" for assessment of gliomas (ESMO, 2014).

World Health Organization (WHO)

In 2016 and 2021, the WHO published guidelines on the classification of central nervous system tumors. These WHO guidelines, for the first time, incorporated molecular testing in the diagnosis of gliomas and medulloblastomas. The following key points were given by the WHO regarding molecular testing:

- "*IDH1* R132H, which accounts for approximately 90% of *IDH* mutations, can be detected immunohistochemically. If this testing is negative, sequencing of *IDH1* and *IDH2* is necessary to ensure that no other *IDH* mutations are present.
- Given the importance of *IDH* mutational status in the diagnosis or gliomas, at a minimum, it will be important that most institutions have the capacity to both stain tumor specimens for *IDH1* R132H by immunohistochemistry and, ideally, sequence those tumors that are negative for both *IDH1* and *IDH2* mutations" (Wen & Huse, 2016).
- "Because of the growing importance of molecular information in CNS tumor classification, diagnoses and diagnostic reports need to combine different data types into a single, 'integrated' diagnosis. To display the full range of diagnostic information available, the use of layered (or tiered) diagnostic reports is strongly encouraged. Such reports feature an integrated diagnosis at the top, followed by layers that display histological, molecular, and other key types of information" (Louis et al., 2021).
- Certain tumors (Diffuse astrocytoma, MYB- or MYBL1-altered; Angiocentric glioma; Polymorphous low-grade neuroepithelial tumor of the young; and Diffuse low-grade glioma, MAPK pathway-altered) "require molecular characterization and the integration of histopathological and molecular information in a tiered diagnostic format as molecular work-up helps to characterize the lesion as one type or the other" (Louis et al., 2021).
- For other tumors such as Myxopapillary ependymoma and Subependymoma, "although these can be identified with methylome studies, molecular classification does not provide added clinicopathological utility for these two tumors" (Louis et al., 2021).
- "Several molecular biomarkers are also associated with classification and grading of meningiomas, including SMARCE1 (clear cell subtype), BAP1 (rhabdoid and papillary subtypes), and KLF4/TRAF7 (secretory subtype) mutations, TERT promoter mutation and/or homozygous deletion of CDKN2A/B62, H3K27me3 loss of nuclear expression (potentially worse prognosis), and methylome profiling (prognostic subtyping)" (Louis et al., 2021).

European Association of Neuro-Oncology (EANO)

In 2021, the EANO published guidelines regarding diagnosis and management of adult patients with diffuse gliomas. The following recommendations were made on molecular testing:

- "Patients with relevant germline variants or suspected hereditary cancer syndromes should receive genetic counselling and might subsequently be referred for molecular genetic testing.
- Immunohistochemistry for mutant *IDH1* R132H protein and nuclear expression of *ATRX* should be performed routinely in the diagnostic assessment of diffuse gliomas.
- If immunohistochemistry for *IDH1* R132H is negative, sequencing of *IDH1* codon 132 and *IDH2* codon 172 should be conducted in all WHO grade 2 and 3 diffuse astrocytic and oligodendroglial gliomas as well as in all glioblastomas of patients aged < 55 years to enable integrated diagnoses according to the WHO classification and to guide treatment decisions.
- 1p/19q codeletion status should be determined in all *IDH*-mutant gliomas with retained nuclear expression of *ATRX*.
- *MGMT* promoter methylation status should be determined in glioblastoma, notably in elderly or frail patients, to aid in decision-making for the use of temozolomide.
- *CDKN2A/B* homozygous deletions should be explored in *IDH*-mutant astrocytomas.
- Combined chromosome seven gain and chromosome 10 loss (+7/–10 signature), *EGFR* amplification and *TERT* promoter mutation should be tested in *IDH*-wild-type diffuse gliomas lacking microvascular proliferation and necrosis as histological features of WHO grade 4 to allow for a diagnosis of *IDH*-wild-type glioblastoma" (Weller et al., 2021).

In addition, EANO published a table to summarize the molecular markers used for the diagnosis and management of gliomas.

Table 1: Molecular Markers for the Diagnosis and Management of Gliomas (Weller et al., 2021)

Molecular Marker	**Diagnostic Roles**
IDH1 R132 or IDH2 R172 mutation	"Distinguishes diffuse gliomas with IDH mutation from IDH-wild-type glioblastomas and other IDH-wild-type gliomas
1p/19q codeletion	Distinguishes oligodendroglioma, IDH-mutant and 1p/19q-codeleted from astrocytoma, IDH-mutant

Loss of nuclear ATRX	Loss of nuclear ATRX in an IDH-mutant glioma is diagnostic for astrocytic lineage tumours
Histone H3 K27M mutation	Defining molecular feature of diffuse midline glioma, H3 K27M-mutant
Histone H3.3 G34R/V mutation	Defining molecular feature of diffuse hemispheric glioma, H3.3 G34-mutant
MGMT promoter methylation	None, but is a predictive biomarker of benefit from alkylating chemotherapy in patients with IDH-wild-type glioblastoma
Homozygous deletion of CDKN2A/CDKN2B	A marker of poor outcome and WHO grade 4 disease in IDH-mutant astrocytomas
EGFR amplification	EGFR amplification occurs in ~40–50% of glioblastoma, IDH wild type Molecular marker of glioblastoma, IDH wild type, WHO grade 4
TERT promotor mutation	TERT promoter mutation occurs in ~70% of glioblastoma, IDH wild type and >95% of oligodendroglioma, IDH-mutant and 1p/19q-codeleted Molecular marker of glioblastoma, IDH wild type, WHO grade 4
+7/–10 cytogenetic signature	Molecular marker of glioblastoma, IDH wild type, WHO grade 4
$BRAF^{V600E}$ mutation	Rare in adult diffuse gliomas but amenable to pharmacological intervention" (Weller et al., 2021).

College of American Pathologists

In 2022, The College of American Pathologists in Collaboration with the American Association of Neuropathologists, Association for Molecular Pathology, and Society for Neuro-Oncology published guidelines that suggests these following recommendations for molecular biomarker testing for the diagnosis of diffuse gliomas:

- "IDH mutational testing must be performed on all diffuse gliomas (DG) (Strong recommendation)"
- "ATRX status should be assessed in all IDH-mutant DG unless they show 1p/19q codeletion (Strong recommendation)"
- "TP53 status should be assessed in all IDH-mutant DGs unless they show 1p/19q codeletion (Conditional recommendation)"
- "1p/19q codeletion must be assessed in IDH-mutant DGs unless they show ATRX loss or *TP53* mutations (Strong recommendation)"

- "*CDKN2A/B* homozygous deletion testing should be performed on IDH-mutant astrocytomas (Conditional recommendation)"
- "*MGMT* promoter methylation testing should be performed on all glioblastoma (GBM), IDH-wild type (WT) (Strong recommendation)"
- "For IDH-mutant DG, *MGMT* promoter methylation testing may not be necessary (Conditional recommendation)"
- "*TERT* promoter mutation testing may be used to provide further support for the diagnosis of oligodendroglioma and IDH-WT GBM (Conditional recommendation)"
- "For histologic grade 2-3 DGs that are IDH-WT, testing should be performed for whole chromosome 7 gain/whole chromosome 10 loss, *EGFR* amplification, and *TERT* promoter mutation to establish the molecular diagnosis of GBM, IDH-WT, grade IV (Strong recommendation)"
- "H3 K27M testing must be performed in DGs that involve the midline in the appropriate clinical and pathologic setting (Strong recommendation)"
- "H3 G34 testing may be performed in pediatric and young adult patients with IDH-WT DG (Conditional recommendation)"
- "*BRAF* mutation testing (V600) may be performed in DGs that are IDH-WT and H3-WT (Conditional recommendation)"
- "*MYB/MYBL1* AND *FGFR1* testing may be performed in children and young adults with DGs that are histologic grade 2-3 and are IDH-WT and H3-WT (Conditional recommendation)" (Brat et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration

has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81120	IDH1 (isocitrate dehydrogenase 1 [NADP+], soluble) (eg, glioma), common variants (eg, R132H, R132C)
81121	IDH2 (isocitrate dehydrogenase 2 [NADP+], mitochondrial) (eg, glioma), common variants (eg, R140W, R172M)
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s);
81287	MGMT (O-6-methylguanine-DNA methyltransferase) (eg, glioblastoma multiforme) promoter methylation analysis
81345	TERT (telomerase reverse transcriptase) (eg, thyroid carcinoma, glioblastoma multiforme) gene analysis, targeted sequence analysis (eg, promoter region)
81479	Unlisted molecular pathology procedure ***H3F3A gene sequencing*** ***RELA Testing*** ***H3F3A testing using a K27M histone antibody***
88341	Immunohistochemistry or immunocytochemistry, per specimen; each additional single antibody stain procedure (List separately in addition to code for primary procedure)
88342	Immunohistochemistry or immunocytochemistry, per specimen; initial single antibody stain procedure
88374	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), using computer-assisted technology, per specimen; each multiplex probe stain procedure
88377	Morphometric analysis, in situ hybridization (quantitative or semi-quantitative), manual, per specimen; each multiplex probe stain procedure

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Molecular Markers in Fine Needle Aspirates of the Thyroid

Policy Number: AHS – M2108 – Molecular Markers in Fine Needle Aspirates of the Thyroid	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Thyroid nodules are growths or enlargements on the thyroid gland. These nodules may be caused by several different disorders such as thyroiditis or cysts. However, these nodules may also be caused by thyroid cancer, which occurs in 4-6.5% of nodules. A biopsy is often performed to assess the histological components of this nodule, usually through a fine needle aspiration (FNA). A 23 to 27-gauge (commonly 25 gauge) needle is used, with or without local anesthesia. This technique can obtain an acceptable sample in 90-97% of solid nodules (Ross, 2023).

Molecular markers, such as genetic mutations or microRNA (miRNA) expression, may be used to help identify malignant nodules. Mutational analysis by sequencing or PCR can identify mutations, such as *BRAF*, *RAS*, *RET/PTC*, and *PAX8/PPARG*. Another tool is a gene expression classifier, which measures mRNA to determine the activity level of several genes and uses an algorithm to predict malignancy based on gene expression (Nikiforov et al., 2013).

II. Related Policies

Policy Number	Policy Title
AHS-G2045	Thyroid Disease Testing
AHS-M2066	Genetic Cancer Susceptibility Using Next Generation Sequencing
AHS-M2078	Genetic Testing for Germline Mutations of the RET Proto-Oncogene
AHS-M2087	Genetic Testing for PTEN Hamartoma Tumor Syndrome

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) To assist in patient management decisions for individuals 18 years of age or older being evaluated for thyroid carcinoma, mutation analysis (e.g., *BRAF* V600, *RET/PTC*, *RAS*, *PAX8/PPARG*) and/or the use of a gene expression classifier in fine-needle aspirates (FNAs) of the thyroid **MEETS COVERAGE CRITERIA** when the FNA is cytologically characterized as **any** of the following:
   a) Bethesda-III (atypia of undetermined significance [AUS] or follicular lesion of undetermined significance [FLUS]).
   b) Bethesda-IV (follicular neoplasm [FN] or suspicious for follicular neoplasm [SFN]).

2) For individuals 18 years of age or older being evaluated for thyroid carcinoma, mutation analysis (e.g., *BRAF* V600, *RET/PTC*, *RAS*, *PAX8/PPARG*) and/or the use of a gene expression classifier in FNAs of the thyroid) **DOES NOT MEET COVERAGE CRITERIA** when the FNA is cytologically characterized as **any** of the following:
   a) Bethesda-I (nondiagnostic or unsatisfactory).
   b) Bethesda-II (benign).
   c) Bethesda-V (suspicious for malignancy).
   d) Bethesda-VI (malignant).

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of a patient's illness.

3) For individuals under 18 years of age, mutation analysis (e.g., *BRAF* V600, *RET/PTC*, *RAS*, *PAX8/PPARG*) or the use of a gene expression classifier in FNAs of the thyroid **DOES NOT MEET COVERAGE CRITERIA**.

4) MicroRNA profiling tests (e.g., ThyraMIR) in FNAs of the thyroid **DO NOT MEET COVERAGE CRITERIA**.

5) For all other situations not discussed above, mutation analysis (e.g., *BRAF* V600, *RET/PTC*, *RAS*, *PAX8/PPARG*) or the use of a gene expression classifier **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note: For 5 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AACE	American Association of Clinical Endocrinologists
AAP	American Academy of Pediatrics
ACE	American College of Endocrinology
ALK	*Anaplastic lymphoma kinase* gene
ALS	*Argininosuccinate lyase* gene
AME	Associazione medici endocrinologi
ARID1A	*AT-rich interaction domain 1A* gene
ATA	American Thyroid Association
ATC	Anaplastic thyroid cancer
ATM	*ATM serine/threonine kinase* gene
AUS	Atypia of undetermined significance
BRAF	*B-Raf proto-oncogene* gene
CDKN2A	*Cyclin dependent kinase inhibitor 2A* gene
CLIA/CAP	Clinical Laboratory Improvement Amendments/College of American Pathologists
CMS	Centers for Medicare and Medicaid Services
CTNNB1	*Catenin beta 1* gene
DNA	Deoxyribonucleic acid
ERBB2	*Erb-b2 receptor tyrosine kinase 2* gene
ERBB4	*Erb-b2 receptor tyrosine kinase 4* gene
ESMO	European Society for Medical Oncology
EU-TIRADS	European Thyroid Imaging Reporting and Data System
ETA	European Thyroid Association
FISH	Fluorescence in situ hybridization
FLUS	Follicular lesion of undetermined significance
FN	Follicular neoplasm
FNA	Fine needle aspiration
FNAs	Fine needle aspirates
GC	Genomic classifier
GEC	Gene expression classifier
GSC	Genomic sequencing classifier
HRAS	*HRAS proto-oncogene*

KRAS	*KRAS proto-oncogene*
LDTs	Laboratory-developed tests
MEN1	*Menin 1*
MET	*Met proto-oncogene, receptor tyrosine kinase* gene
MPTX	Thygenext expanded mutation panel
mRNA	Messenger ribonucleic acid
miRNA	Micro-ribonucleic acid
MSI	Microsatellite instability
MTC	Medullary thyroid cancer
NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
NICE	National Institute of Care and Health Excellence
NIFTP	Noninvasive follicular thyroid neoplasm with papillary-like nuclear features
NKX2-1	NK2 homeobox 1
NPV	Negative predictive value
NTRK	*Neurotrophic tyrosine receptor kinase* gene
PAX8/PPARG	*Paired box gene 8/peroxisome proliferator-activated receptor gamma* gene
PCR	Polymerase chain reaction
PD-L1	Programmed death-ligand 1
PIK3CA	*Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha* gene
PTEN	*Phosphatase and tensin homolog* gene
PPV	Positive predictive value
RAS	Rat sarcoma virus
RET/PTC	*Rearranged during transfection)/papillary thyroid carcinoma type 1* gene
RNA	Ribonucleic acid
RT-PCR	Reverse transcriptase polymerase chain reaction
SFN	Suspicious for follicular neoplasm
SMAD4	*SMAD family member 4* gene
SMO	*Smoothened, frizzled class receptor* gene
SRC	*Proto-oncogene tyrosine-protein kinase Src* gene
TBP	TATA-box binding protein
TERT	*Telomerase reverse transcriptase* gene
Tg	Thyroglobulin
TMB	Tumor mutation burden
US	Ultrasound

USP33	Ubiquitin specific peptidase 33
XA	Xpression atlas

V. Scientific Background

Fine needle aspiration (FNA) is a traditional diagnostic approach to differentiate malignant thyroid nodules that need surgery from benign nodules that do not require surgery. It offers definitive diagnosis in most cases; however, 20–30% of nodules yield an indeterminate cytologic diagnosis in which cancer cannot be ruled out, and such nodules can exhibit malignancy risk ranging from 12% to 33% (Jackson et al., 2020). This may lead to suboptimal management of these patients and can result in unnecessary resections and surgical interventions (Nikiforov et al., 2013). FNA results are normally categorized according to the National Cancer Institute into six categories. They are, in order of severity: nondiagnostic or unsatisfactory (Bethesda-I), benign (II), atypia of undetermined significance (AUS) or follicular lesion of undetermined significance (FLUS) (III), follicular neoplasm (FN) or suspicious for follicular neoplasm (SFN) (IV), suspicious for malignancy (V), and malignant, which includes lymphomas and carcinomas (VI) (Ali et al., 2023). A benign result is reported in 60-70% of FNAs. Nondiagnostic does not refer to an absence of cancer; rather it means that the sample provided was inadequate for a conclusive result and another sample must be provided. Categories III and IV are typically referred to as "indeterminate" and typically have a malignancy risk of as high as 40%. Patients with indeterminate nodules will frequently have a surgery to treat the issue; however, up to 95% of these nodules are ultimately evaluated as benign. Further testing must be done with indeterminate cases to categorize these lesions (Cibas & Ali, 2009; Douglas, 2023).

Molecular markers have been used to identify the true status of an indeterminate FNA. Assessing components of FNA aspirates, such as micro-RNA, mutational status of certain genes, or genomic sequencing could prove useful, especially as these components can be reliably detected during the FNA itself (Hodak & Rosenthal, 2013; Xing et al., 2013). Prior to the emergence of molecular markers as an indicator, a repeat FNA was often performed, ultimately leading to a surgery to remove the nodule. Molecular markers could thus reduce unnecessary surgeries as well as provide better risk stratification (Douglas, 2023).

Proprietary Testing

Commercially available panels of molecular markers utilizing FNA specimens from the thyroid include the following tests:

ThyGeNEXT and ThyraMIR

ThyGeNEXT (Interpace Diagnostics, Parsippany, NJ) is a specific oncogene, mutational panel that tests genetic alterations across 10 genes associated with papillary carcinoma and follicular carcinoma. ThyGeNEXT uses a next generation sequencing (NGS) platform to identify genetic alterations across those 10 genes, which are as follows: *ALK, BRAF, GNAS, HRAS, KRAS, NRAS, PIK3CA, PTEN, RET, TERT*. This test is primarily for category III or IV nodules. Recently, Interpace Diagnostics has developed a new molecular test, ThyraMIR. This test is based on microRNA analysis of the expression of 10 microRNAs. The manufacturer claims that this test can identify malignancy in nodules that otherwise evince no or "weak" mutation for ThyGeNEXT. According to Interpace Diagnostics, combined test performance has negative predictive value of 99%, positive predictive value of 96%, with 98% sensitivity and 98% specificity. The sensitivity and specificity for the ThyGeNEXT panel alone is 63% and 84%, respectively, for cases of indeterminant cytology (Interpace, 2023).

Lupo et al. (2020) featured a blinded multicenter study centered around the performance of the ThyGeNext expanded mutation panel (MPTX) and the expanded panel with the microRNA classifier ThyraMIR by comparing them to the histopathology diagnosis by three pathologists. The expanded mutation panel included *NTRK* and *ALS* fusions that have targeted therapies as well as proto-oncogenes *TERT* and *RET*, which are indicative of aggressive disease. The study found that the performance of the expanded mutation panel (ThyGeNext) alone unsatisfactory due to numerous false positives, 90% of which were attributed to individual *RAS* mutations primarily found in benign adenomas, with a few additional errors due to *TERT* mutations in benign disease. It was therefore reported that the expanded mutation panel of ThyGeNext alone demonstrated an NPV of 81% while the PPV was even less stellar, a mere 56% (Lupo et al., 2020). This contrasts with the reported high sensitivity for malignancy (95%) in negative mutation panel testing results and high (90%) specificity in nodules with Bethesda III and IV cytology, purportedly driving an increase in the NPV to 97% and the PPV to 75%, as aforementioned above. The researchers suggest that the increases in NPV and PPV from the inclusion of the microRNA classifier, therefore, possess great power and potential in ruling in and out the need for surgery for indeterminate thyroid nodule cytology, leading them to conclude that ancillary use of the three category MPTX approach can be leveraged to accurately inform the need for surgery in four out of five indeterminate nodules tested (Lupo et al., 2020).

The same optimism may be found in Jackson et al. (2020), where researchers aimed to better understand the incremental use of using expanded mutation panels, along with the integration of microRNA classifier testing to provide additional and more accurate diagnostic information. Using molecular results from two consecutive cohorts of patients totaling 12993 members, who had FNAs performed on thyroid nodules resulting in Bethesda Diagnostic categories III or IV cytology results, underwent either

focused mutation panel testing (n=8619) alone or expanded mutation panel testing (n=4374), the latter of which included the microRNA classifier test ThyraMIR. The study found that 89% of patients who underwent the simple focused panel testing lacked detectable oncogenic mutations and fusions as compared to the 74% in the cohort who underwent the expanded panel testing ($P < 0.001$). Moreover, weak drivers were more frequently identified in patients who underwent expanded (20%) compared with focused (9%) panel testing ($P < 0.001$), and strong drivers were likewise more frequent in patients who underwent expanded (6%) compared with focused (2%) panel testing ($P < 0.001$). Thus, the power of the expanded panel was not limited to detecting weak drivers, as 16% of those who underwent focused panel testing had strong drivers, while 24% of those who underwent expanded panel testing had strong drivers ($P < 0.001$). Inclusion of less common mutations in the expanded panel increased the detection of multiple coexisting mutations by 4%, which provides increased utility in identifying aggressive forms of thyroid cancer. However, the study concluded broadly that all oncogenic changes can contribute to neoplastic growth and progression, and therefore both strong and weak drivers should be considered clinically important. From the results of the study, the researchers contend that subsequent microRNA testing can help overcome uncertainty as to the presence of cancer, as approximately half of nodules with weak drivers had positive microRNA results consistent with a higher risk of malignancy, and 33% of those with positive microRNA results likewise had strong positive microRNA levels specific for malignancy that are prevalent in nodules with strong drivers (Jackson et al., 2020).

Ciarletto et al. (2021) used ThyraMIR to study if pairwise comparisons of differentially expressed miRNAs can identify medullary thyroid carcinoma in FNA. Differential pairwise analysis was performed on 10 miRNAs in 7557 specimens. Nine differential pairs were determined to have significant power to differentiate medullary thyroid carcinoma and non- medullary thyroid carcinoma samples. The test accuracy was 100%, "the assay correctly classified all MTC [medullary thyroid carcinoma] and non-MTC samples." The authors conclude that "pairwise miRNA expression analysis of ThyraMIR results were found to accurately predict medullary thyroid carcinoma in thyroid FNA samples, including those with indeterminate FNA findings" (Ciarletto et al., 2021).

ThyroSeq v3

ThyroSeq is a test intended for assessment of thyroid nodules with undetermined cytology initially designed to target 12 cancer genes with 284 mutational hotspots. The latest version of this test, ThyroSeq v3, is based on NGS of DNA and RNA. This test detects 4 types of alterations; mutations, gene fusions, expression alterations, and copy number alterations. This test analyzes 112 genes, providing information on more than

12,000 mutation hotspots and more than 120 gene fusion types. First, the sample is ensured to have enough material to proceed (such as amount of thyroid follicular cells). Then, the NGS is performed and reviewed by a pathologist. Finally, the report is sent to the patient in about 2 weeks (ThyroSeq, 2024).

ThyroSeq test

In a multicenter study, this test was produced a negative predictive value of 97%, positive predictive value of 66%, with 94% sensitivity and 82% specificity in 257 cases of Bethesda-III and -IV nodules. The authors concluded that up to 61% of patients with indeterminate cytology could avoid diagnostic surgery through multigene genomic classifier testing (Steward et al., 2018). Other NGS-based molecular tests for thyroid nodules are available from other labs.

Nikiforova et al. (2018) evaluated the analytical performance of ThyroSeq v3 (intended to analyze 112 genes for alterations). A genomic classifier (GC) is used to differentiate malignant nodules from benign. 238 tissue samples and 175 FNA samples were included in the cohort. ThyroSeq detected over 100 genetic alterations. The GC cutoff identified malignant nodules in the tissue samples from benign at 93.9% sensitivity, 89.4% specificity, and 92.1% accuracy. For the FNA sample, the GC sensitivity was 98.0%, the specificity was 81.8%, and the accuracy was 90.9% (Nikiforova et al., 2018).

Afirma Series

The Afirma Genomic Sequencing Classifier (GSC) is offered by Afirma. This test is intended to assess indeterminate nodules (Bethesda categories III and IV) and "conclusively rule out" surgery (Afirma, 2022a). This test is based on the Afirma Gene Expression Classifier (GEC), which measured the activity level of 167 genes. The GSC added several features to better classify nodules, such as classifiers for medullary thyroid cancer, parathyroid lesions, *BRAF V600E* mutations, and overall better discrimination of Hurthle cell neoplasms (Douglas, 2023). Wei et al note that the GSC is an "updated" version of the GEC, available since 2011. Wei et al also published a study discussing proposed advantages of the GSC over the GEC, namely its improved specificity (as a weakness of the GEC was its inability to identify true oncocytic lesions in the "suspicious" category). The authors compared the results of indeterminate FNA specimens (Bethesda categories III and IV) that were tested by Afirma GEC or GSC. 272 tests (194 GEC, 78 GSC) were evaluated. 221 samples were classified as AUS/FLUS and 51 were classified as FN/SFN. Out of the 194 samples tested with GEC, 88 were considered benign (45.4%) whereas 52 of the 78 GSC samples were considered benign (66.7%). In the AUS/FLUS category, 47.1% of cases were considered benign by GEC whereas 71.2% were considered benign by GSC (Wei et al., 2019).

A component of the Afirma GSC is the medullary thyroid cancer (MTC) component. This component includes 108 genes and is performed along with the primary GSC at no extra charge (Afirma, 2021a, 2021b). Randolph et al. performed a validation of this test using 211 samples (21 MTC cases, 190 controls), and all 211 samples were identified correctly. These sample results were confirmed by surgery (for positive cases) and pathology (for negative cases) (Randolph, 2017).

Another test is the Afirma Xpression Atlas. This test is a comprehensive panel encompassing 511 genes, 761 variants, and 130 fusion pairs. Genes such as *BRAF, RET*, and the *RAS* pathway of genes are included in this panel. This test is intended to inform surgical and therapeutic decisions for high-risk patients. Afirma lists three populations for this test; those who are "suspicious" per the Afirma GSC test, Bethesda category V, and Bethesda category VI. Angell et al validated this test. The XA was compared to the results of multiple other methodologies (such as whole-transcriptome RNA-seq, targeted DNA-seq, et al) and concordance was evaluated. 943 blinded FNA samples were used to compare the DNA and RNA detection and 695 blinded FNAs were used to compare the fusion detections. At the cutoff of 5% variant frequency, 74% of allele variants detected by traditional methods were also detected by the XA, with 88% detected by the XA at a 20% variant frequency cutoff. 82% of fusions detected by the targeted RNA fusion assay were detected by the XA. From an analytical validity standpoint, intra-plate reproducibility was found to be 89%-94%, and inter-plate reproducibility was found to be 86%-91% (Angell et al., 2019). More recently, Krane et al. (2020) compiled evidence for the analytical validity, clinical validity, and clinical utility of the Afirma series in an evidence-based assessment. Analytical validation of the Afirma XA test using 69 variant-positive FNA samples demonstrated that there was high accuracy between the detection of variants (90%) and detection of fusion (94%) across two different laboratories. Clinical validation on the Afirma XA test's ability to detect genomic variants was measured against those of currently accepted methods of DNA and RNA sequencing using the aforementioned 943 FNA-blinded samples. However, it should be noted that 95% or more of the variants and fusions identified by Afirma XA can be identified simply through the reference DNA and RNA method. Moreover, some variants that were identified by DNA were absent or poorly expressed in RNA, and important promoter variants such as *TERT* are not identified by said test.

Jug et al. (2018) evaluated the performances of ThyroSeq and Afirma GEC within the context of ultrasonographic features and with the incorporation of the "noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) nomenclature." The ultrasonographic pattern evaluations were derived from the 2015 American Thyroid Association guidelines. A total of 304 cases were evaluated, with 119 resections. All cases that met criteria for NIFTP were considered high-risk by both tests.

However, when these NIFTP cases were moved from the malignant to the non-malignant category, the positive predictive value of ThyroSeq dropped from 42.9% to 14.3% and Afirma's dropped from 30.1% to 25.3% (Jug et al., 2018).

Endo et al. (2019) compared Afirma's GEC to its Gene Sequencing Classifier (GSC), using cytologically indeterminate nodules. 343 GEC-tested nodules and 164 GSC-tested nodules were identified. The GSC was found to have a "statistically significant higher benign call rate (76.2% vs. 48.1%), PPV (60.0% vs. 33.3%), and specificity (94.3% vs. 61.4%)." The authors noted that the improvement was statistically significant for Bethesda III and IV nodules. The GSC benign call rate was significantly higher in Hürthle cell changes (88.8% vs 25.7%). 52.5% of indeterminate nodules went to surgery when using the GEC compared to only 17.6% when using the GSC (Endo et al., 2019). Vuong et al. (2021) completed a meta-analysis of seven studies comparing the clinical impact and diagnostic performance of Afirma's GEC and GSC. Similarly, this study showed that GSC had a higher benign cell rate, particularly in Hürthle cell predominated nodules, as well as a lower resection rate and higher risk of malignancy. The authors conclude that "the specificity (43.0% vs 25.1%; P = .003) and PPV (63.1% vs 41.6%; P = .004) of Afirma GSC were significantly improved while it still maintained a high sensitivity (94.3%) and a high NPV (90.0%)" compared to the GEC (Vuong et al., 2021).

RosettaGX Reveal

The RosettaGX Reveal test from Rosetta Genomics is a micro-RNA-based diagnostic test that evaluates indeterminate thyroid nodules. The test measures 24 sequences of miRNA through quantitative RT-PCR, as well as a medullary carcinoma marker (hsa-miR-375). Each sample is classified as benign or suspicious for malignancy.

The test has a claimed negative predictive value of 99%, a 98% sensitivity, and a 78% specificity from a sample of 150 in which three pathologists all agreed on the evaluation. Out of the 189 total samples, the negative predictive value was 91%, sensitivity was 85%, and specificity was 72%. The nodule sizes were >0.5 cm. The authors concluded that this test may be able to differentiate between malignant and benign from a previously evaluated indeterminate sample (Lithwick-Yanai et al., 2017). This test has been discontinued.

NeoGenomics

NeoGenomics offers a "NeoTYPE" thyroid profile, intended for evaluation of "fine needle aspirates of thyroid nodules that are indeterminate or suspicious on cytology." NeoGenomics states that FISH detects mutations and other gene rearrangements, and that *BRAF* mutation V600E is associated with poor prognosis of papillary thyroid

carcinoma. The test measures the following genetic features: "*AKT1, ALK, ARID1A, ATM, BRAF, CDKN2A, CTNNB1, ERBB2, ERBB4, HRAS, KRAS, MEN1, MET*, Microsatellite Instability (MSI), *NF1, NF2, NRAS, PIK3CA, PTEN, RET, SMAD4, SMO, SRC, TERT* Promoter, *TP53, TSC1, TSC2,* Tumor Mutation Burden (TMB)", *MET* and *RET* by FISH, PD-L1, and Pan-TRK (NeoGenomics, 2023).

Clinical Utility and Validity

A study focusing on detection of *BRAF*, *RAS*, *RET/PTC*, and *PAX8/PPARg* mutations found that detection of any mutation resulted in a risk of histologic malignancy of 88%, 87%, and 95% for samples of Bethesda categories III, IV, and V, respectively. 967 samples were taken, and 87 mutations were found. The risk of cancer in mutation-negative samples was 6%, 14%, and 28%, respectively. Unfortunately, there was also a 14% false negative rate, limiting the usefulness of this panel (Douglas, 2023; Nikiforov et al., 2011).

Additional point mutations (including *TERT*, *TP53*, and others), as well as gene fusions that occur in thyroid cancer were found in another study using a next-generation sequencing (NGS) assay. 143 samples with a classification of follicular neoplasm or suspicious for follicular neoplasm were assessed, and the NGS panel "ThyroSeq v2" was used, which tests for point mutations in 13 genes and 42 types of gene fusions. 104 samples were found to be benign with the other 39 sample results being malignant. Overall, the NGS panel performed at a negative predictive value of 96%, a positive predictive value of 83%, 90% sensitivity, 93% specificity, and 92% accuracy for FN/SFN nodules (Nikiforov et al., 2014).

Another method that has been used is assessment of mRNA expression through a gene expression classifier. This is the basis of the Afirma genomic sequencing classifier, which identifies markers for features, such as medullary thyroid cancer, as well as distinguishes between Hürthle cell neoplasms from non-neoplastic Hürthle cell neoplasms. The second version of this test was assessed with 191 indeterminate samples. The sensitivity and specificity were 91% and 68%, respectively, and the negative and positive predictive values were 96% and 47%, respectively (Douglas, 2023; Patel et al., 2018). Afirma has produced a similar gene expression classifier "Xpression Atlas" that can be used to assess B-III to B-VI category neoplasms. Xpression Atlas evaluates a total of 761 gene variants and 130 fusion pairs (Afirma, 2022b; Douglas, 2023).

The above methods may be combined to better evaluate neoplasms, for instance, an miRNA gene expression classifier using both mutation analysis and miRNA expression. Labourier et al. (2015) evaluated a diagnostic algorithm that combined mutation analysis and miRNA expression to assess preoperative FNAs. This algorithm contained

17 validated gene alterations using the *miRInform* thyroid test and a 10-miRNA gene expression classifier. 109 samples of either AUS/FLUS or FN/SFN were evaluated with this combined algorithm, and this algorithm correctly identified 64% of malignant samples and 98% of benign ones. The sensitivity and specificity were 89% and 85%, respectively. For AUS/FLUS and FN/SFN, the negative predictive value was 97% and 91%, and the positive predictive value for malignancy was 68% and 82%, respectively (Douglas, 2023; Labourier et al., 2015).

No single methodology has achieved clinical utility to reliably resolve all indeterminate cytology, and thus several professional organizations, including the American Association of Clinical Endocrinologists (AACE), the American Thyroid Association (ATA), and the National Comprehensive Cancer Network (NCCN), have published guidelines for the evaluation of thyroid nodules, all of which endorse a similar multistep strategy suggesting molecular markers can be of use when cytology is indeterminate, yet acknowledging its current limitations (Gharib et al., 2016; Haugen et al., 2016; NCCN, 2023).

Banizs and Silverman (2019) evaluated the utility of "combined mutation analysis and microRNA classification in reclassifying cancer risk of cytologically indeterminate thyroid nodules." A three-tiered microRNA threshold was determined based on nodules with known disease status, and an expected rate of malignancy calculated from mutation analysis and the microRNA approach was validated in an independent cohort of "atypia of undetermined significance or follicular lesion of undetermined significance (AUS/FLUS) and follicular neoplasm or suspicious for follicular neoplasm (FN/SFN) nodules with surgically derived outcomes." From there, 2685 patients were included in the intended analysis. 82% of these samples lacked mutations, with *BRAF, PIK3CA, PAX8/PPARg*, and *RET/PTC* mutations all comprising 2% or less. The maximum expected risk of malignancy in these nodules without mutation was 9% for AUS/FLUS nodules and 17% for FN/SFN nodules, but with positive microRNA status, these rates increased to 36% and 54% respectively. *RAS* mutations occurred in 15% of mutations, and the expected malignancy rates in nodules with *RAS* or *PAX8/PPARg* mutations was 49% for AUS/FLUS nodules and 65% for FN/SFN nodules. With positive microRNA status, these rates increased to 85% and 91%, respectively (Banizs & Silverman, 2019).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

NCCN guidelines for thyroid carcinoma state that molecular diagnostic testing to detect individual mutations (such as *BRAF V600E* or *RET/PTC*) or pattern recognition approaches using molecular classifiers may be useful in the evaluating indeterminate FNA samples to assist in management decisions. NCCN states molecular diagnostics

may be used to reclassify indeterminate lesions such as AUS/FLUS. Molecular markers should be interpreted within the context of each patient. The NCCN states that molecular testing may be considered to drive treatment decisions, and some mutations may have prognostic importance.

When FNA results suggest atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS, Bethesda III) and there is not a high clinical and/or radiographic suspicion of malignancy, the NCCN recommends that one considers repeat FNA with second opinion pathology, diagnostic lobectomy, molecular diagnostics, or node surveillance as recommended by the ATA or TI-RADS as treatment. However, they remind readers that "Molecular markers should be interpreted with caution and in the context of clinical, radiographic, and cytologic features of each individual patient. If molecular diagnostics are technically inadequate or not done, then repeat FNA" (NCCN, 2023).

The NCCN further clarifies that "The choice of the precise molecular test depends on the cytology and the clinical question being asked. Indeterminate groups include: 1) follicular or oncocytic neoplasms; and 2) AUS/FLUS." The NCCN panel recommends molecular diagnostic testing for evaluating FNA results that are suspicious for follicular cell neoplasms or AUS/FLUS (category 2A), including oncocytic carcinoma, as studies historically do not perform well on Hürthle neoplasms. However, the NCCN has acknowledged promising studies for assessing oncocytic carcinoma neoplasms, with both the Afirma and ThyroSeq v3 tests providing better evaluations than their predecessors. The NCCN notes that molecular diagnostic testing may include individual mutation analysis or a multigene assay such as a gene expression classifier. Molecular markers may also help with treatment decisions or with eligibility in clinical trials.

However, they also note that "The diagnosis of follicular carcinoma or oncocytic carcinoma requires evidence of either vascular or capsular invasion, which cannot be determined by FNA. Molecular diagnostics may be useful to allow reclassification of follicular lesions (i.e., follicular neoplasm, AUS, FLUS) as either more or less likely to be benign or malignant based on the genetic profile. If molecular testing suggests papillary thyroid carcinoma, especially in the case of BRAF V600E, see PAP-1 Given the challenges of cytology to explicitly diagnose MTC in limited samples, molecular tests may be used to identify them. If molecular testing, in conjunction with clinical and ultrasound features, predicts a risk of malignancy comparable to the risk of malignancy seen with a benign FNA cytology (approximately 5% or less), consider nodule surveillance. Molecular markers should be interpreted with caution and in the context of clinical, radiographic, and cytologic features of each individual patient. If molecular diagnostics are technically inadequate or not done, then repeat FNA" (NCCN, 2023).

For individuals with or suspected with having papillary carcinoma, the NCCN recommends the following procedures as part of the diagnostic workup: thyroid and neck ultrasound (including central and lateral compartments), if not previously done, CT/MRI with contrast for locally advanced disease or vocal cord paresis, Consider assessment of vocal cord mobility (ultrasound, mirror indirect laryngoscopy, or fiberoptic laryngoscopy), FNA for suspicious lateral neck nodes (NCCN, 2023). FNA is important to consider in this case as "Tg washout is useful in diagnosis of lymph node metastases and recommended if cytology is negative" (NCCN, 2023).

The NCCN further notes that active surveillance may be an option for patients whose molecular diagnostics demonstrate a risk of malignancy under 5% and that the predictive value of molecular diagnostics may be influenced by pre-test probability of disease based on various FNA cytology groups. The NCCN states that molecular diagnostic testing may be useful for follicular cell carcinomas and diagnosing NIFTP [noninvasive follicular thyroid neoplasm with papillary-like nuclear features], although current tests for assessing NIFTP have not been validated. Molecular testing is not recommended for diagnosing anaplastic thyroid carcinoma. Finally, the NCCN highlights that the diagnostic utility of molecular diagnostics in pediatric patients is still unclear because most of the published literature is on adult patients with thyroid nodules (NCCN, 2023).

American Thyroid Association (ATA)

The 2015 ATA guidelines on the management of adult patients with thyroid nodules and differentiated thyroid cancer make the following recommendations on the use of molecular markers:

- "If molecular testing is being considered, patients should be counseled regarding the potential benefits and limitations of testing and about the possible uncertainties in the therapeutic and long-term clinical implications of results." (Strong recommendation; low-quality evidence)
- "If intended for clinical use, molecular testing should be performed in Clinical Laboratory Improvement Amendments/College of American Pathologists (CLIA/CAP)-certified molecular laboratories, or the international equivalent, because reported quality assurance practices may be superior compared to other settings." (Strong recommendation; low-quality evidence)
- "For nodules with AUS/FLUS cytology, after consideration of worrisome clinical and sonographic features, investigations such as repeat FNA or molecular testing may be used to supplement malignancy risk assessment in lieu of proceeding directly with a strategy of either surveillance or diagnostic surgery. Informed

patient preference and feasibility should be considered in clinical decision-making." (Weak recommendation; moderate-quality evidence)

- "Diagnostic surgical excision is the long-established standard of care for the management of FN/SFN cytology nodules. However, after consideration of clinical and sonographic features, molecular testing may be used to supplement malignancy risk assessment data in lieu of proceeding directly with surgery. Informed patient preference and feasibility should be considered in clinical decision-making." (Weak recommendation; moderate-quality evidence)
- In general, only nodules >1 cm should be evaluated as they have a greater chance to become a clinically significant cancer. However, there are some cases where nodules <1 cm may be evaluated due to other clinical symptoms. The ATA states that "attempts to diagnose and treat all such small thyroid cancers in an effort to prevent exceedingly rare outcomes is deemed to cause more harm than good."
- "If the nodule is benign on cytology, further immediate diagnostic studies or treatment are not required."
- "Each nodule that is >1 cm carries an independent risk of malignancy and therefore multiple nodules may require FNA" (Haugen et al., 2016).

The guidelines also state that "there is currently no single optimal molecular test that can definitively rule in or rule out malignancy in all cases of indeterminate cytology, and long-term outcome data proving clinical utility are needed" (Haugen et al., 2016).

The ATA Guidelines Task Force on Pediatric Thyroid Cancer have developed unique guidelines for children and adolescents with thyroid tumors. They have presented 34 recommendations including recommendations on molecular markers testing and nodules. The ATA panel recommended the pediatric age to be limited to a patient that is $\leq$ 18 years of age to more accurately define the impact of the physiologic changes of growth and development on tumor behavior. These guidelines note that a size criterion is more difficult in children as age affects volume greatly and size of the nodule is not predictive of malignancy. Overall, studies focusing on molecular diagnostics in children have not been validated and so cannot be recommended at this time (Francis et al., 2015).

The 2021 ATA Guidelines for Management of Patients with Anaplastic Thyroid Cancer notes that FNA cytology can be an important diagnostic tool for ATC diagnosis but recommends a parallel core biopsy to obtain sufficient material for molecular testing and accurate diagnosis (ATA, 2021; Bible et al., 2021). Other notable recommendations are reported below.

"RECOMMENDATION 2

Every effort should be made to establish a diagnosis via biopsy before proceeding with surgical resection, as surgical resection may be inappropriate.
Strength of Recommendation: Strong
Quality of Evidence: Low"

Moreover, the ATA asserts that "Generous sampling of the tumor, including its advancing edge, is indicated and necessary to fully characterize the neoplasm and increase the probability of finding any coexistent carcinoma and/or other pathologic findings. Additional or repeat immunohistochemical analysis should be performed as needed." Consequently, surgical pathology evaluation is indicated in the below situations.

"**RECOMMENDATION 3**
Routine surgical pathology evaluation of resection specimens should focus on confirming a definitive diagnosis of ATC, documenting the extent of disease, and defining the presence of any coexisting DTC and/or other pathologies. The proportion of tumor that represents ATC should also be documented.
Strength of Recommendation: Strong
Quality of Evidence: Low

RECOMMENDATION 4
Once ATC diagnosis is considered, assessment of *BRAF*^{V600E} mutation should be expeditiously performed by IHC and confirmed/expeditiously assessed by molecular testing.
Strength of Recommendation: Strong
Quality of Evidence: Moderate"

Regarding the timing of molecular profiling, the ATA offers the following recommendation:

"**RECOMMENDATION 5**
Molecular profiling should be performed at the time of ATC diagnosis to inform decisions related to the use of targeted therapies, especially as there are now FDA-approved mutation-specific therapies in this context.
Strength of Recommendation: Strong
Quality of Evidence: Moderate."

For initial evaluations, "There are a number of preoperative staging procedures of importance in ATC." The ATA propounds the below procedures.

"**RECOMMENDATION 6**
Initial radiological tumor staging should include cross-sectional imaging, in particular, CT neck, chest, abdomen, and pelvis with contrast (or MRI), and, if available, FDG PET/CT. Contrast-enhanced imaging of the brain (MRI preferred) should also be performed, if clinically indicated.
Strength of Recommendation: Strong
Quality of Evidence: Moderate" (Bible et al., 2021).

American Academy of Pediatrics (AAP)

The AAP endorsed the guidelines of the American Thyroid Association Guidelines Task Force on Pediatric Thyroid Cancer (as presented in Francis et al. (2015)) in a publication released in 2018 (AAP, 2018).

American Association of Clinical Endocrinologists (AACE), American College of Endocrinology (Interpace) and Associazione Medici Endocrinologi

These joint guidelines recommend the following:

- "Molecular testing should be considered to complement, not replace cytologic evaluation, and only if the results are expected to influence clinical management. As a general rule, molecular testing is not recommended in nodules with established benign or malignant cytologic characteristics."
- FNA is recommended for high ultrasound (US) risk lesions of ≥10 mm, intermediate risk lesions of >20 mm, and low risk lesions >20 mm and growing or with a risk history.
- "FNA is not recommended for nodules that are functional on scintigraphy."
- Repeat FNA is recommended in benign nodules with suspicious clinical or US findings, a nondiagnostic initial FNA on a solid nodule, and nodules that become symptomatic or increase in volume by 50%. Pregnancy does not affect cytologic diagnostic criteria. Routine repeat FNA is generally not necessary.
- Nodules with a major diameter of <5 mm should be monitored instead of biopsied.
- Consider the detection of *BRAF* and *RET/PTC* and possibly *PAX8/PPARG* and *RAS* mutations if available.
- There is no stance on gene expression classifiers for indeterminate nodules, due to insufficient evidence and limited follow-up.
- There is also insufficient evidence to take any stance on mutation testing to guide surgery decisions, except on mutations with a PPV approaching 100% for papillary thyroid carcinoma such as BRAFV600E (Gharib et al., 2016).

National Institute for Care and Health Excellence (NICE)

The guidelines concerning the use of fine needle aspiration in the assessment and management of thyroid cancer are reported below.

"**Management options based on ultrasound results**
1.2.9 Offer fine needle aspiration cytology (FNAC) to people who meet the threshold using an established system for grading ultrasound appearance.
1.2.10 Consider FNAC or active surveillance for people who do not meet the threshold for FNAC on ultrasound grading alone if there are other reasons for clinical concern." (NICE, 2022)

"**FNAC testing**
Performing and reporting FNAC

1.2.11 See the recommendation on using ultrasound [1.2.9, 1.2.10] guidance when performing FNAC in the NICE guideline on thyroid disease.
1.2.12 Use liquid-based cytology, direct smear or both when processing FNAC samples.
1.2.13 Use the Royal College of Pathologists modification of the British Thyroid Association (BTA) reporting system to report cytology results.
1.2.14 Consider rapid on-site evaluation of FNAC adequacy rates to improve the diagnostic yield of samples if the Thy1 (inadequate) rate for the centre or individual clinicians is higher than 15% (when Thy1c is excluded)" (NICE, 2022).

"**Management and further sampling after initial FNAC**

"1.2.15 Use the initial FNAC results to determine further management and sampling options, as shown in table 1."

Table 1 is captured below. Repeat sampling with FNAC is recommended for Thy1c (cystic lesion).

Table 1 Management options after initial fine-needle aspiration cytology

Initial fine-needle aspiration cytology result	Management and further sampling
Thy1 (inadequate)	Offer repeat sampling Consider core-needle biopsy (CNB) or fine-needle aspiration cytology (FNAC) with rapid on-site evaluation (ROSE) as the first choice Consider FNAC alone if ROSE is unavailable and CNB is unavailable or inappropriate Consider diagnostic hemithyroidectomy if the repeat sample is also Thy1
Thy1c (cystic lesion)	Offer repeat sampling with FNAC Consider diagnostic hemithyroidectomy if the repeat sample is also Thy1c and the ultrasound appearances are concerning
Thy2 and Thy2c (benign)	Consider repeat ultrasound Offer repeat sampling with FNAC if the second ultrasound also reaches the threshold for FNAC Consider CNB as an alternative to FNAC Discharge people if there is no evidence of malignancy after all investigations are complete, unless there are other reasons for clinical concern
Thy3a (atypia, neoplasia possible)	Offer repeat sampling Consider CNB (or FNAC if CNB unavailable or inappropriate) Consider diagnostic hemithyroidectomy or active surveillance if repeated samples are still Thy3a
Thy3f (suggesting follicular neoplasm)	Consider diagnostic hemithyroidectomy
Thy4 (suspicion of malignancy) and Thy5 (malignant)	Offer diagnostic hemithyroidectomy, or treatment with therapeutic hemithyroidectomy or total thyroidectomy

(NICE, 2022)

European Thyroid Association (ETA)

The ETA states that molecular testing for *BRAF, RET/PTC* and possibly *PAX8*, *PPARG,* and *RAS* mutations may be considered for cytologically indeterminate lesions. The search for molecular markers in B-II class lesions is not recommended, although one member of the panel did not agree with this non-recommendation. A GEC test cannot be recommended to exclude malignancy to replace diagnostic surgery or close surveillance, although one member did not agree with this non-recommendation. The targeted NGS approach is considered the most promising, with larger panels potentially becoming a rule-in and rule-out test if >95% negative predictive value can be reached. The ETA notes that molecular diagnostics may reduce completion thyroidectomies or other surgeries due to clearer assessments of an indeterminate lesion (Paschke et al., 2017).

In their 2023 Clinical Practice Guidelines for thyroid nodule management, the ETA stated that

- "Combine clinical factors, laboratory evaluation, and US risk stratification when defining the indication for FNA, in a shared decision with the patient *(Ungraded good practice statement. Agreement: 9/9 (100%); round: 1)*
- US guidance and use of either capillary action or suction is recommended when performing thyroid nodule FNA *(Strength of recommendation: 1; quality of evidence: ØØØO. Agreement: 9/9 (100%); round: 1)*
- FNA indication should be based on the following size cut-offs:
  - EU-TIRADS 5: >10 mm
  - EU-TIRADS 4: >15 mm
  - EU-TIRADS 3: >20 mm

  (*Strength of recommendation: 2; quality of evidence: ØOOO. Agreement: 9/9 (100%); round: 1*)
- Repeat FNA should be considered in case of a first non-diagnostic sample (excluding the solitary cyst), a Bethesda class III cytology, discrepancy between US risk score (i.e. high risk) and cytological findings (i.e. benign cytology), and significant nodule growthc *(Strength of recommendation: 1; quality of evidence: ØØØO. Agreement: 8/9 (88.9%); round: 1)*
- FNA is recommended in suspicious lymph nodes, with thyroglobulin or calcitonin washout dependent on phenotype *(Strength of recommendation: 1; quality of evidence: ØØØO. Agreement: 9/9 (100%); round: 1)*
- Core-needle biopsy should not be used as a first-line tool to assess thyroid nodules after US but could be considered a second-line procedure for specific conditions *(Strength of recommendation: 1; quality of evidence: ØØOO. Agreement: 8/9 (88.9%); round: 1)*" (Durante et al., 2023)

Regarding cytopathology-based management, the ETA recommend that practitioners "Correlate the cytological diagnosis with clinical, ultrasound and laboratory results *(Ungraded good practice statement. Agreement: 9/9 (100%); round: 1).*" Moreover, "Clinical surveillance of benign thyroid nodules which do not require therapeutic intervention, should be followed up according to the management schedule" below.

- Bethesda I
  - EU-TIRADS 3 (>20 mm): repeat FNA. If still non-diagnostic, consider CNB. If still non-diagnostic, re-evaluate the nodule within 1 year or offer surgery
  - EU-TIRADS 4 (>15 mm) and 5 (>10 mm): repeat FNA. If still non-diagnostic, consider CNB or, molecular testing (if available and sufficient material). If still non-diagnostic, offer active surveillance or surgery

(*Strength of recommendation: 2; quality of evidence: ØOOO. Agreement: 7/9 (77.8%); round: 2*)

- Bethesda II
  - EU-TIRADS 3 (>20 mm) and 4 (>15 mm): re-evaluate the nodule in 3–5 years[d]
  - EU-TIRADS 5 (>10 mm): repeat FNA[f]

(*Strength of recommendation: 2; quality of evidence: ØOOO. Agreement: 9/9 (100%); round: 2*)

- Bethesda III
  - Repeat FNA regardless of EU-TIRADS class
  - EU-TIRADS 3 (>10 mm), with repeat Bethesda III: re-evaluate the nodule within 1 year, consider molecular testing if available or offer surgery
  - EU-TIRADS 4 and 5 (>10 mm), with repeat Bethesda III: offer surgery or active surveillance; molecular testing if available

(*Strength of recommendation: 2; quality of evidence: ØOOO. Agreement: 9/9 (100%); round: 2*)

- Bethesda IV
  - All nodules, regardless of EU-TIRADS class: offer surgery[g]; molecular testing if available

(*Strength of recommendation: 2; quality of evidence: ØØOO. Agreement: 8/9 (88.9%); round: 1*)

- Bethesda V and VI
  - All nodules, regardless of EU-TIRADS class: recommend surgery[h]
  - Active surveillance and MIT may be considered in patients with 5-10 mm nodules, in the absence of suspicious lymph nodes or risk of extra-thyroidal extension[i]
  - Multidisciplinary workup is warranted in case of advanced cancer

(*Strength of recommendation: 1; quality of evidence: ØØØO. Agreement: 8/9 (88.9%); round: 1*)

(Extracted from Table 1 of Durante et al. (2023).)

However, the ETA also states that "Molecular testing may be considered in cytologically indeterminate nodules, if available *(Strength of recommendation: 1; quality of evidence: ØØØO. Agreement: 9/9 (100%); round: 1).*"

Regarding the use of non-ultrasound imaging modalities, it is recommended that FNA be avoided in specific instances: "Thyroid scintigraphy should be performed when serum TSH is subnormal in order to diagnose functioning nodules and/or multinodularity, avoid FNA and determine eligibility for RAI as an alternative to surgery *(Strength of recommendation: 1; quality of evidence: ØØØO. Agreement: 9/9 (100%); round: 1)*" (Durante et al., 2023).

European Society for Medical Oncology (ESMO)

The ESMO remarks that preoperative FNA for cytology is "not required" for nodules 1 cm or smaller. ESMO states that FNA diagnosis "can be facilitated" by assessment of malignancy markers and molecular alterations. Specifically designed gene panels are "reportedly" useful for identifying malignancy with indeterminate samples (Filetti et al., 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81445	Solid organ neoplasm, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants and copy number variants or rearrangements, if performed; DNA analysis or combined DNA and RNA analysis
81455	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform

	expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
81479	Unlisted molecular pathology procedure
81546	Oncology (thyroid), mRNA, gene expression analysis of 10,196 genes, utilizing fine needle aspirate, algorithm reported as a categorical result (eg, benign or suspicious) Proprietary test: Afirma® Genomic SequencingClassifier Lab/Manufacturer: Veracyte, Inc
81599	Unlisted multianalyte assay with algorithmic analysis
0018U	Oncology (thyroid), microRNA profiling by RT-PCR of 10 microRNA sequences, utilizing fine needle aspirate, algorithm reported as a positive or negative result for moderate to high risk of malignancy Proprietary test: ThyraMIR Lab/Manufacturer: Interpace Diagnostics
0026U	Oncology (thyroid), DNA and mRNA of 112 genes, next-generation sequencing, fine needle aspirate of thyroid nodule, algorithmic analysis reported as a categorical result ("Positive, high probability of malignancy" or "Negative, low probability of malignancy") Proprietary test: Thyroseq Genomic Classifier Lab/Manufacturer: CBLPath, Inc/University of Pittsburgh Medical Center
0204U	Oncology (thyroid), mRNA, gene expression analysis of 593 genes (including BRAF, RAS, RET, PAX8, and NTRK) for sequence variants and rearrangements, utilizing fine needle aspirate, reported as detected or not detected Proprietary test: Afirma Xpression Atlas Lab/Manufacturer: Veracyte, Inc
0245U	Oncology (thyroid), mutation analysis of 10 genes and 37 RNA fusions and expression of 4 mRNA markers using next-generation sequencing, fine needle aspirate, report includes associated risk of malignancy expressed as a percentage Proprietary test: ThyGeNEXT® Thyroid Oncogene Panel Lab/Manufacturer: Interpace Diagnostics
0287U	Oncology (thyroid), DNA and mRNA, next-generation sequencing analysis of 112 genes, fine needle aspirate or formalin-fixed paraffin-embedded (FFPE) tissue, algorithmic prediction of cancer recurrence, reported as a categorical risk result (low, intermediate, high) Proprietary test: ThyroSeq® CRC Lab/Manufacturer: CBLPath, Inc/University of Pittsburgh Medical Center

Molecular Profiling for Cancers of Unknown Primary Origin

Policy Number: AHS – M2065 – Molecular Profiling for Cancers of Unknown Primary Origin	Prior Policy Name and Number, as applicable: • AHS-M2065-Gene Expression Based Assays for Cancers of Unknown Primary
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Cancers of unknown primary origin (CUPs) are defined as the four to five percent of invasive cancers for which no primary site can be identified despite an extensive diagnostic work-up (Fizazi et al., 2015; Varadhachary & Raber, 2014). The American Cancer Society (ACS) estimates that about 34,950 cases of cancer of unknown primary will be diagnosed in 2024 in the United States (ACS, 2024). CUPs are generally considered to represent metastases and are associated with a very poor prognosis (Vikeså et al., 2015).

Gene expression assays measure the number of specific messenger RNAs (mRNAs) being transcribed to assess the genes that are active in a particular cell or tissue. Analyses of gene expression can be clinically useful for disease classification, diagnosis, prognosis, and tailoring treatment to underlying genetic determinants of pharmacologic response (Steiling, 2023).

For guidance concerning Tumor Mutational Burden Testing (TMB) and/or Microsatellite instability (MSI) analysis, please refer to AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing policy.

Policy Number	Policy Title

AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

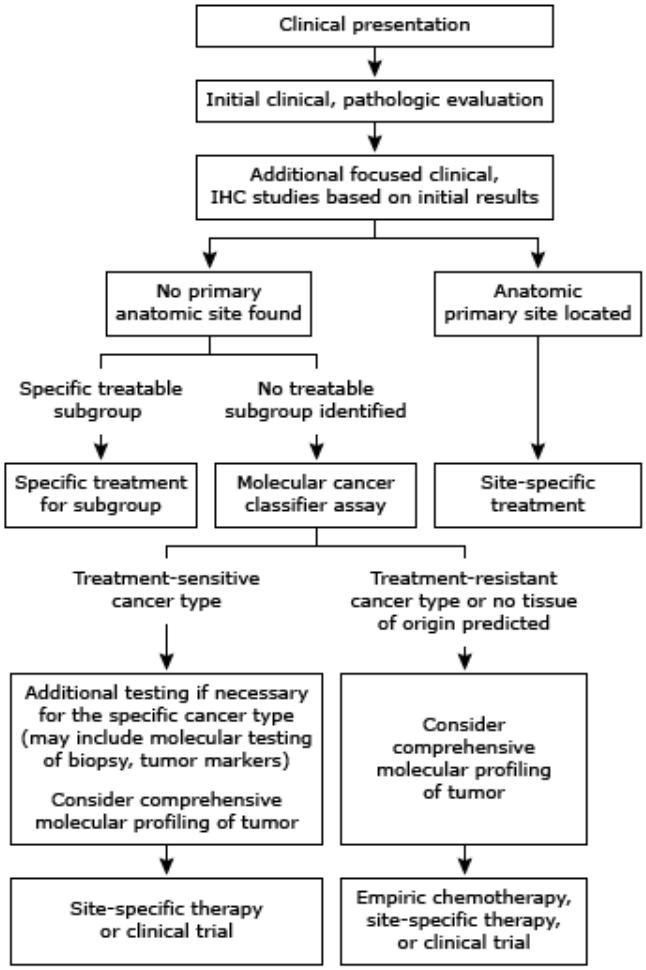
Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

1) To evaluate the site of origin of a tumor of unknown primary, to distinguish a primary from a metastatic tumor, or to guide site-specific therapy, molecular cancer classifiers **and/or** gene expression profiling assays **DO NOT MEET COVERAGE CRITERIA.**

IV. Table of Terminology

Term	Definition
ACS	American Cancer Society
ACUP	Adeno carcinomas of unknown primary site
ARID1A	*AT-rich interactive domain-containing protein 1A*
CDKN2A	*Cyclin-dependent kinase inhibitor 2a*
CUP	Cancers of unknown primary origin
ESMO	European Society of Medical Oncology
FFPE	Formalin-fixed paraffin-embedded
Gas	Genomic alterations
GEP	Gene expression profiling
ICI	Immune checkpoint inhibitor
IHC	Immunohistochemistry
KRAS	*Kirsten rat sarcoma viral oncogene homolog*
MAKP	*Mitogen-Activated Protein Kinase*
MDM2	*Mouse double minute 2 homolog*
MSI	Microsatellite instability
mRNA	Messenger ribonucleic acid
NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute
NICE	National Institute for Health and Clinical Excellence
NSCLC	Non-small cell lung cancer



PD-L1	Programmed death-ligand 1
RTK	*Receptor tyrosine kinase*
RT-PCR	Reverse transcription polymerase chain reaction
SMAD4	*SMAD family member 4*
TML	Total mutational load
TNBC	Triple-negative breast cancer
TP53	*Tumor protein p53*

V. Scientific Background

Cancers of unknown primary origin (CUPs) typically present with symptoms attributable to metastases where subsequent work-up fails to identify the primary site (J. Hainsworth & F. Greco, 2023). Given their rapid progression and dissemination, it was assumed that regardless of the site of origin, the tumors in unknown primary cancers shared biologic properties common to their pathogenesis and that identification of the exact tissue of origin would not have a substantial effect on therapeutic approaches or survival. However, biologic events that allow development of metastases without a discernable tumor at the primary site have not yet been determined (Varadhachary & Raber, 2014).

Accurate prediction of the tissue of origin using immunohistochemical staining and/or gene expression profiling is now possible in certain CUP cases. Appropriate classification, based upon all available evidence, is essential to identify patients for whom a specific treatment may be particularly useful and site-specific therapy based on these predictions is replacing empiric chemotherapy as the new treatment standard (J. Hainsworth & F. Greco, 2023). Tumors in unknown primary cancer despite different degrees of loss of differentiation retain the signature of their primary origin, even after metastasis (Fizazi et al., 2015).

Presently, patients are initially placed into one of four categories (adenocarcinoma, squamous cell carcinoma, neuroendocrine carcinoma, poorly differentiated) based upon the light microscopic examination of the initial biopsy. This classification is then used to guide further evaluation as indicated below (J. D. Hainsworth & F. A. Greco, 2023):

Although the true tissue of origin may not be identifiable in any given case, recent evidence suggests it may be useful to provide "site-specific" treatment based on tumor type (J. Hainsworth & F. Greco, 2023). Certain characteristics of a tumor, such as its histology, may indicate more responsive cases and as such, may warrant specific treatments. For example, an individual with peritoneal carcinomatosis may benefit from therapies that are effective against advanced epithelial ovarian cancer, as the histology in both types may be similar. However, although several of these subgroups have been identified, most patients will not fall in these groups; approximately 70% of cancers of unknown primary are classified as adenocarcinomas, and 80-85% of these adenocarcinomas are not yet classified into these subgroups. In the absence of a targeted therapy, "empiric" chemotherapy with efficacy against a broad swath of cancer types is usually provided (J. Hainsworth & F. Greco, 2023; Hainsworth, 2024).

Proprietary Testing

Several proprietary tests exist for the assessment of the origin of cancer. One of these tests is "Tissue of Origin" from Cancer Genetics Inc. This test assesses the expression level of over 2000 genes and reports the likeliest tissue of origin from the most 15 common tumor types ("breast, non-small cell lung, pancreas, gastric, colorectal, liver, bladder, kidney, thyroid, non-Hodgkin lymphoma, melanoma, ovarian, sarcoma, testicular germ cell, and prostate"). An RNA "profile" is generated from the expression levels and compared to tissue profiles representative of the 15 tumors (Cancer Genetics Inc., 2018).

Tissue of Origin was validated by Pillai et al. (2011) where they created microarray data files for 462 "metastatic, poorly differentiated, or undifferentiated FFPE tumor specimens, all of which had a reference diagnosis" and analyzed these files with the Tissue of Origin model. Overall agreement with the reference diagnosis was 89%, and an average of 12 tissues could be ruled out with >99% probability (Pillai et al., 2011). Nystrom et al. (2012) examined the utility of this test by sending a survey to 65 physicians overseeing 107 patients. They found that, with the gene expression profile results, the diagnosis was changed for 50% of patients and management was changed for 65% of patients (Nystrom et al., 2012).

Hologic (2024) released CancerTYPE ID used to identify tumor origin in metastatic cancers. CancerTYPE ID is a gene expression assay that uses "real-time RT-PCR to measure the expression of 92-genes in the patient's tumor and classifies the tumor by matching the gene expression pattern to a database of over 2,000 known tumor types and subtypes. CancerTYPE ID can differentiate between 50 different tumor types and subtypes, covering >95% of all solid tumors based on incidence" (Hologic, 2024). CancerTYPE ID has been validated with 87% accuracy, 98% tumor type identified, and 37% improved survival.

Other than proprietary tests, The Jackson Laboratory developed CUP-AI-Dx, an RNA-based classifier, that uses RNA sequencing data from 817 genes to determine the metastatic cancer's primary tissue of origin and identify a tumor's molecular subtype. This machine was trained with the transcriptional profiles of 18,217 primary tumors and 32 cancer types. CUP-AI-Dx may be an important tool to help guide therapies for those who are limited to generalized treatment approaches (Zhao et al., 2020).

Analytical Validity

Kerr et al. (2012) conducted a large multi-institution validation study to examine the performance of a 92-gene molecular cancer classifier. The assay showed overall sensitivities of 87% for tumor type and 82% for subtype. No decrease in comparative

performance was observed when metastatic tumors, high-grade tumors or cases with limited tissue were analyzed. The authors concluded that the assay showed strong performance for accurate molecular classification for various tumor histologies. They further state that "results support potential use of the assay as a standardized molecular adjunct to routine clinicopathologic evaluation for tumor classification and primary site diagnosis" (Kerr et al., 2012).

Handorf et al. (2013) published the results of a prospectively conducted, blinded, multicenter study that compared the diagnostic accuracy of gene expression profiling (GEP) with IHC in identifying the primary site of metastatic tumors with known primaries. Overall, GEP accurately identified 89% of specimens, compared with 83% accuracy using IHC. In the subset of 33 poorly differentiated and undifferentiated carcinomas, GEP had higher accuracy (91%) compared to IHC (71%). The authors concluded that GEP "was significantly more accurate than IHC when used to identify the primary site of metastatic tumors" (Handorf et al., 2013).

In a similar study design, Handorf et al. (2013) compared the diagnostic accuracy of IHC analysis versus molecular classification using a 92-gene RT-PCR assay for determination of the primary tumor site. The authors reported 79% accuracy for gene expression profiling compared with 69% for immunohistochemistry. The authors concluded that the results "demonstrate superior accuracy with the 92-gene assay versus standard-of-care IHC analysis and strongly support the diagnostic utility of molecular classification in difficult-to-diagnose metastatic cancer" (Weiss et al., 2013).

Loffler et al. (2016) performed next-generation sequencing (of 50 genes) on 55 patients with adenocarcinoma or undifferentiated carcinoma. 46 cases harbored tumor-specific mutations and other alterations. *TP53, KRAS, CDKN2A* and *SMAD4* were the most mutated genes, and 8 cases were identified as having targetable mutations by currently approved drugs. The authors concluded that mutations of relevant driver genes were present in "vast majority" of CUP tumors and that these genes may carry impact on prognosis and targeted therapy" (Loffler et al., 2016).

Santos et al. (2017) aimed to develop and validate a gene-expression classifier to identify potential primary sites for metastatic cancers more accurately. "The gene-expression classifier correctly identified, by a cross-validation, 86.6% of the expected cancer superclasses of 4429 samples from the RefDB, with a specificity of 99.43%. Next, the performance of the algorithm for classifying the validation set of metastatic FFPE samples was 83.81%, with 99.04% specificity. The overall reproducibility of our gene-expression-classifier system was 97.22% of precision, with a coefficient of variation for inter-assays and intra-assays and intra-lots <4.1%" (Santos et al., 2017).

In a study by Zhao et al. (2020),the CUP-AI-DX was tested on 394 metastatic samples of unknown primary origin. The machine correctly identified the tissue of origin 96.7% of the time. The authors also compared the classification accuracy to the CancerTypeID GEP test. While the accuracy of CUP-AI-DX was 98.54% in cross-validation, while CancerType ID was 87% in cross-validation. The authors conclude that "The CUP-AI-Dx predicts tumour primary site and molecular subtype with high accuracy and therefore can be used to assist the diagnostic work-up of cancers of unknown primary origin" (Zhao et al., 2020).

Raghav et al. (2020) studied the use of CancerType ID GEP assay to identify cancers of unknown primary for immune checkpoint inhibitor (ICI) therapy. A total of 9,250 cases were studied, and the assay found that non-small cell lung cancer (NSCLC) accounted for 33% of the molecular diagnosis. The assay also frequently recognized urothelial carcinomas, gastric cancer, and head and neck squamous cell carcinoma, all of which could be treated with ICI therapy. This assay identified 40% of cases for which an FDA-approved ICI was available. Currently, ICIs are only indicated for CUP on rare occurrences; therefore, identifying ICI-eligible CUP patients with this assay is an important step towards improving treatments (Raghav et al., 2020).

Sun et al. (2022) studied the diagnostic utility of a 90-gene expression test for tumor classification. 1,417 samples were analyzed using the 90-gene expression test and the results were compared to histopathological diagnosis. Overall, the 90-gene expression test reached an accuracy of 94.4%. "Among different tumor types, sensitivities ranged from 74.2% (head & neck tumor) to 100% (adrenal carcinoma, mesothelioma, and prostate cancer). Sensitivities for the most prevalent cancers of lung, breast, colorectum, and gastroesophagus are 95.0%, 98.4%, 93.9%, and 90.6%, respectively. Moreover, specificities for all 21 tumor types are greater than 99%" (Sun et al., 2022). The authors conclude that this 90-gene expression test can be used as an adjunct for tumor classification in clinical practice.

Clinical Utility and Validity

Several studies have investigated the validity and diagnostic utility of gene expression profiling in addition to or in place of standard immunohistochemistry in the diagnosis and management of CUP.

Hainsworth et al. (2013) conducted a prospective trial testing the tumor biopsy specimens from previously untreated patients with CUP with a 92-gene reverse transcriptase polymerase chain reaction cancer classification assay. Molecular tumor profiling correctly identified tissue of origin in 85% of carcinomas of known primary origin. The study showed that molecular tumor profiling predicted a tissue of origin in 247 of 252 (98%) patients with CUP. The authors concluded that "molecular tumor

profiling contributes to the management of patients with CUP and should be a part of their standard evaluation" (Hainsworth et al., 2013).

Greco et al. (2013) demonstrated that 18 of 24 patients (75%) with latent primaries discovered months to years later were predicted by molecular tumor profiling. The authors concluded that molecular tumor profiling "complements standard pathologic evaluation in determining the tissue of origin in patients with CUP, particularly when IHC is inconclusive" (Greco et al., 2013).

Oien and Dennis (2012) concluded that "in already well worked-up poorly differentiated and/or metastatic tumours, including CUP, molecular profiling performs well, with sensitivities of 72%–95% and may outperform optimal IHC by 10%–20%" (Oien & Dennis, 2012). The authors conclude that molecular profiling could thus contribute to diagnosis of poorly differentiated and/or metastatic tumors.

Ross et al. (2015) conducted comprehensive genomic profiling on 200 CUP formalin-fixed paraffin-embedded specimens (mean, 756× coverage) using the hybrid-capture-based FoundationOne assay for presence of targetable genomic alterations (GAs) in CUP and responses to targeted therapies. They concluded that "Almost all CUP samples harbored at least 1 clinically relevant GA with potential to influence and personalize therapy. The ACUP [adenocarcinomas of unknown primary site] tumors were more frequently driven by GAs in the highly druggable RTK/Ras/mitogen-activated protein kinase (MAPK) signaling pathway than the non-ACUP tumors. Comprehensive genomic profiling can identify novel treatment paradigms to address the limited options and poor prognoses of patients with CUP" (Ross et al., 2015).

Groschel et al. (2016) investigated if their results from a difficult case could be extrapolated. The authors described an advanced-stage malignancy that mimicked a poorly differentiated soft-tissue sarcoma and did not respond to multiagent chemotherapy. Despite molecular profiling and histopathology analysis, the tissue of origin was not identified. However, the authors believed that immune checkpoint inhibitor therapy was warranted, and several differential diagnoses were theorized, including triple-negative breast cancer (TNBC). The authors assessed 157 TNBC cases from the Cancer Genome Atlas and found PD-L1 copy number gains (leading to excess PD-L1 mRNA expression) in 24% of cases. The authors concluded that their results "illustrate the impact of multidimensional tumor profiling in cases with nondescript histology and immunophenotype, show the predictive potential of PDL1 amplification for immune checkpoint inhibitors (ICIs), and suggest a targeted therapeutic strategy in Chromosome 9p24.1/PDL1-amplified cancers" (Groschel et al., 2016).

Zehir et al. (2017) attempted to characterize the mutational landscape of metastatic cancer. 10945 tumor samples from 10336 patients were included. Tumors were

sequenced with two panels, one of 341 genes, and another of 410 genes (with all 341 genes from the former panel included). Tumors were sequenced to an average of 718x coverage. Non-small cell lung cancer was the most common, with 1563 patients, followed by breast carcinoma at 1237 patients and colorectal cancer at 978 patients. Cancers of unknown primary comprised of a total of 160 patients. Overall, the authors identified 36.7% of patients as having actionable mutations (n = 3792). Gastrointestinal stromal tumors (76%), thyroid cancer (60%) and breast cancer (57%) were found to have the highest proportion of actionable mutations. However, the highest standard of actionable mutation met for cancers of unknown primary was "level 2B", or "standard of care biomarker for an FDA-approved drug in another indication". The authors concluded that their data "demonstrate [d] the feasibility and utility of large-scale prospective clinical sequencing of matched tumor-normal pairs to guide clinical management (Zehir et al., 2017).

Varghese et al. (2021) aimed to provide a "clinical and pathologic" description of patients with cancers of unknown primary. A total of 150 patients had targeted next-generation sequencing performed. There were 45 patients identified to have "potentially actionable" mutations, and 15 patients received targeted therapies. The authors remarked that CUP patients may benefit from targeted therapies (Varghese et al., 2021).

Gatalica et al. (2018) attempted to identify predictive biomarkers for immune checkpoint blockade therapy in cancers of unknown primary (CUP). A total of 389 cases were analyzed for 592 mutations and 52 gene fusions through next-generation sequencing. Microsatellite instability (MSI), total mutational load (TML), and PD-L1 expression were all evaluated. The authors identified "high" TML in 11.8% of tumors, high MSI in 7 tumors, and PD-L1 expression in 80 (of 362 tested cases) tumors. Other predictive biomarkers such as *MDM2* gene amplification were identified. *TP53* gene mutations were found in 54% of cases, followed by *KRAS* (22%) and *ARID1A* (13%). Overall, the authors identified 28% of CUP cases as carrying a predictive biomarker for immune checkpoint blockade therapy (Gatalica et al., 2018).

Clynick et al. (2018) attempted to identify actionable mutations in cancers of unknown primary. There were 21 cases included, and two gene panels were used to evaluate variants in 76 cancer-related genes. The authors found variants in 17 of 21 cases, with 11 considered "potentially actionable". The most common variants detected were *TP53* (47%), *KRAS* (12%), *MET* (12%) and *MYC* (12%). The authors also remarked that CUP adenocarcinomas and poorly differentiated carcinomas tended to harbor gene mutations involved in signal transduction pathways (eight of eleven cases harboring mutations such as *BRAF, HRAS,* and *KRAS*), whereas squamous cell carcinomas tended to harbor mutations in genes involved in cell cycle control and DNA repair genes (all

eight cases harboring mutations such as *TP53, MLH1*, and *CDKN2A*). Overall, the authors identified mutations in "biologically relevant" genes in the "vast majority" of CUP tumors, noting that half provided a "potentially novel treatment not generally considered in CUP" (Clynick et al., 2018).

Hayashi et al. (2019) compared two treatments for cancers of unknown primary site. Empirical chemotherapy was compared against site-directed therapy (directed by comprehensive microarray-based gene expression profiling). Efficacy analysis was performed for 50 patients in the site-specific arm and 51 patients in the empirical chemotherapy arm. One-year survival rate was found to be 44% for site-specific treatment and 54.9% for empirical treatment (p = .264). Median overall and progression-free survival was found to be 9.8 months and 5.1 months respectively for site-specific treatment and 12.5 months and 4.8 months respectively for empirical treatment (p=.896 and .550, respectively). Overall, the authors concluded that "Site-specific treatment that was based on microarray profiling did not result in a significant improvement in one-year survival compared with empirical PC [treatment]" (Hayashi et al., 2019).

Fizazi et al. (2019) evaluated the utility of "tailored treatment" for cancers of unknown primary. 243 patients with cancers of unknown primary were included and were randomized to Arm A ("Cisplatin 100 mg/m2 d1þ Gemcitabine 1250 mg/m2, day one and eight, q3w", empiric treatment) or Arm B ("gene expression test followed by a la carte treatment according to the suspected primary", tailored). The gene expression tests used were Pathwork's Tissue of Origin (n = 21) or CancerTYPE (n = 222), and the primary endpoint was defined as progression-free survival at a hazard ratio of 0.625. The four most common tissues of origin were "pancreatico-biliary cancer (19%), squamous cell carcinoma (eleven percent, kidney cancer (eight percent) and lung cancer (eight percent)". A total of 91 out of the 123 patients in Arm B were given tailored treatment. Progression-free survival in both arms were similar (both by central and local review), overall survival was similar in both arms (hazard ratio = 0.92). Overall, the authors concluded that "using a molecular test followed by tailored systemic treatment did not improve outcomes of pts [patients] with CUP" (Fizazi et al., 2019).

Cobain et al. (2021) studied which patients have the greatest clinical benefit from NGS profiling. NGS was performed in 1,015 patients and clinically actionable genomic alterations were found in 817 patients (80.5%). Of the 817 patients, 132 (16.2%) received sequencing-directed therapy, and 49 had clinical benefit (37.1%). "For 55 patients with carcinoma of unknown primary origin, NGS identified the primary site in 28 (50.9%), and sequencing-directed therapy in 13 patients resulted in clinical benefit in 7 instances (53.8%), including 5 exceptional responses" (Cobain et al., 2021). The

authors conclude directed germline testing and genomic profiling should be used as a standard of care for patients with cancer of unknown origin.

Saeed et al. (2022) studied the utility and impact of genomic profiling to determine tissue origin of CUPs. The study included tissue or cytology specimens from 22 CUPs, 15 of which were adequate for analysis. "Primary tumor site was suggested in 12 cases (80%), whereas it remained indeterminate in 3 (20%)." The doctors concluded that "genomic profiling helped confirm the original diagnosis and suggested primary sites in two third of our cases" (Saeed et al., 2022).

Posner et al. (2023) compared gene expression profiling (GEP) and DNA sequencing as tools for predicting primary tissue of origin in CUP. The study included 215 CUP patients, 82% of whom received both tests. Based on retrospective clinicopathological data, 77%, of cases had insufficient evidence to support a tissue of origin diagnosis. After DNA sequencing, "mutations and mutational signatures provided additional diagnostic evidence in 31% of cases." Alternatively, "GEP classification was useful in only 13% of cases and oncoviral detection in 4%." The authors conclude that DNA mutation profiling was "the more diagnostically informative assay" compared to GEP (Posner et al., 2023).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

The NCCN lists two primary applications of molecular profiling in management of CUP; using gene expression profiling and molecular cancer classifier assays to determine tissue of origin for site-specific therapy, and identifying actionable mutations for targeted therapy (NCCN, 2024).

The 2023 NCCN guidelines for the workup of an occult primary malignancy address the use of molecular methods in the classification of tumors. The guidelines state "Gene sequencing to predict tissue of origin is not recommended." The guidelines also state that "molecular profiling of tumor tissue using NGS or other technique to identify gene fusions can be considered after an initial determination of histology has been made." Further, the guidelines note that "While there may be a diagnostic benefit to GEP, a clinical benefit has not been demonstrated." The guidelines further recommend that "until more robust outcomes and comparative effectiveness data are available, pathologists and oncologists must collaborate on the judicious use of IHC and GEP on a case-by-case basis, with the best possible individualized patient outcome in mind" (NCCN, 2024).

Overall, the NCCN states that "the clinical benefit of using molecular profiling to guide treatment decisions in CUP remains to be determined." The NCCN also states that "currently, there is no evidence of improved outcomes with the use of site-specific therapy guided by molecular testing results in patients with CUP" (NCCN, 2024).

National Institute for Health and Clinical Excellence (NICE)

A 2010 clinical guideline from NICE, which was reaffirmed in 2017, recommended against the use of gene expression-based profiling to identify primary tumors in patients with provisional CUPs. The guideline also states, "do not use gene-expression-based profiling when deciding which treatment to offer patients with confirmed CUP" (NICE, 2010).

In the April 2023 update of the Metastatic malignant disease of unknown primary origin in adults: diagnosis and management clinical guideline, NICE withdrew recommendations on gene-expression-based profiling (NICE, 2010).

European Society of Medical Oncology (ESMO)

In 2023, EMSO updated their clinical practice guidelines for the diagnosis, treatment, and follow-up of cancer of unknown primary. The guideline states that "The clinical utility of gene expression profiling to help elucidate the likely primary is not currently supported by high-level evidence. Consequently, it is not generally recommended outside of clinical research." Additionally, "there is currently no high-level evidence that gene expression profiling-directed therapy leads to an improvement in patient outcomes. Consequently, such strategies are not recommended outside of clinical trials" (Krämer et al., 2023).

National Cancer Institute (NCI)

The NCI acknowledges the possible utility of gene expression profiling and next generation sequencing to identify a potential site of origin in patients with CUP (NCI, 2023).

American Cancer Society (ACS)

The American Cancer Society acknowledges the possible use of gene expression profiling and molecule genetic testing for the diagnosis of cancers of unknown primary. However, they note that molecular genetic testing "is not needed in most cases, but it's sometimes helpful in classifying some cancers when other tests have not provided clues regarding their origin." Regarding gene expression profiling, the ACS

states that "these tests can sometimes help your doctor discover where the cancer may have started, but so far, they haven't been linked to better outcomes in patients" (ACS, 2018; Losa et al., 2018).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

No FDA-approved tests for the assessment of cancer from an unknown primary site were found. Additionally, many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
81504	Oncology (tissue of origin), microarray gene expression profiling of > 2000 genes, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as tissue similarity scores
81540	Oncology (tumor of unknown origin), mRNA, gene expression profiling by real-time RT-PCR of 92 genes (87 content and 5 housekeeping) to classify tumor into main cancer type and subtype, utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a probability of a predicted main cancer type and subtype
81599	Unlisted multianalyte assay with algorithmic analysis

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Molecular Testing for Cutaneous Melanoma

Policy Number: AHS – M2029 – Molecular Testing for Cutaneous Melanoma	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Cutaneous melanoma is a common and serious form of skin cancer. Diagnosis of this type of cancer often involves visual examination of the skin by a dermatologist; however, due to the various presentations of nodules, it can be difficult to properly recognize a melanoma case. Although several visual systems have been developed to assist in diagnosis (such as the ABCDE system for signature features), a biopsy is often performed to diagnose a case (Swetter, 2024).

Genetic testing (particularly gene expression panels) has been explored by researchers to assist in diagnosing cases without a biopsy (Bollard et al., 2021). Another application of genetic testing is "targeted testing"; certain genetic mutations show better patient response with targeted treatment, and it is therefore clinically useful to identify these mutations to help guide selection of the most appropriate therapy.

II. Related Policies

Policy Number	Policy Title
AHS-M2026	Molecular Testing for Cutaneous Melanoma
AHS-M2030	Testing for Targeted Therapy of Non-Small-Cell Lung Cancer

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who have received genetic counseling and who have a diagnosis of cutaneous melanoma, multigene panel testing for cutaneous melanoma-associated likely pathogenic or pathogenic variants (see Note 1, Note 2) **MEETS COVERAGE CRITERIA** when **one** of the following conditions is met:
   a) When the individual has three or more invasive cutaneous melanomas.
   b) When the individual has invasive cutaneous melanoma and **one** of the following:
      i) A personal history of astrocytoma.
      ii) A personal or family history (first-degree relative; see Note 3) with pancreatic cancer.

2) For individuals without a diagnosis of melanoma who have received genetic counseling and who are in a family with a known deleterious familial likely pathogenic or pathogenic variant in a cutaneous melanoma-associated gene, the following genetic testing for inherited forms of melanoma **MEETS COVERAGE CRITERIA**:
   a) Testing restricted to the known familial likely pathogenic or pathogenic variant.
   b) Comprehensive genetic testing, including muti-gene panel testing (see Note 1, Note 2), when the specific familial likely pathogenic or pathogenic variant is unknown.

3) For individuals without a diagnosis of melanoma who have received genetic counseling, multi-gene panel testing for cutaneous melanoma-associated likely pathogenic or pathogenic variants (see Note 1, Note 2) **MEETS COVERAGE CRITERIA** only if a family likely pathogenic or pathogenic variant is unknown **and** the individual has a family history of **one** of the following:
   a) Three or more invasive cutaneous melanomas.
   b) Renal cancer.
   c) Astrocytoma.
   d) Uveal melanoma.
   e) Mesothelioma.

4) For individuals who are being considered for molecular-targeted therapy and who have stage III or stage IV cutaneous melanoma, testing of tumor tissue for *BRAF, KIT*, and *NRAS* gene mutations (single gene or multi-gene panel testing) **MEETS COVERAGE CRITERIA**.

5) For individuals with a suspicious primary melanocytic skin lesion, risk assessment of the lesion using the DermTech Pigmented Lesion Assay (PLA) (see Note 4) **MEETS COVERAGE CRITERIA** to help inform a biopsy decision when **all** of the following conditions are met:
   a) When lesion size is 5-19 mm;
   b) When the lesion meets one or more ABCDE criteria (Asymmetry, Border, Color, Diameter, Evolving);
   c) When the lesion is located where the skin is intact (i.e., non-ulcerated or non-bleeding lesions) and free of psoriasis, eczema, or similar skin conditions;
   d) When the lesion does not contain a scar;
   e) When the lesion has not been previously biopsied;
   f) When the lesion is not already clinically diagnosed as benign or melanoma;
   g) When the lesion is **NOT** located on the palms of hands, soles of feet, nails, mucous membranes, or hair covered areas that cannot be trimmed.

6) For individuals with a primary cutaneous melanocytic lesion that has not been re-excised, gene expression profiling (GEP) of the lesion with the myPath® Melanoma Assay **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:
   a) When the lesion has not already been definitively diagnosed as benign or malignant;
   b) When diagnostic GEP has not already been performed on the same lesion.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

7) For all other situations not described above, genetic testing for inherited forms of cutaneous melanoma **DOES NOT MEET COVERAGE CRITERIA**.

8) For all other situations not described above, genetic expression profiling tests for cutaneous melanoma **DO NOT MEET COVERAGE CRITERIA**.

9) For all situations not described above (e.g., individuals not being considered for targeted therapy, other forms or stages of melanoma), testing for *BRAF, KIT, NRAS*, and other mutations **DOES NOT MEET COVERAGE CRITERIA**.

10) Prognostic biomarker testing of a tumor biopsy to assess the risk of melanoma progression (e.g., AMBLor®) **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: When germline multi-gene panel testing is performed, the panel should at minimum include the following melanoma susceptibility genes: *BAP1, CDK4, CDKN2A, MC1R, MITF, PTEN,* and *TERT*.

Note 2: For two or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

Note 3: First-degree relatives include parents, full siblings, and children of the individual.

Note 4: While this is not considered a surgical procedure, it is recommended that individuals who are receiving this test should first undergo an informed consent process to discuss the benefits and risks of pursuing this test versus receiving a biopsy to rule out melanoma.

IV. Table of Terminology

Term	Definition
AAD	The American Academy of Dermatology
ABCDE	Asymmetry, border, color, diameter and evolving
ACD	Adrenocortical dysplasia protein homolog
ACMG	American College of Medical Genetics and Genomics
AMBRA1	Autophagy and beclin 1 regulator 1
AMLo	Loricrin
anti-CTLA-4	Anti-cytotoxic T-lymphocyte-associated protein 4
ARAF	Serine/threonine-protein kinase A-Raf
ASCO	American Society of Clinical Oncology
ATM	*Ataxia-telangiectasia mutated*
BAP1	*Breast cancer susceptibility gene-associated protein-1*
BRAF	*B-RAF Proto-Oncogene, serine/threonine kinase*
BRCA1	*Breast cancer susceptibility gene*
BRCA2	*Breast cancer susceptibility gene 2*
CAP	College of American Pathologists
CDK4	*Cyclin-dependent kinase 4*
CDKN2A	*Cyclin-dependent kinase inhibitor 2a*
CDx	Companion diagnostic

CGH	Comparative genomic hybridization
CHEK2	*Checkpoint kinase 2*
C-KIT	*Proto-oncogene c-KIT*
CLIA'88	Clinical Laboratory Improvement Amendments of 1988
CLND	Completion lymph node dissection
CM	Cutaneous melanoma
CMS	Centers for Medicare and Medicaid
COVID-19	Coronavirus disease 2019
CP-GEP	Clinicopathological and Gene Expression Profile
CRAF	RAF proto-oncogene serine/threonine-protein kinase
ddPCR	Droplet digital polymerase chain reaction
DFS	Disease-free survival
DMFS	Distant metastasis-free survival
DNA	Deoxyribonucleic acid
E	Glutamate
EADO	European Association of DermatoOncology
EDF	European Dermatology Forum
EORTC	European Organization of Research and Treatment of Cancer
ESMO	European Society for Medical Oncology
FAMMM	Familial atypical multiple mole-melanoma
FDA	Food and Drug Administration
FFPE	Formalin-fixed, paraffin-embedded
FISH	Fluorescence in situ hybridization
GEP	Gene expression profile
GIST	Gastrointestinal stromal tumor
HR	Hazard ratio
KIT	*KIT proto-oncogene, receptor tyrosine kinase*
LDTs	Laboratory developed tests
LINC00518	*Long intergenic non-protein coding ribonucleic acid 518*
MAS	Melanoma-astrocytoma syndrome
MC1R	*Melanocortin-1 receptor*
MDM2	*Mouse double minute 2*
MEK	Mitogen-activated protein kinase/extracellular signal-regulated kinase-1 kinase
MITF	*Microphthalmia-associated transcription factor*
MPWG	Melanoma Prevention Working Group
NBN	*Nibrin*
NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute

NED	Without evidence of disease
NER	Nucleotide excision repair
NGS	Next-generation sequencing
NP	Nurse practitioners
NPV	Negative predictive value
NRAS	*Neuroblastoma RAS viral [v-ras] oncogene homolog*
NSGC	National Society of Genetic Counselors
OS	Overall survival
p14ARF	Adenosine pyrophosphate -ribosylation factor tumor suppressor
p16	Cyclin-dependent kinase inhibitor 2A
p53	Tumor protein P53
PA	Physician assistants
PCR	Polymerase chain reaction
PFS	Progression-free survival
PIK3CA	*Phosphoinositide 3-kinases catalytic subunit alpha*
PLA	Pigmented lesion assay
PLA(−)	Pigmented legion assay negative
POT1	*Protection of telomeres 1*
PRAME	*Preferentially expressed antigen in melanoma*
PTEN	*Phosphatase and tensin homolog*
qPCR	Quantitative polymerase chain reaction
RB1	*Retinoblastoma protein*
RCM	Reflectance confocal microscopy
RFS	Recurrence-free survival
RNA	Ribonucleic acid
ROC	Receiver operating characteristic
RTK	Receptor tyrosine kinase
RT-PCR	Real-time polymerase chain reaction
SIC	Satisfactory disease free
SIGN	Scottish Intercollegiate Guidelines
SLN	Sentinel lymph node
SLNB	Sentinel lymph node biopsy
SLNBx	Sentinel lymph node biopsy
SSE	Skin self-examination
SSO	Society of Surgical Oncology
TERT	*Telomerase reverse transcriptase*
TMB	Tumor mutation burden
TN	True-negative
TP	True-positive

UV	Ultraviolet
WRN	Werner's syndrome protein
WT	Wild type
XP	*Xeroderma pigmentosum*
XPC	*Xeroderma pigmentosum group c*
XPD	*Xeroderma pigmentosum group d*

V. Scientific Background

Skin cancer is the most common form of cancer, arising from the metaplastic transformation from any of the cell types of the skin (Linares et al., 2015). Melanomas, which develop from the pigment-producing melanocytes, although much less prevalent than non-melanoma skin cancer, are increasing in incidence (Holmes, 2014; Lee & Lian, 2018). Early and accurate diagnosis is essential, as late-stage melanoma is among the most fatal forms of skin cancer (Cockerell et al., 2017). This, however, presents a significant challenge due to the difficulty of interpreting the histopathology of melanoma and the resulting interobserver and intra-observer variability (Elmore et al., 2017; Gerami et al., 2014).

Genetic Testing for Familial Cutaneous Melanoma

A family history of melanoma is reported by about 10% of melanoma patients (Soura et al., 2016b), and inherited germline mutations reportedly "increase melanoma risk from 4- to >1000-fold" (Ransohoff et al., 2016). Determining the genetic origin, however, is complicated, as a portion of familial melanoma can be attributed to shared sun exposure experiences in family members with susceptible skin types (Goldstein & Tucker, 2001).

The majority of familial cases lack identifiable germ-line mutations in either known susceptibility genes or in genes commonly mutated in sporadic melanoma (Hawkes et al., 2016). Uncommon, but high-risk, alleles have been found to contribute to the hereditary cancer phenotype that includes unilateral lineage, multi-generational, multiple primary lesions, and early onset of disease (Soura et al., 2016b). Additional research has identified a relationship between telomere length and familial melanoma; patients with familial melanoma had longer telomeres compared to patients with sporadic melanoma (Menin et al., 2016). As such, genes such as *TERT*—which encodes for the catalytic subunit of telomerase—and proteins such as POT1—a shelterin complex protein—have been implicated in the presence of multiple primary melanomas and early-onset melanoma in a subset of high-density families (Rossi et al., 2019).

Cyclin-dependent kinase inhibitor 2A (*CDKN2A*) and cyclin-dependent kinase 4 (*CDK4*) are the most identified gene mutations in familial forms of melanoma, which can be defined as a family where either two first-degree relatives or three or more melanoma patients on the same side of the family are diagnosed with melanoma. Germline *CDKN2A* mutations have been identified in approximately 20-40% of familial melanoma cases where three or more family members are affected (Harland et al., 2016; Rossi et al., 2019). *CDKN2A* encodes several proteins involved in cell cycle regulation, including p16, which inhibits *CDK4* (Hussussian et al., 1994; Koh et al., 1995), and p14ARF, which inhibits *MDM2* from regulating p53 (Zhang et al., 1998). Germline *CDKN2A* mutations in melanoma families are usually missense or nonsense changes that impair the function of the p16 protein, allowing for unchecked cell cycle progression; however, rare mutations in the p14ARF protein have also been reported and result in proteasomal degradation of p53 with subsequent accumulation of DNA damage (Marzuka-Alcala et al., 2014). Overall survival is worse in those with a germline *CDKN2A* mutation than those with sporadic melanoma or familial melanoma with wild-type *CDKN2A* genes. Germline mutations also predisposed individuals to an increased number of malignancies, such as pancreatic and lung cancer (Tsao & McCormick, 2024).

Mutations in *CDKN2A*/p16 are associated with familial atypical multiple mole-melanoma (FAMMM syndrome), which is characterized by numerous nevi (some atypical), a family history of melanoma, and an increased risk of pancreatic cancer (Goldstein et al., 2007; Lynch & Krush, 1968). Carriers of a FAMMM mutation typically present with cancer at a younger age than non-carriers (Middlebrooks et al., 2019). Mutations in p14ARF are linked to Melanoma-Astrocytoma Syndrome (MAS), a variant of FAMMM characterized by both cutaneous melanomas and nervous system tumors (Randerson-Moor et al., 2001). Inheritance of *CDKN2A* mutations are autosomal dominant, but these mutations have variable penetrance based on sun exposure patterns and coinheritance of other melanoma-associated variants, conferring a 76% lifetime risk of developing melanoma in the US (Bishop et al., 2002; Cust et al., 2011). Mutations in *CDK4* are even less common, but were most often found affecting arginine 24, resulting in a CDK4 protein that is insensitive to inhibition by the p16 protein. No apparent differences exist in the phenotype (e.g., age at diagnosis, number of melanomas) of families carrying either *CDKN2A* or *CDK4* mutations. In aggregate, between 20-45% of familial melanomas are associated with germline mutations in *CDKN2A* or *CDK4* (Goldstein et al., 2007; Nelson & Tsao, 2009).

Other rare mutations have been associated with melanoma. Germline variations in the melanocortin-1 receptor (*MC1R*) gene alter the risk of melanoma in individuals with and without *CDKN2A* mutations (Marzuka-Alcala et al., 2014; Pasquali et al., 2015; Wendt et al., 2018). Germline variants in genes that encode for *BRCA1*-associated

protein-1 (*BAP1*), telomerase reverse transcriptase (*TERT*), and microphthalmia-associated transcription factor (*MITF*) have also been added to the list of genes harboring familial melanoma-predisposing mutations (Simone et al., 2017; Soura et al., 2016a). These are more often associated with "mixed cancer syndrome," where melanoma may appear in the context of a more general predisposition for malignancy. The *BAP1* tumor syndrome is associated with the appearance of cutaneous melanoma, uveal melanoma, and various internal malignancies (Wiesner et al., 2011). Mutations in the promoter region of *TERT*, the protein component of telomerase, and in various components of the shelterin complex have been associated with a higher incidence of melanoma and other internal malignancies (Burke et al., 2013; Horn et al., 2013). Mutations in *MITF* are associated with a higher nevus count, cutaneous malignant melanoma onset before 40 years of age, and non-blue eye color with no association to freckling, skin color, or hair color (Bertolotto et al., 2011; Yokoyama et al., 2011). Xeroderma pigmentosum (XP) is a rare disorder in which patients have a mutation in genes involved in nucleotide excision repair (NER). Patients with mutations in *XPC* and *XPD* have an increased risk of melanoma (Paszkowska-Szczur et al., 2013). Lastly, Cowden syndrome, a type of *PTEN* hamartoma tumor syndrome characterized by the appearance of trichilemmomas, papillomatous papules, mucosal lesions (papules) and palmar-plantar keratosis within the first three decades of life, is associated with a higher risk of melanoma (Bubien et al., 2013; Soura et al., 2016a).

Several proprietary gene panels exist for assessment of familial cutaneous melanoma. For example, the DermTech Pigmented Legion Assay (PLA) leverages their "Smart Sticker" technology to remove cellular material from the stratum corneum, the material of which is then analyzed for over-expression of *LINC00518* (*long intergenic non-coding RNA 518*) and *PRAME* (*preferentially expressed antigen in melanoma*), which may be incidental with genomic atypia associated with melanomas (Gerami et al., 2017). Moreover, Invitae offers a 12-gene panel (nine primary genes plus three genes with "preliminary evidence for melanoma"), Fulgent offers a 14-gene panel, and GeneDx offers a 9-gene panel (Fulgent, 2023; GeneDx, 2023; Invitae, 2024). These panels may include genes traditionally associated with familial melanoma itself (such as *CDKN2A*) as well as genes whose variants are not primarily associated with familial melanoma, but confer added risk regardless (Tsao & McCormick, 2024)

Clinical Utility and Validity of Genetic Testing for Familial Cutaneous Melanoma

The frequency of *CDKN2A* mutations in patients with a single primary melanoma or multiple primary melanoma were 1.2% and 2.9%, respectively (Berwick et al., 2006); however, depending on selection criteria, mutation frequency rates of *CDKN2A* can range from 5% to 72% (Delaunay et al., 2017) with a family history of melanoma considered the most important risk factor. The established rule of three is used when

proposing genetic testing for primary melanomas; it is generally understood that when three or more melanomas or genetically related cancers are identified in the same patient, or in first- and second-degree relatives, the pretest probability is increased above ten percent and the cost of genetic screening can be justified (Leachman et al., 2017).

In a study on *CDK2NA* genetic testing conducted in Sweden between 2015 and 2020, 913 members across 403 families were identified with cutaneous melanoma. Pissa et al. (2021) found that melanoma cases found in families testing positive for pathogenic variants of *CDK2NA* boasted significantly higher mortality rates, such that families with the variants had 37.6% melanoma cases that died from melanoma as compared to the 10.0% without ($p<0.001$), independent of age, sex, and tumor stage. This significant melanoma-specific mortality associated with families with *CDK2NA* variants is motivation to identify and enroll carrier families in a preventive surveillance program (Pissa et al., 2021). However, a potential confounding variable involves the diagnoses of pancreatic cancers in the subjects in the study; as pathogenic strains of CDK2NA are also associated with cancers other than melanomas, the 129 of the 913 members present a limitation to the specificity of the study as there did not appear to be a clear manner of segregating its influence.

Stolarova et al. (2020) analyzed 264 Czech melanoma patients with early onset, double primary tumors or family history by next generation sequencing NGS analysis of 217 genes, and they identified that "mutations in high-to-moderate melanoma risk genes and in other cancer syndrome genes were significantly associated with melanoma risk," with those genes including *CDKN2A, POT1,* and *ACD* for high-to-moderate melanoma risk, and *NBN, BRCA1/2, CHEK2, ATM, WRN,* and *RB1* for other cancer syndrome genes. An increased potential of carrying mutations was found in "patients with double primary melanoma, melanoma and other primary cancer, but not in patients with early age at onset" (Stolarova et al., 2020). *CDK2NA* was the most frequently mutated gene among those with high-to-moderate risk, and in other studies reviewed by Stolarova et al. (2020), there was an increased risk for pancreatic cancer among families with *CDK2NA* mutation, and a more established family history.

Leachman et al. (2017) published an updated algorithm for the identification, testing, and management of hereditary melanoma; the rule of three has been incorporated into this algorithm as an indication for genetic testing in multiple melanomas. The researchers state that "Any patient or family that meets the updated rule of threes should be considered a candidate for genetic testing. If melanoma is the only cancer in a pedigree, then to meet the threshold of genetic testing, a pedigree should have three primary melanomas in first- or second-degree relatives in areas with a high melanoma incidence or two primary melanomas in a low-incidence area. This

melanoma panel should include *BAP1*, *CDK4*, and *CDKN2A*. Genes for which risk has not been established but for which studies suggest an elevated risk include *MITF* and *POT1* and we recommend including these in the melanoma panel" (Leachman et al., 2017).

Genetic testing for commonly known cutaneous melanoma mutations can be utilized to determine prognosis and overall survival. Aoude et al. (2020) found that "germline mutation status was the most significant biomarker for OS [overall survival]" and "survival outcomes for germline carriers are poor with the current standards of care." When using BRAF status and tumor mutation burden (TMB) for prognosis of cutaneous melanoma patients, "BRAF V600 wild-type patients had significantly longer PFS [progression-free survival] than the V600 mutant group ($p = 0.0317$) … For stage III/IV resected patients, TMB was also significantly associated with longer PFS ($p = 0.0034$)" (Aoude et al., 2020). The greater the number of recognizable mutations, the more targeted attacks against cancerous cells can be made and the better the prognosis.

Genetic Testing for Acquired Cutaneous Melanoma

Melanoma is a particularly lethal and aggressive cancer with the ability to metastasize to any organ (Leong et al., 2011). Cutaneous tumors as little as one mm in thickness are capable of lymph node metastasis (Stage III), resulting in a significant decrease in the five-year survival rate from 90% to 56% (Yee et al., 2005). If the cancer has spread beyond the lymph nodes (Stage IV), an even more dramatic decrease in five-year survival to 15% will occur (Grossmann et al., 2012). Genetic testing for acquired melanoma can identify the activating genetic alterations.

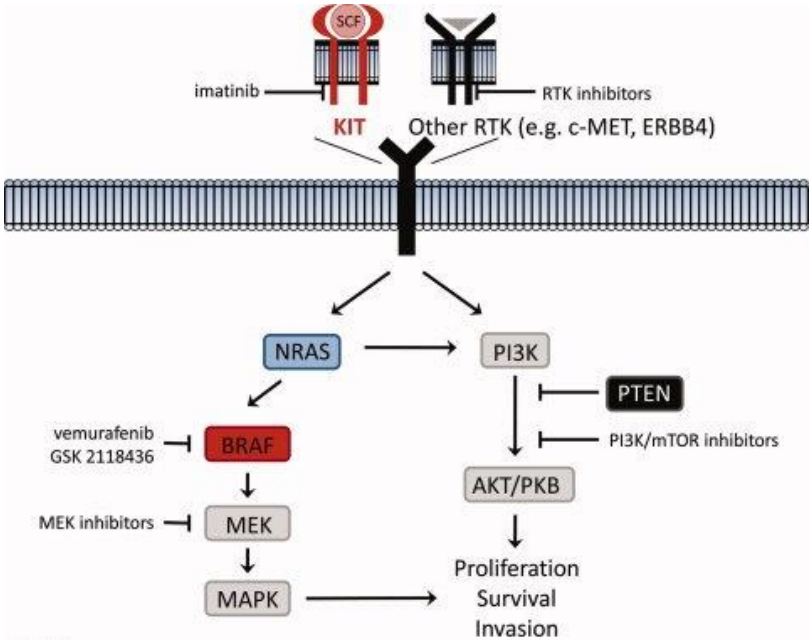
Genetic testing is important to determine the most efficient treatment method for a melanoma patient. Despite the high frequency in nevi, the role of *BRAF* mutations in oncogenesis is well established (Davies & Gershenwald, 2011) and has been confirmed in clinical trials (Flaherty et al., 2010). BRAF is a member of the RAF family of protein serine/threonine kinases (ARAF, BRAF, CRAF) that is activated by Ras proteins during intracellular signaling cascades. Mutations in *BRAF* appear to be the most common genetic alteration in melanoma (Hocker & Tsao, 2007) and occur more frequently in melanoma than lung, colon, and ovarian carcinoma (Grossmann et al., 2012). The remarkable efficacy of *BRAF* inhibitors led to the accelerated approval of vemurafenib for unresectable and metastatic melanoma. Importantly, *BRAF* mutation testing is warranted for determining therapeutic eligibility as selective *BRAF* inhibitors pose significant risk of cutaneous squamous cell carcinoma and have the potential to increase disease progression in *BRAF* wild type (mutation negative) tumors (Grossmann et al., 2012).

The mutations, *BRAF, KIT, PIK3CA* and *NRAS,* are commonly seen in melanoma cases (Alrabadi et al., 2019; Lokhandwala et al., 2019) with an estimated 50% of melanomas exhibiting the *BRAF* V600E mutation (Burjanivova et al., 2019).

Table 1. Frequency of Melanoma Subtypes with Activating Genetic Alterations in *BRAF* and *KIT* (taken from (Grossmann et al., 2012))

Aberration	Cutaneous –CSD	Cutaneous + CSD	ALM	MM
***BRAF* mutation**	53%	8–11%	10%	15%
***KIT* mutation; amplification**	0	17%	11–38%; 19–27%	6–19%; 20–33%

A variety of methods are utilized for *BRAF* and *KIT* mutational analysis testing in melanoma, which has resulted in no standardized procedures for testing. Because numerous techniques are available and updated methods continue to be released, labs have been reluctant to switch *BRAF* platforms to accommodate one specific drug for one disease (Grossmann et al., 2012). Current *BRAF* genetic testing methods include *BRAF* V600E by real-time PCR, *BRAF* V600E mutation only by Sanger sequencing, *BRAF* full gene sequence analysis, and *BRAF* next generation sequencing (CMGL, 2014).



However, a recent study found good overall compliance of labs with the College of American Pathologists (Bellomo et al.) (Cree et al., 2014) and National Comprehensive Cancer Network (NCCN) guidelines for molecular diagnosis of tumors (Volmar et al., 2015) despite not using the specific FDA-approved test.

Table 2. Molecular Testing Adherence to NCCN Guidelines (taken from (Volmar et al., 2015))

	All Institutions Percentiles					
	n	**10th**	**25th**	**Median**	**75th**	**90th**
Retrospective study (lung, colorectal, melanoma)						
Percentage of tests that strictly meet the guideline	26	32.6	64.7	70.9	82.7	89.7
Percentage of tests that at least loosely meet the guideline	26	57.4	90.7	95.1	98.9	100.0
Prospective study (all case type)						
Percentage of tests that strictly meet the guideline	23	20.0	31.4	53.3	66.7	70.5
Percentage of tests that at least loosely meet the guideline	23	75.0	87.0	94.3	100.0	100.0

Historically, systemic therapy for metastatic melanoma provided very low response rates and little to no benefit in overall survival (Atkins et al., 2000; Tsao et al., 2004). However, this is beginning to change. For example, researchers have now identified that those with the *BRAF* V600 mutation are able to obtain both immune checkpoint inhibitor therapy and other targeted therapies for an improved overall treatment regimen (Ghate et al., 2019). Moreover, the immune-boosting anti-CTLA-4 antibody ipilimumab (Hodi et al., 2010) and testing and development of small molecule kinase (*KIT* and *BRAF*) inhibitors have yielded improvements in long-term survival for melanoma patients (Davies & Gershenwald, 2011; Ribas & Flaherty, 2011; Woodman & Davies, 2010).

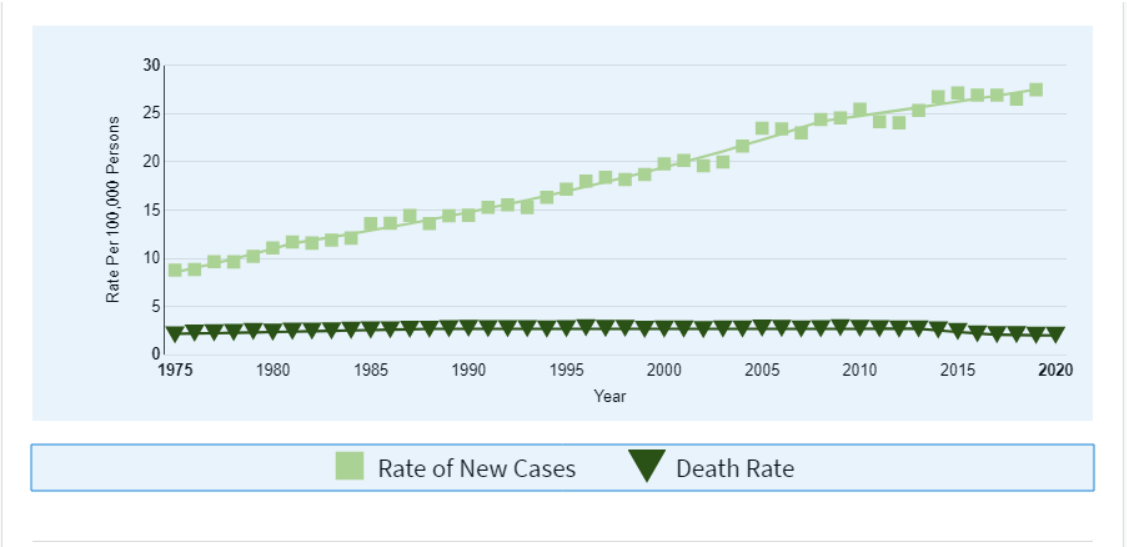


Figure 1: Imatinib and RTK Inhibitor Pathways for Melanoma Treatment (image taken from (Grossmann et al., 2012))

The lifetime risk for the general population of developing melanoma is one in 55 (NCI, 2023) and that risk has increased approximately two percent annually since 1960 (Rashid & Zager, 2015). National Cancer Institute now reports that melanoma of the skin represents 5.2% of all new cancer cases in the United States; approximately 99,780 Americans in total will be diagnosed with melanoma in 2022 (NCI, 2023).

In 2022, the number of new cases of melanoma of the skin per 100,000 people was 21.5. Further, the number of melanoma patient deaths in 2022 was 2.1 per 100,000 individuals, accounting for 1.3% of all cancer deaths in United States (NCI, 2023).

Figure 2. New Cases and Deaths of Melanoma of the Skin per 100,000 Persons (taken from (NCI, 2023))

Clinical Utility and Validity of Genetic Testing for Acquired Cutaneous Melonama

O'Brien et al. (2017) analyzed samples to determine if *BRAF* mutation identification by immunohistochemistry was a suitable alternative to PCR. The study included 132 patients, and the anti-*BRAF* V600E VE1 clone antibody was used for immunohistochemistry detection. A sensitivity of 86.1% and specificity of 96.9% was shown with the anti-*BRAF* V600E VE1 clone antibody; "The concordance rate between PCR and immunohistochemical BRAF status was 95.1% (116/122)" (O'Brien et al., 2017). As both methods were in high agreement, immunohistochemistry may be a viable alternative to PCR for *BRAF* mutation testing.

Corean et al. (2019) utilized several different techniques on metastatic melanoma samples, including bone marrow morphology, histology, immunophenotyping, molecular genetic testing and *BRAF* V600E immunohistochemistry. *BRAF* immunohistochemistry was detected in two patients, and molecular testing confirmed these results; researchers then stated that "*BRAF* V600E immunohistochemistry is useful as a surrogate marker of molecular results," once again highlighting the fact that immunohistochemistry may be a viable alternative for *BRAF* mutation testing (Corean et al., 2019).

Available *BRAF* tests and analytical sensitivities:

- "The *BRAF* V600E by real-time PCR test uses a TaqMan® Mutation Detection Assay to detect the V600E mutation in exon 15 of *BRAF* in tumor (somatic) cells.

The sensitivity of the TaqMan assay is ~0.1% mutant DNA in a wild-type background. Poor DNA quality, insufficient DNA quantity or the presence of PCR inhibitors can result in uninterpretable or (rarely) inaccurate results.

- The *BRAF* (V600E) mutation only by Sanger sequencing uses a DNA-based PCR-sequencing assay to detect the V600E in exon 15 of *BRAF*. The limit of detection for Sanger sequencing is >20% mutant DNA in a wild-type background.
- The *BRAF* full gene sequence analysis test uses a DNA-based PCR-sequencing assay to detect point mutations in the coding sequence and intron/exon boundaries of the *BRAF* gene. The sensitivity of DNA sequencing is over 99% for the detection of nucleotide base changes, small deletions and insertions in the regions analyzed. Rare variants at primer binding sites may lead to erroneous results. The limit of detection for Sanger sequencing is >20% mutant DNA in a wild-type background" (CMGL, 2014).
- The *BRAF* NGS with TruSeq had sensitivity of over 99% (Froyen et al., 2016).

Colombino et al. (2020) compared *BRAF* mutation testing performed with conventional nucleotide sequencing approaches (Sanger sequencing and pyrosequencing) with real-time polymerase chain reaction (RT-PCR) or next-generation sequencing (NGS) assays to assess the levels of concordance between these various techniques. There were 319 tissue samples analyzed and initially screened with conventional approaches. The initial screen found pathogenic *BRAF* mutations in 144 (45.1%) cases. RT-PCR (Idylla™ *BRAF* mutation assay) detected 11 (16.2%) and three (4.8%) additional *BRAF* mutations after Sanger sequencing and pyrosequencing, respectively. NGS detected one additional *BRAF*-mutated case (2.1%) among 48 wild-type cases previously tested with pyrosequencing and RT-PCR. According to the data, RT-PCR is more accurate than both Sanger sequencing and pyrosequencing in detecting *BRAF* mutations. Overall, RT-PCR had a good concordance with the other tests; "real-time PCR is a rapid method which achieves the same maximum level of sensitivity of NGS (up to 98%), without requiring particular skills" (Colombino et al., 2020). According to the author, "[RT-PCR and NGS] improved the diagnostic accuracy of *BRAF* testing via the detection of additional *BRAF* mutations in a subset of false-negative cases previously tested with Sanger sequencing or pyrosequencing. In attendance of further confirmations in larger prospectively designed studies, the use of two sensitive molecular methods may ensure the highest level of diagnostic accuracy" (Colombino et al., 2020).

The *BRAF* analysis is an accepted medical practice for patients with unresectable, metastatic stage IV melanoma (NCCN, 2024). However, recent randomized controlled trials have indicated the benefits of expanding *BRAF* analysis. A study published in The Lancet Oncology by Amaria et al. (2018) compared standard of care in patients with high-risk, surgically resectable melanoma (stage III or IV) to similar patients receiving a regimen of a neoadjuvant plus adjuvant dabrafenib and trametinib. All patients had to

be of confirmed *BRAF* V600E or *BRAF* V600K status to participate in either the control or experimental groups. In the follow-up (median of 18.6 months), 10/14 (or 71%) of patients in the experimental group remained event-free (i.e., alive without disease progression), whereas zero out of seven (0%) of the control group receiving standard of care remained event-free. The authors conclude that the "Neoadjuvant plus adjuvant dabrafenib and trametinib significantly improved event-free survival versus standard of care in patients with high-risk, surgically resectable, clinical stage III-IV melanoma" (Amaria et al., 2018).

Another study published by Zippel et al. (2017) researched the use of perioperative *BRAF* inhibitors on patients with stage III melanoma. All patients had to be confirmed *BRAF* V600E to participate in the study. Of the thirteen patients, twelve "patients showed a marked clinical responsiveness to medical treatment, enabling a macroscopically successful resection in all cases"; moreover, "at a median follow up of 20 months, 10 patients remain free of disease" (Zippel et al., 2017). One patient died prior to surgery in this study. The authors conclude that the "Perioperative treatment with *BRAF* inhibiting agents in *BRAF*V600E mutated Stage III melanoma patients facilitates surgical resection and affords satisfactory disease free (sic) survival" (Zippel et al., 2017).

Gene Expression Profiling and Biomarkers for Diagnosis and Prognosis

Currently, patients presenting with a suspicious pigmented lesion undergo excisional biopsy which is then subjected to histopathologic examination by a pathologist (NCCN, 2024). The majority of melanocytic neoplasms can be accurately classified by this approach; however, in some cases confidently differentiating benign melanocytic nevi from malignant melanoma can be extremely difficult or impossible despite additions to histopathologic assessment, such as the evaluation of Breslow depth (Chiaravalloti et al., 2018; Lee & Lian, 2018). In these cases, even diagnoses from expert pathologists can be discordant (Elmore et al., 2017; Farmer et al., 1996; Gerami et al., 2014) and subject to diagnostic drift (Bush et al., 2015).

A number of diagnostic and prognostic genetic tests for melanoma have been developed as ancillary tests to assist in this differentiation and resultant risk stratification (Lee & Lian, 2018), including microRNAs as biomarkers to distinguish between melanomas and nevi (Torres et al., 2019). Gene expression profiling is growing in popularity for the diagnosis and prognosis of cutaneous melanoma. Molecular tests based on gene expression profiling of cutaneous melanoma are commercially available. They include the myPath Melanoma (Castle Biosciences, 2024b), 2-GEP Pigmented Lesion Assay (DermTech, 2023a), DecisionDx-Melanoma

(Castle Biosciences, 2024a), and a clinicopathologic (CP)-GEP model by SkylineDx (SkylineDx, 2024).

Another risk stratification test is the melanoma prognostic test, AMBLor®, described by Avero Diagnostics as a test used to identify "early-stage melanomas at low risk of progression." Avero Diagnostics licensed this biotechnology from AMLo Biosciences Ltd. The AMBLor® test looks for the presence of two prognostic biomarker proteins, AMBRA1 and loricrin, both of which are found in the skin overlying the tumor. An absence of these biomarkers in AJCC stages I and II indicates melanoma at a normal or high risk of progression, while normal expression of the biomarkers is linked to a low risk of cancer progression(AMLo Biosciences, 2023).

Clinical Utility and Validity of Gene Expression Profiling and Biomarkers for Diagnosis and Prognosis

myPath Melanoma (Castle Biosciences)

A 23-gene expression profile and algorithm that assigns various weights and thresholds of expression for each gene was developed to differentiate benign melanocytic nevi from malignant melanoma; this gene expression profile and algorithm was determined to have a sensitivity of 89% and specificity of 93% (Clarke et al., 2015). Further, three experienced dermatopathologists validated this method against an independent histopathologic evaluation; a sensitivity of 91.5% and a specificity of 92.5% was determined (Clarke et al., 2017). This gene expression profile was developed into a commercial test known as myPath Melanoma, which generates a single numerical score along with a classification of likely malignant, likely benign, or indeterminate, for a given cutaneous lesion. Across various validation studies, myPath Melanoma has demonstrated a sensitivity in the range of 90-94% and a specificity in the range of 91-96% (Ko et al., 2017).

myPath Melanoma correlates closely with long-term clinical outcomes by adding valuable adjunctive information to aid in the diagnosis of melanoma. The test is intended for "the in vitro analysis of primary cutaneous melanocytic lesions for which malignant potential is uncertain", but has not been validated on "metastatic melanomas, recurrent tissue specimens, non-melanocytic neoplasms, or biopsies from a patient receiving immunosuppressant therapy or radiation treatment" (Castle Biosciences Inc., 2022). An examination of the utility of this test (Cockerell et al., 2017) found that the results of this gene expression signature have a significant clinical impact with 71.4% (55/77) of cases changing from pretest recommendations to actual treatment. Majority of changes were consistent with the test result. There was an 80.5% (33/41) reduction in the number of biopsy site re-excisions performed for cases with a benign test result. However, when more challenging samples were included (Minca et

al., 2016) with 39 histopathologically unequivocal lesions (15 malignant, 24 benign) and 78 challenging lesions interpreted by expert consensus (27 favor malignant, 30 favor benign, and 21 ambiguous), myPath Melanoma had a lower sensitivity and specificity than fluorescence in situ hybridization (Yokoyama et al.) (FISH: 69% sensitivity, 91% specificity; myPath; 55% sensitivity, 88% specificity).

In contrast, Clarke et al. (2020) completed another study that evaluated the accuracy of myPath melanoma in diagnostically uncertain neoplasms. Out of 125 diagnostically "uncertain" cases, myPath melanoma demonstrated a sensitivity of 90.4%. In this study, the test displayed no significant difference in sensitivity between the diagnostically uncertain (equivocal) and unequivocal lesion groups.

Pigmented Lesion Assay (PLA) (DermTech)

DermTech has developed a pre-diagnostic quantitative polymerase chain reaction (qPCR)-based pigmented lesion assay (PLA) that measures the expression of two genes in the stratum corneum to assist with diagnostic or prognostic information for potential melanoma cases (Varedi et al., 2019). DermTech's PLA identifies malignant changes on a genomic level that cannot be detected with the human eye; this assay can be used to support clinicians in their decision to biopsy suspicious nevi. This test has the potential to increase the number of early melanomas biopsied and reduce the number of benign lesions biopsied, thereby improving patient outcomes (Ferris et al., 2017). A recent study has given this pigmented lesion assay a sensitivity of 91-96%, a specificity of 69-91%, and a negative predictive value of approximately 99% (Ferris, Rigel, et al., 2019).

To help support clinicians in their decision to biopsy, this noninvasive two gene expression assay of the *LINC00518* and *PRAME* genes has been developed for use on adhesive patch biopsies. Skin sampling via an adhesive patch allows for DNA, RNA, skin tissue and microbiome samples to be safely obtained and transported cost effectively by mail at room temperature; skin cells, T-cells, dendritic cells, melanocytes and other types of cells can be analyzed by this method (Yao et al., 2017). The use of an adhesive patch also allows 100% of the lesion's surface to be sampled, compared to less than one to two percent of surgical biopsies (DermTech, 2023b). Further, this technique is a much more cost-effective option. Hornberger and Siegel (2018) report that PLA testing could save approximately $447 per lesion compared to traditional biopsies.

Gerami et al. (2017) tested the validity of the two-gene panel based on *LINC00518* and *PRAME* on differentiating melanoma from nonmelanoma in a multicenter study across 28 sites in the United States, Europe, and Australia. In a sample of 398 (87 melanomas and 311 nonmelanomas), it was found that this classification method was able to

accurately identify melanomas from nonmelanomas with a sensitivity of 91% and a specificity of 69%. An application study of 381 patients found that the estimated real-world sensitivity of the DermTech PLA was 95% and specificity was 91% (Ferris et al., 2018); overall, 93% of PLA results positive for both *LINC00518* and *PRAME* were diagnosed histopathologically as melanoma. Further, this study was also used to identify if the real-world clinical use of the DermTech PLA could change physician behavior and reduce the overall number of biopsies performed. The PLA identified 51 PLA(+) test results, and 100% of these pigmented skin lesions were biopsied (37% were melanomas). Furthermore, "Nearly all (99%) of 330 PLA(-) test results were clinically managed with surveillance. None of the three follow-up biopsies performed in the following three to six months, were diagnosed as melanoma histopathologically" (Ferris et al., 2018). The PLA test altered clinical management of pigmented lesions and shows high clinical performance. However, it is uncertain if the negative samples—as determined by the PLA—will remain so, as "we [the authors] cannot rule out that some PLA(−) lesions may not have been adequately reassessed in the follow-up period and we certainly recommend erring on the side of caution and surgically biopsying a lesion in question if additional risk factors, further clinical suspicion, or patient concern mandate such a step" (Ferris et al., 2018).

The PLA test has also been validated against driver mutations in melanoma, including *BRAF, NRAS,* and *TERT*. Ferris, Moy, et al. (2019) studied the mutation frequency of these genes using samples obtained from the PLA technique (e.g., adhesive patch) in both histopathologically confirmed melanomas (n = 30) and non-melanoma controls (n = 73). "The frequency of these hotspot mutations in samples of early melanoma was 77%, which is higher than the 14% found in nonmelanoma samples ($P < 0.0001$). *TERT* promoter mutations were the most prevalent mutation type in PLA-positive melanomas; 82% of PLA-negative lesions had no mutations, and 97% of histopathologically confirmed melanomas were PLA and/or mutation positive" (Ferris, Moy, et al., 2019). A total of 86% of the non-melanomas within this validation cohort contained no mutations. The authors next analyzed 519 real-world PLA samples for the same mutations. Similar to the previous validation cohort, 88% of this larger cohort also contained no mutations, indicating that the PLA test can rule out lesions with few mutational risk factors for melanoma.

further confirmed the "real-world" negative predictive value (NPV) and positive predictive value (PPV) of the PLA, "by following a cohort of 1,233 PLA-negative pigmented lesions for evidence of malignancy for up to 36 months and by re-testing a separate prospective cohort of 302 PLA-negative lesions up to two years after initial testing." Out of this total PLA-negative cohort, 1,233 lesions had a confirmed follow-up evaluation; of these, ten melanomas were subsequently detected by way of biopsy, resulting in an NPV of 99.2%. Out of 316 PLA-positive cases, 59 were diagnosed as

melanoma by histopathology, resulting in a PPV of 18.7% (Skelsey et al., 2021). The PPV achieved through use of the PLA may represent a five-fold improvement over the current standard according to the test's developers.

In a continuing medical education series, Skudalski et al. (2022) confirm that the PLA is to be used as a risk stratification aid in determining whether to biopsy a skin lesion. The authors recommend that in the case of a positive PLA result, "biopsy i*n toto* should be performed immediately." They further comment that after a negative PLA result, clinicians have chosen to follow up within 12 months to further evaluate the skin lesion; however, a biopsy *in toto* should be considered if a patient remains concerned about a lesion, or if the lesion has evolved (Skudalski et al., 2022).

A recent report by Robinson and Jansen (2020) outlined a proof-of-concept pilot program of remote physician-guided self-sampling (i.e. telehealth administration of the adhesive patch) during the Illinois stay-at-home order of the COVID-19 pandemic. The authors also surveyed skin self-examination (SSE) anxiety as well. Two cohorts were used in this pilot, an experimental group (n=7), and a randomly selected physician-sampled control case group (n=10). The authors report that SSE-induced anxiety has increased during the COVID-19 pandemic. It should be noted that surveys were administered to much larger groups than those administering self-sampling tests. There were 258 surveys about SSE anxiety conducted prior to the COVID-19 pandemic, and 211 surveys during the COVID-19 pandemic. The authors state, "Guided self-sampling led to molecular risk factor analyses in 7/7 (100%) of cases compared to 9/10 (90%) randomly selected physician-sampled control cases... Adhesive patch self-sampling under remote physician guidance is a viable specimen collection option" (Robinson & Jansen, 2020).

DecisionDx-Melanoma (Castle Biosciences)

After a melanoma case has been identified, several management approaches may be considered. However, best melanoma management practices are constantly evolving. A common technique to assess the spread of a tumor, such as melanoma, is a sentinel lymph node biopsy (SLNB). This procedure is used to evaluate whether the cancer has spread beyond the original tumor site and into the lymphatic system. The lymphatic or lymph system transports fluid known as lymph throughout the body; this fluid contains white blood cells which help to fight infections. The lymphatic system also aids in ridding the body of other waste and toxins. The SLNB technique essentially helps the physician to stage the tumor. However, melanoma-related lymph node spread is very complex and is associated with many factors, including age, location, thickness, ulceration, gender, and regression (Ribero et al., 2017).

The DecisionDx-Melanoma test is a gene expression profile (GEP) test that measures the expression of 31 different genes in a tumor tissue sample. This test was designed for cutaneous melanoma patients undergoing or considering SLNB and can help to identify the risk of cancer recurrence or metastasis in stage I-III melanoma (Castle Biosciences, 2024a). DecisionDx-Melanoma may help physicians guide treatment options, including whether to perform a SLNB in eligible patients, and what type of follow up treatment is necessary (Castle Biosciences, 2024a). After GEP analysis, the DecisionDx-Melanoma provides a score of either Class 1 (low risk) or Class 2 (high risk), as well as A or B scores with "A" reflecting a better outcome and "B" reflecting a worse outcome; this allows physicians to receive final scores of Class 1A, 1B, 2A, and 2B (Gastman et al., 2019).

The DecisionDx-Melanoma is performed on tumor tissue biopsies that have been preserved as formalin-fixed, paraffin-embedded (FFPE) samples (Castle Biosciences, 2024a; CastleBiosciences, 2024). Researchers have highlighted that the identification of tissue-based prognostic markers in melanoma has been a challenging obstacle for researchers, as "One major limitation is that most primary melanomas are preserved as formalin-fixed, paraffin-embedded (FFPE) samples rather than fresh-frozen tissues because of the small size of the specimens" (Weiss et al., 2015). High-quality genetic material is more challenging to extract from FFPE samples, and messenger RNA is inconsistent in FFPE samples (Weiss et al., 2015).

The prognostic utility of this test has been measured by Keller et al. (2019); a total of 159 patients participated in this study and were followed up with, on average, 44.9 months after initial testing. Gene expression profiling results helped to categorize patients into two groups: low-risk patients were placed in Class 1, and high-risk patients in Class 2; 117 patients were placed in Class 1 and 42 patients in Class 2 (Keller et al., 2019). Results showed that this gene expression profiling test had great prognostic abilities. "Gender, age, Breslow thickness, ulceration, SNB positivity, and AJCC stage were significantly associated with GEP classification ($P < 0.05$ for all). Recurrence and distant metastasis rates were five percent and one percent for Class 1 patients compared with 55% and 36% for Class 2 patients. Sensitivities of Class 2 and SNB for recurrence were 79% and 34%, respectively" (Keller et al., 2019).

Berman et al. (2019) gathered an expert panel of nine dermatologists/dermatologic surgeons/ dermatopathologists and completed 29 clinical scenarios in which gene expression tests could be used appropriately; several gene expression profiling (GEP) tests were used including a 2-GEP assay, 23-GEP assay and 31-GEP assay. "The 2-GEP assay for melanoma diagnosis received one B-strength and six C-strength recommendations. The 23-GEP diagnostic test received one A-strength, three B-strength, and four C-strength recommendations. The 31-GEP prognostic assay received

one A-strength, seven B-strength, and six C-strength recommendations"; this report shows that the 31-GEP assay received the highest overall recommendations by the expert panel (Berman et al., 2019).

Another study reported that the 31-GEP was validated in almost 1600 patients "as an independent predictor of risk of recurrence, distant metastasis and death in Stage I-III melanoma and can guide SLNB decisions in patient subgroups, as demonstrated in 1421 patients"; further, an appropriate 31-GEP testing population was identified and concluded that it is best used on patients with cutaneous melanoma tumors greater than or equal to 0.3 mm thick (Marks et al., 2019). However, this study reports several conflicts of interest that are important to note as multiple authors are employees at Castle Biosciences, Inc., and one author is a consultant and speaker for the company (Marks et al., 2019).

Greenhaw et al. (2020) completed a meta-analysis of the DecisionDx-Melanoma 31-GEP prognostic test in a total of 1,479 patients. This meta-analysis included participants from three different studies. The patient analysis showed that the five-year recurrence and distant metastasis-free survival rate for Class 1A patients was 91.4% and 94.1% respectively and were 43.6% and 55.5% for Class 2B patients. The 31-GEP was then used to estimate the likelihood of recurrence and distance metastasis. The GEP test exhibited a sensitivity of 76% for each endpoint, showing consistency and accuracy for the identification of at increased risk of metastasis (Greenhaw et al., 2020).

Moreover, Marchetti et al. (2020) completed an assessment of the prognostic accuracy of the 31-GEP in patients that had cancer labeled as AJCC state I or II disease. Patients with localized melanoma were included from external validation studies, and after exclusion criteria, there were seven studies analyzed. Five of these studies used the DecisionDx-Melanoma test. Authors looked at the results of the seven included studies (1450 study participants) and concluded that the performance of both GEP tests (Melagenix and DecisionDx-Melanoma) varied by AJCC stage. "For patients tested with DecisionDx-Melanoma, 623 had stage I disease (six true-positive ([TP], 15 false-negative, 61 false-positive, and 541 true-negative [TN] results) and 212 had stage II disease 959 TP, 13 FN, 78 FP, and 62 TN results). Among patients with recurrence, Decision Dx-Melanoma correctly classified 29% with stage I disease and 82% with stage II disease. Among patients without recurrence, the test correctly classified 90% with stage I disease, and 44% with stage II disease." The overall conclusion by authors was that the prognostic ability was "poor" in terms of accurately identifying recurrence in patients with stage I cancer (Marchetti et al., 2020).

Kangas-Dick et al. (2021) evaluated the DecisionDx-Melanoma assay in a retrospective chart review of patients at a large cancer institute. A total of 361 patients' data were

analyzed, and a follow-up period median of 15 months was established. First, sentinel node biopsy was performed for 75.9% of the patients, of which, 19.4% tested positive for recurrent cancer. Authors considered GEP class 2B status and noted that it was "significantly associated" with recurrence-free survival (RFS) and distant metastasis-free survival (MDFS) in a univariate analysis. The authors concluded that "genetic profiling of cutaneous melanoma can assist in predicting recurrence and help determine the need for close surveillance. However, traditional pathologic factors remain the strongest independent predictors of recurrence risk" (Kangas-Dick et al., 2021).

CP-GEP (Merlin Assay) (SkylineDx)

An eight gene expression profile test called CP [clinicopathologic]-GEP was developed to help identify patients who might safely avoid SLNB through reclassification of their risk of nodal metastasis to less than five percent. In considering certain CP variables, the developers determined that Breslow thickness and patient age were sufficiently predictive of the risk of SLN metastasis. Double-loop cross-validation [DLCV] and least absolute shrinkage and selection operator (LASSO) further identified several genes that distinguished between patients with positive and negative SLNB results. Ultimately, eight genes (*MLANA, GDF15, CXCL8, LOXL4, TGFBR1, ITGB3, PLAT, and SERPINE2*) along with the two CP variables (Breslow thickness and patient age) completed the CP-GEP model.

The CP-GEP model was tested in a cohort of 754 patients diagnosed with cutaneous melanoma, who underwent SLNB within 90 days of their diagnosis. The validity of the model changed based on different T categories of melanoma and demonstrated increasingly higher sensitivity with increasing T category. An inverse relationship was observed between specificity and T category. Theoretically, the model could have reduced the SNLB rate in T1b patients by 80%, though the rate reduction dropped as the T category increased across the patient population. The negative predictive value was 91% or higher across all T categories (Bellomo et al., 2020).

The CP-GEP model was independently validated by Yousaf et al. (2021) in a separate cohort of 208 adult patients with primary cutaneous melanoma and confirmed the trends originally published by (Bellomo et al., 2020). As the T category of melanomas increased, the sensitivity of the model sequentially increased, while the specificity decreased. The highest SLNB reduction rates were observed in lower T category patients (T1), and an NPV of at least 93.3% was observed across all T categories in the study. Importantly, the model was further validated focusing only on patients 65 years of age or older, as the incidence of melanoma is greater in older patient populations. Similar results were obtained compared to the full patient cohort, demonstrating the

applicability of the model across all age ranges included in the study (Yousaf et al., 2021).

11-GEP (Melagenix) (NeraCare)

Another GEP test was developed to better define the probability of patient survival at the time of first diagnosis. Eleven prognostically-relevant genes previously identified through whole-transcriptome analysis (Brunner et al., 2013) of fresh-frozen melanomas were evaluated (*KRT9, DCD, PIP, SCGB1D2, SCGB2A2, COL6A6, GBP4, KLHL41, ECRG2, HES6, and MUC7*), and eight of these were found to be statistically- significantly associated with melanoma-specific survival (all but *ECRG2, HES6, and MUC7*). Based on the coded expression data of the eight significantly associated genes, a binary GEP "score" of either zero or one was generated, representing "low risk" or "high risk", respectively.

To validate the GEP score, inter-assay variability was examined across four different laboratories. Concordance was high between replicates, with 93% of replicate determinations confirming the score. Next, the GEP score was challenged with a cohort of 211 melanomas whose prognostic assessment was erroneous by AJCC staging alone, where the test discriminated successfully between short-term and long-term survivors (Brunner et al., 2018).

An investigation by Amaral et al. (2020) supported the clinical validity of the Melagenix test (referred to in this study as the 11-gene expression profiling score [GEPS]). GEPS was calculated for 245 patients diagnosed with stage II cutaneous melanoma, and the scores were determined to be either "high" (median: 1.06) or "low" (median: –0.21). A significant difference in melanoma-specific survival, distant metastasis free survival, and relapse-free survival was confirmed between high-score and low-score patients. Similarly, Gambichler et al. (2021) used the 11-GEP test to determine whether a high or low score correlated with melanoma-specific survival. The authors documented decreasing probability of melanoma-specific survival with increasing 11-GEP scores. The authors further concluded that the 11-GEP is capable of identifying patients with ten year survival probabilities above 90% (Gambichler et al., 2021).

AMBLor® test (Avero Diagnostics)

Cosgarea et al. (2022) investigated the potential contribution of melanoma paracrine transforming growth factor (TGF)-β signaling in the loss of a protein called AMBRA1 in the skin overlying a primary tumor. The study included 109 all-stage melanoma samples, in which AMBRA1 and (TGF)-β were analyzed. Another cohort had 30 samples analyzed for (TGF)-β and 42 samples analyzed for claudin-1. Results showed "increased tumoral TGF-β2 was significantly associated with loss of peritumoral AMBRA1

(P < 0·05), ulceration (P < 0·001), AMLo high-risk status (P < 0·05) and metastasis (P < 0·01)." Although the American Joint Committee on Cancer (AJCC) staging system is an important tool, the authors noted, it leaves gaps in being unable to identify AJCC early-stage I/II tumors which are at risk of metastasis. The authors described an "urgent need" for credible prognostic information such as biomarkers in these early-stage tumors. "The combined loss of the autophagy regulatory protein autophagy-and-beclin-1 regulator one (AMBRA1) and epidermal differentiation marker loricrin (AMLo Biosciences) in the tumour microenvironment as a prognostic biomarker for early-stage primary melanoma [is] associated with significantly increased risk of metastasis" (Cosgarea et al., 2022).

Labus et al. (2020) investigated the use of the combined immunohistochemical (IHC) expression of AMBRA1 and Loricrin in the top layer of skin as a prognostic biomarker. The study was a retrospective analysis of AMBLor performed in three different cohorts of people with AJCC stage II melanomas. A clinically validated IHC assay and semi quantitative scoring method was used to define risk groups. The results showed a loss of AMBLor in the epidermis over high risk AJCC state IIA or B tumours- that was "correlated with significant reduction in disease free survival (DFS) at 12 years to 55% compared to 89% for patients with AMBLor low risk tumours (P = 0.015; HR 4.83, 95% CI: 2.29-10.14)." In addition, multivariate analysis of 80 of these tumors showed reduced disease-free survival at 12 years to 68% in the AMBLor high-risk cohort compared to 83% in AMBLor low-risk groups. The assay sensitivity was 97% and had a negative predictive value of 90%. The authors concluded that "these data indicate AMBlor as a novel prognostic biomarker for patients with non-ulcerated AJCC stage II melanomas as well as companion/stratifying biomarker for adjuvant immunotherapy" (Labus et al., 2020).

Ellis et al. (2020) sought to determine the utility of AMBRA1 and loricrin (AMLo Biosciences) expression as prognostic biomarkers for AJCC stage one cutaneous melanoma. This retrospective discovery study involved 76 AJCC stage I melanoma samples. Additionally, AMLo expression was correlated against clinical outcomes for up to 12 years in two independent and retrospective validation cohorts of 379 AJCC stage I melanomas. The outcome of decreased AMBRA1 expression was a seven year disease-free survival rate (DFS) of 81.5% vs. 100% when AMBRA1 expression was maintained (P < 0·081). A combined cohort analysis also revealed a DFS rate of 98.3% in the AMLo low-risk cohort vs. 85.4% in the AMLo high-risk group. The authors concluded that "loss of AMLo expression in the epidermis overlying primary AJCC stage I melanomas identifies high-risk tumour subsets independently of Breslow depth," and advocated for these biomarkers to be integrated into risk stratification: "The integration of peritumoral epidermal AMBRA1/loricrin biomarker expression into

melanoma care guidelines will facilitate more accurate, personalized risk stratification for patients with AJCC stage I melanomas" (Ellis et al., 2020).

VI. Guidelines and Recommendations

The National Comprehensive Cancer Network

The NCCN provides common follow-up recommendations for all patients:

- "Clinical and family history can identify patients in whom multigene testing might indicate an increased genetic risk for cutaneous and uveal melanoma, astrocytoma, mesothelioma, and cancers of the breast, pancreas, and kidney. This information can guide recommendations for surveillance and early detection in appropriate patients and their relatives.
  - Consider genetic counseling referral for *p16/CDKN2A* mutation testing in the presence of three or more invasive cutaneous melanomas, or a mix of invasive melanoma, pancreatic cancer, and/or astrocytoma diagnoses in an individual or family.
  - Multigene panel testing that includes *CDKN2A* is recommended for patients with invasive cutaneous melanoma who have a first-degree relative diagnosed with pancreatic cancer . . .
  - Testing for other genes that can harbor melanoma-predisposing mutations [see Genetic Predisposition below] may be warranted" (NCCN, 2024).

The NCCN includes the following as a risk factor for development of single or multiple primary melanomas:

- Genetic predisposition
  - Presence of germline mutations or polymorphisms predisposing to melanoma (eg, *CDKN2a, CDK4, MC1R, BAP1* [especially for uveal melanoma], *TERT, MITF, PTEN*, and potential other genes).
  - Family history of cutaneous melanoma (especially if multiple); pancreatic, renal, and/or breast cancer; astrocytoma; uveal melanoma; and/or mesothelioma" (NCCN, 2024).

Regarding indications for genetic testing using emerging molecular technologies for diagnosis and prognostication, the NCCN recommended the following:

- "The panel does not recommend *BRAF* or NGS [next generation sequencing] testing for resected stage I-II cutaneous melanoma unless it will inform clinical trial participation.
- The *BRAF* mutation testing is recommended for patients with stage III at high risk for recurrence for whom *BRAF*-directed therapy may be an option.

- For initial presentation with stage IV disease or clinical recurrence, obtain tissue to ascertain alterations in *BRAF*, and in the appropriate clinical setting, *KIT* from either biopsy of the metastasis (preferred) or archival material if the patient is being considered for targeted therapy. Broader genomic profiling (e.g., larger NGS panels, *BRAF* non-V600 mutation) is recommended if feasible, especially if the test results might guide future treatment decisions or eligibility for participation in a clinical trial.
- If *BRAF* single-gene testing was the initial test performed, and is negative, clinicians should strongly consider larger NGS panels to identify other potential genetic targets (e.g., *KIT*, *BRAF* non-V600)" (NCCN, 2024).

The NCCN also recognizes *NRAS* as a relevant mutation for melanoma, noting that *NRAS* mutations are present in "approximately 15% of melanomas with chronic and intermittent sun exposure, acral surfaces, and mucosal surfaces." Due to the low probability of overlapping targetable mutations (such as *BRAF* or *KIT*), the NCCN remarks that "the presence of an *NRAS* mutation may identify patients who will not benefit from additional molecular testing" (NCCN, 2024).

NCCN acknowledges that GEP tests may have clinical utility for diagnostic purposes, noting that "melanocytic neoplasms of uncertain biologic potential present a unique challenge to pathologists and treating clinicians. Ancillary tests to differentiate benign from malignant melanocytic neoplasms include immunohistochemistry (IHC) and molecular testing via comparative genomic hybridization (CGH), fluorescence in situ hybridization (FISH), gene expression profiling (GEP), single-nucleotide polymorphism (SNP) array, and next-generation sequencing (NGS). These tests may facilitate a more definitive diagnosis and guide therapy in cases that are diagnostically uncertain or controversial by histopathology. Ancillary tests should be used as adjuncts to clinical and expert dermatopathologic examination and therefore be interpreted within the context of these findings." Similarly, NCCN comments that "noninvasive patch testing" may also be helpful to guide biopsy decisions for melanocytic neoplasms that are clinically/dermoscopically suspicious for melanoma (NCCN, 2024).

For prognostic indications, however, NCCN guidelines are more cautionary:

- "Current GEP platforms do not provide clinically actionable prognostic information when combined or compared with known clinicopathologic (CP) factors (e.g., sex, age, primary tumor location, thickness, ulceration, mitotic rate, lymphovascular invasion, microsatellites, and/or SLNB status). Furthermore, the clinical utility of these tests to inform treatment recommendations and improve health outcomes by prompting an intervention has not been established.

- Various studies of prognostic GEP tests suggest their role as an independent predictor of worse outcome. However, GEP studies to date have not demonstrated added benefit beyond comprehensive CP variables, and it remains unclear whether available GEP tests are reliably predictive of outcome across the risk spectrum of cutaneous melanoma. Validation studies on prospectively collected, independent cohorts (similar to those performed in breast cancer) are necessary to define the clinical utility of molecular prognostic GEP testing as an adjunct to AJCC staging and other known prognostically significant CP variables or as part of the multidisciplinary decision-making process to guide surveillance imaging, SLBN, and adjuvant therapy" (NCCN, 2024).

The American Academy of Dermatology (AAD)

The AAD recently published guidelines for the care and management of primary cutaneous melanoma. Regarding skin biopsies, the AAD states that while many different molecular and imaging techniques have been developed, "skin biopsy remains the first step to establish a definitive diagnosis of CM [cutaneous melanoma]"; further, the guidelines also state that "Newer noninvasive techniques (eg, reflectance confocal microscopy [RCM], as well as electrical impedance spectroscopy, gene expression analysis, optical coherence tomography, and others [see the section Emerging Diagnostic Technologies]) can also be considered as these become more readily available" (Swetter et al., 2019).

The AAD notes that these guidelines highlight several gaps in research including "the clinical utility and prognostic significance of various biomarkers and molecular tests; optimal clinical situations in which to pursue multigene somatic and germline mutational analysis; and the value of ancillary molecular tests in comparison with well-established clinicopathologic predictors of outcome" (Swetter et al., 2019). It is then noted that "Efforts to standardize the histopathologic diagnosis and categorization of melanocytic neoplasms are under way to reduce the significant interobserver variability among pathologists. Ongoing advances in genomic medicine may make many of the aforementioned issues obsolete before the next AAD melanoma CPG is issued" (Swetter et al., 2019).

Regarding patients with a family history of invasive cutaneous melanoma (at least three affected members on one side of the family), "Cancer risk counseling by a qualified genetic counselor is recommended" (Swetter et al., 2019).

Finally, the AAD states "There is insufficient evidence to recommend routine molecular profiling assessment for baseline prognostication. Evidence is lacking that molecular classification should be used to alter patient management outside of current guidelines (eg. NCCN and AAD). The criteria for and the utility of prognostic molecular

testing, including GEP, in aiding clinical decision making (eg. SLNB eligibility, surveillance intensity, and/or therapeutic choice) needs to be evaluated in the context of clinical study or trial" (Swetter et al., 2019).

European Society for Medical Oncology (ESMO)

The ESMO has stated that "testing for actionable mutations is mandatory in patients with resectable or unresectable stage III or stage IV [melanoma] [I, A], and is highly recommended in high-risk resected disease stage IIC but not for stage I or stage IIA-IIB. *BRAF* testing is mandatory [I, A]. If the tumour is *BRAF* wild type (WT) at the V600 locus (Class I *BRAF* mutant) sequencing the loci of the other known minor *BRAF* mutations (Class II and Class III *BRAF* mutant) to confirm WT status and testing for *NRAS* and *c-kit* mutations are recommended [II, C]." Additionally, "patients with metastatic melanoma should have metastasis (preferably) or the primary tumour screened for detection of *BRAF* V600 mutation treatment options for the first- and second-line settings include anti-PD-1 antibodies (pembrolizumab, nivolumab), PD-1 and ipilimumab for all patients, and BRAFi/MEKi combination for patients with *BRAF*-mutated melanoma [II, B]" (ESMO, 2019).

American Society of Clinical Oncology (Cust et al.)

The ASCO expert panel recommends needle biopsy as the preferred diagnostic approach to clinically detected lymphadenopathy in any patient with known or suspected metastatic melanoma in regional nodes. Excisional biopsy, a more invasive approach, is not routinely required for diagnosis or characterization of melanoma. The Expert Panel recommends that *BRAF* mutation testing should be performed at time of diagnosis, but clinicians are not required to wait for the results of that testing if the decision has been made to initiate immunotherapy. If prior testing resulted in a false negative, the panel states that re-testing RAF status upon progression could be considered, but it would not be of value as the panel is not aware of data that supports re-testing. Regarding immunohistochemistry, the panel states "Immunohistochemistry for the *BRAF* V600E mutation has the most rapid turnaround time; however, less common mutations may be found with other methodologies such as *BRAF* gene sequencing." Beyond *BRAF* testing though, the Expert Panel did not make formal recommendations about other genetic testing (e.g., *NRAS* and *KIT*), given insufficient data regarding the efficacy of inhibitors targeting these pathways (Seth et al., 2020).

The ASCO notes that some cancer treatments most commonly used in metastatic melanoma patients (e.g., BRAF inhibitors) may increase the risk of secondary skin cancers; hence, clinicians should be aware of this potential adverse effect when considering such therapeutic agents (Alberg et al., 2020).

European Dermatology Forum (EDF), the European Association of DermatoOncology (EADO), and the European Organization of Research and Treatment of Cancer (EORTC)

A panel of experts from EDF, EADO, and EORTC recommend that *BRAF* mutation testing be required "in patients with distant metastasis or non-resectable regional metastasis to identify those who are eligible to receive treatment with combined BRAF and MEK inhibitors, and in resected high-risk stage III melanoma patients in the adjuvant setting" (Garbe et al., 2020). Mutational analysis should be performed on metastatic tissue, either distant or regional, or on the primary tumor if metastatic tissue is not feasible. Though there may be a discrepancy rate in the *BRAF* status between the primary versus metastatic melanoma lesions, the authors note that there is "a high concordance rate in the *BRAF* status…between primary and metastatic melanoma lesions" (Garbe et al., 2022). Regarding next generation sequencing, the panel claims that it may help in identifying genetic alterations and, when limited to currently actionable genes like *BRAF*, *NRAS*, and *KIT* in a single experiment, may be cost and time effective in the clinical setting (Garbe et al., 2022).

The guideline also commented on *NRAS*, stating that *NRAS* mutations are present in 15-20% of melanoma cases and are almost always mutually exclusive with *BRAF* mutations. The guideline remarked that *NRAS* status may inform clinicians regarding the *BRAF* status, although *NRAS*-based treatments are still under investigation.

Regarding c-*KIT*, the guideline states that acral and mucosal melanomas should initially be tested for *BRAF* and *NRAS* mutations; if both genes were found to be wild-type, the sample should be tested for c-*KIT* (Garbe et al., 2020).

Tumor mutational burden (TMB) is highlighted in the guideline as a predictive tool for response to immune checkpoint inhibitors in melanoma. The panel recognized a study that demonstrated the positive association of a high TMB value with response and overall survival of melanoma patients treated with a combination of ipilimumab and nivolumab (Forschner et al., 2019).

Finally, the guideline comments on GEP tests like DecisionDx-Melanoma™ and their increased use by clinicians. While a growing pool of literature describes the potential application of GEP tests in the management of various cancers, the authors state "additional data are required in melanoma to address if they provide independent prognostic information in addition to known clinicopathologic factors before they can be integrated into clinical decision-making" (Garbe et al., 2022).

Melanoma Prevention Working Group (MPWG)

This Working Group published a guideline regarding prognostic gene expression profile [GEP] testing for cutaneous melanoma. Although the Group is "optimistic" about the future use of prognostic GEP testing to "improve risk stratification and enhance clinical decision-making", it states that "more evidence is needed to support GEP testing to inform recommendations regarding SLNB [sentinel lymph node biopsy], intensity of follow-up or imaging surveillance, and postoperative adjuvant therapy." Overall, the Group remarks that "there are insufficient data to support routine use of currently available prognostic GEP tests to inform management of patients with CM [cutaneous melanoma]" (Grossman et al., 2020).

Skin Cancer Prevention Working Group (SCPWG)

An expert consensus on the appropriate use of prognostic gene expression profiling tests for the management of cutaneous melanoma was published in 2022. The SCPWG reviewed literature for DecisionDx-Melanoma, the 11-GEP (Melagenix) test by NeraCare, and the 8-GEP (CP-GEP; Merlin Assay) by SkylineDx. The eight-person consensus panel of dermatologists unanimously agreed that:

- "Gene expression profile (GEP) tests are validated, reproducible, and consistent across studies;
- Integrating GEPs into AJCC8 and NCCN models can improve prognostic accuracy;
- Prognostic GEP tests can inform clinical decision-making regarding sentinel lymph node biopsies;
- Incorporating GEPs into real-world clinical management has positively impacted patient outcomes"

Additionally, seven out of eight panelists agreed that "the AJCC8 and NCCN prognostic model, which does not account for genomic expression, may not optimize melanoma prognostic assessment" (Farberg et al., 2022).

The National Society for Cutaneous Medicine (NSCM)

An expert panel gathered to develop consensus-based guidelines on the appropriate use criteria for the integration of diagnostic and prognostic GEP assays into the management of cutaneous malignant melanoma. These guidelines include recommendations for the 2-GEP test (DermTech PLA), the 23-GEP test (myPath®), and the 31-GEP test (DecisionDx-Melanoma). Regarding use of the 31-GEP test, a total of 14 recommendations were considered:

A-strength recommendation:

- "Use of the 31-GEP test to aid in the management of patients who are SLNBx negative"

B-strength recommendation:

- "Integration of 31-GEP results into the decision to adjust follow-up frequency
- Integration of 31-GEP results into the decision to order adjunctive imaging studies
- Integration of 31-GEP results into management of patients with T1a tumors with Breslow depth <0.8 mm and other adverse prognostic factors
- Integration of 31-GEP results into management of patients with T1 or T2 tumors who are sentinel lymph node biopsy (SLNBx) eligible
- Integration of 31-GEP results into management of patients with T1b tumors
- Integration of 31-GEP results into management of patients with T2 tumors
- Integration of 31-GEP results into management of patients with a low-risk category based on traditional AJCC factors"

C-strength recommendation:

- "Integration of 31-GEP results into the assessment of prognosis and management options for patients with T1a tumors with a positive deep margin
- Integration of 31-GEP results into the assessment of prognosis and management options for patients with T1b tumors with a positive deep margin
- Integration of 31-GEP results to for risk-stratification of patients in clinical trials
- Use of 31-GEP results as a criterion for eligibility for a chemotherapy regimen
- T4 disease as a contraindication for use of the 31-GEP test
- Melanoma in situ as a contraindication for use of the 31-GEP test"

Seven recommendations for use of the 2-GEP test were considered as follows:

B-strength recommendation:

- "Cases in which patients present with atypical lesions requiring additional assessment beyond inspection in order to aid in the biopsy decision"

C-strength recommendations:

- Cases in which patients refuse surgical biopsy
- Cases in which suspicious lesions present in cosmetically sensitive areas
- Cases in which patients have undergone numerous biopsies in the past and wish to avoid additional biopsy procedures
- Scenarios in which patients have a relative contraindication to surgical biopsy
- Patients with increased risk of infection (e.g., immunosuppressed patients)

- Patients with heightened risk of poor wound healing

Expert consensus was reached on eight recommendations for use of the 23-GEP test:

A-strength recommendation:

- "Differentiation of a nevus from melanoma in an adult patient when the morphologic findings are ambiguous by light microscopic parameters"

B-strength recommendations:

- "Cases with pathology suggestive or suspicious for nevoid melanoma vs. benign melanocytic nevus
- Cases with pathology suggestive or suspicious for atypical Spitz tumor vs. Spitzoid melanoma
- Instances in which pathology is suggestive of or suspicious for severely atypical compound melanocytic proliferation vs melanoma on cosmetically sensitive areas"

C-strength recommendations:

- "Instances of pathology suggestive or suspicious for melanoma arising from within a severely dysplastic nevus
- Cases of pathology suggestive or suspicious for benign vs. malignant blue nevus
- To differentiate suspicious lesions in low-risk populations
- Upon request from the referring dermatologist following an ambiguous pathology report" (Berman et al., 2019)

In a separate editorial published by the NSCM discussing the management of pigmented lesions, the authors conclude that "[u]se of the 2-GEP [DermTech PLA] improves patient care and improves health outcomes by using genomic assessments to minimize avoidable surgical procedures on benign lesions, enriching the population of melanomas within biopsied lesions, and decreasing downstream costs of late-stage melanoma diagnoses. For all of these reasons, creating broad access and coverage to transformative diagnostic technologies such as the 2-GEP is in the best interest of our colleagues, the healthcare system, and most importantly, our patients" (Cockerell et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations

(LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

The FDA-approvals for all the BRAF-targeted therapies include the requirement that *BRAF* mutation testing be performed by an FDA-approved test.

On August 17, 2011, the U.S. Food and Drug Administration (FDA) announced the approval of Zelboraf (vemurafenib) for unresectable or metastatic melanoma with oncogenic *BRAF* mutation (V600E). The Cobas® 4800 *BRAF* V600 Mutation Test was approved as the companion diagnostic for vemurafenib (Bollag et al., 2012).

Dabrafenib was FDA-approved in May 2013 for the treatment of patients with unresectable or metastatic melanoma with *BRAF* V600E mutation, as detected by an FDA-approved test. Dabrafenib is specifically not indicated for the treatment of patients with wild-type *BRAF* melanoma (Tafinlar (dabrafenib), Jan 2014).

Trametinib was FDA-approved in May 2013 for the treatment of patients with unresectable or metastatic melanoma with *BRAF* V600E or V600K mutations, as detected by an FDA-approved test. Trametinib is specifically not indicated for the treatment of patients previously treated with *BRAF* inhibitor therapy (GlaxoSmithKline. Mekinist Aug 2014).

The companion diagnostic test coapproved for both dabrafenib and trametinib is the THxID™ *BRAF* Kit manufactured by bioMérieux. The kit is intended "as an aid in selecting melanoma patients whose tumors carry the *BRAF* V600E mutation for treatment with dabrafenib and as an aid in selecting melanoma patients whose tumors carry the *BRAF* V600E or V600K mutation for treatment with trametinib" (Genentech, Inc. Zelboraf® March 2014).

The FDA approved the use of the Oncomine Dx target test NGS panel for somatic or germline variants, which includes the *BRAF* V600E mutation for consideration with dabrafenib therapy as one of the gene variants (Life Technologies Corporation, approved in June 2017).

The FDA approved the FoundationOne CDx NGS panel in November 2017, which does include both the V600E and V600K mutation for possible dabrafenib or vemurafenib therapy (Foundation Medicine, Inc.).

The FDA approved the use of Therascreen BRAF V600E RGQ PCR Kit in April 2020, a real time PCR test that detects *BRAF V600E* mutations. The Therascreen BRAF V600E RGQ PCR Kit is for use on the Rotor-Gene Q MDx (US) instrument.

New therapies for melanoma continue to receive FDA approval, and the National Cancer Institute summarizes them here: https://www.cancer.gov/about-cancer/treatment/drugs/melanoma (NCI, 2024).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
81272	KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, gastrointestinal stromal tumor [GIST], acute myeloid leukemia, melanoma), gene analysis, targeted sequence analysis (eg, exons 8, 11, 13, 17, 18)
81273	KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, mastocytosis), gene analysis, D816 variant(s)
81311	NRAS (neuroblastoma RAS viral [v-ras] oncogene homolog) (eg, colorectal carcinoma), gene analysis, variants in exon 2 (eg, codons 12 and 13) and exon 3 (eg, codon 61)
81345	TERT (telomerase reverse transcriptase) (eg, thyroid carcinoma, glioblastoma multiforme) gene analysis, targeted sequence analysis (eg, promoter region)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81479	Unlisted molecular pathology procedure
81529	Oncology (cutaneous melanoma), mRNA, gene expression profiling by real-time RT-PCR of 31 genes (28 content and 3 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as recurrence risk, including likelihood of sentinel lymph node metastasis

	Proprietary test: DecisionDx® Melanoma Lab/Manufacturer: Castle Biosciences, Inc
0089U	Oncology (melanoma), gene expression profiling by RTqPCR, PRAME and LINC00518, superficial collection using adhesive patch(es) Proprietary test: Pigmented Lesion Assay (PLA) Lab/Manufacturer: DermTech
0090U	Oncology (cutaneous melanoma), mRNA gene expression profiling by RT-PCR of 23 genes (14 content and 9 housekeeping), utilizing formalin-fixed paraffin-embedded (FFPE) tissue, algorithm reported as a categorical result (i.e., benign, intermediate, malignant) Proprietary test: myPath® Melanoma Lab/Manufacturer: Myriad Genetic Laboratories
0314U	Oncology (cutaneous melanoma), mRNA gene expression profiling by RT-PCR of 35 genes (32 content and 3 housekeeping), utilizing formalin-fixed paraffin-embedded (FFPE) tissue, algorithm reported as a categorical result (i.e., benign, intermediate, malignant) Proprietary test: DecisionDx® DiffDx™- Melanoma Lab/Manufacturer: Castle Biosciences, Inc
0387U	Oncology (melanoma), autophagy and beclin 1 regulator 1 (AMBRA1) and loricrin A by immunohistochemistry, formalin-fixed paraffin-embedded (FFPE) tissue, report for risk of progression Proprietary test: AMBLor® melanoma prognostic test Lab/Manufacturer: Avero® Diagnostics
0474U	Hereditary pan-cancer (eg, hereditary sarcomas, hereditary endocrine tumors, hereditary neuroendocrine tumors, hereditary cutaneous melanoma), genomic sequence analysis panel of 88 genes with 20 duplications/deletions using next-generation sequencing (NGS), Sanger sequencing, blood or saliva, reported as positive or negative for germline variants, each gene Proprietary test: GeneticsNow® Comprehensive Germline Panel Lab/Manufacturer: GoPath Diagnostics, Inc

Molecular Testing for Pulmonary Disease

Policy Number: AHS –M2160 – Molecular Testing for Pulmonary Disease	Prior Policy Name and Number, as applicable: AHS-M2160- Molecular Testing of Pulmonary Specimens AHS-M2151 Molecular Testing of Bronchial Brushings AHS-M2160-Molecular Testing of Bronchial Brushings
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Pulmonary nodules are well-defined lesions found in lung tissue. These nodules are found on cross-sectional imaging and are frequently "incidental" (i.e., found on imaging not originally performed to identify the nodules). Assessment of malignancy risk is critical to managing pulmonary nodules, and a variety of tests have been used to accurately evaluate them. Some of these tests use gene expression profiling (GEP) on cells obtained from bronchoscopies, as these cells are purported to contain molecular markers indicative of malignancy (Islam, 2024; Weinberger, 2024). Other tests employ liquid biopsy and proteomic analysis to assign malignancy risk.

Idiopathic pulmonary fibrosis (IPF) is a disease of unknown etiology that causes irreversible scarring (fibrosis) of the lung. Disease progression and increasing fibrosis often result in breathing difficulties that may subsequently lead to respiratory failure. IPF is a diagnosis of exclusion, and molecular tests are emerging as potentially useful tools that may help differentiate between IPF and other interstitial lung diseases (ILD).

II. Related Policies

Policy Number	Policy Title
AHS-G2054	Liquid Biopsy
AHS-G2124	Serum Tumor Markers for Malignancies

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with a suspicious pulmonary nodule (see Note 1), cancer risk assessment using Nodify XL2 proteomic analysis **MEETS COVERAGE CRITERIA** when **all** of the following conditions are met:
   a) The pulmonary nodule size is 8-30 mm.
   b) The patient is 40 years of age or older.
   c) The pre-test risk of cancer is less than 50% based on the Solitary Pulmonary Nodule Malignancy Risk Score (Mayo Clinic Model).

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For all other indications, molecular testing for pulmonary disease **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: While this is not considered a surgical procedure, it is recommended that individuals who are receiving this test should first undergo an informed consent process to discuss the benefits and risks of pursuing this test versus receiving a biopsy to rule lung cancer.

IV. Table of Terminology

Term	Definition
4MP	Four-marker protein panel
ACCP	American College of Chest Physicians
AEGIS	Airway Epithelial Gene Expression in the Diagnosis of Lung Cancer
ALAT	Latin American Thoracic Society
ALK	*Anaplastic lymphoma kinase*
ATS	American Thoracic Society

AUC	Area under curve
BGC	Bronchial Genomic Classifier
BRAF	*B-Raf proto-oncogene*
CA-125	Cancer antigen 125
CEA	Carcinoembryonic antigen
CLIA	Clinical Laboratory Improvement Amendments
CMS	Centers for Medicare and Medicaid Services
CT	Computed tomography
CYFRA 21–1	Cytokeratin-19 soluble fragment
ddMSP	methylation-specific droplet digital PCR
EGFR	*Epidermal growth factor receptor*
ERS	European Respiratory Society
ESMO	European Society for Medical Oncology
FDA	Food and Drug Administration
GSC	Genomic Sequencing Classifier
HRCT	High resolution computed tomography
ILD	Interstitial lung disease
IPF	Idiopathic pulmonary fibrosis
JRS	Japanese Respiratory Society
LCD	Local coverage determinations
LDCT	Low-dose computed tomography
LCDT1	Lung cancer detector test
LDT	Laboratory developed tests
LG3BP	Galectin-3-binding protein
MRM	Multiple reaction monitoring
mRNA	Messenger ribonucleic acid
NCCN	National Comprehensive Cancer Network
NLST	National Lung Screening Trial
NPV	Negative predictive value
NY-ESO-1	New York esophageal cancer-1 antibody
PANOPTIC	Pulmonary Nodule Plasma Proteomic Classifier
PCR	Polymerase chain reaction
PLCO	Prostate lung colorectal ovarian
PPF	Progressive pulmonary fibrosis
QALY	Quality-adjusted life-years
RNA	Ribonucleic acid

ROS1	*ROS proto-oncogene 1, receptor tyrosine kinase*
SLB	Surgical lung biopsy
TBB	Transbronchial biopsy
TBBx	Transbronchial lung cryobiopsy
TBNA	Transbronchial needle aspirates
TTNA/B	Transthoracic needle aspiration or biopsy
UIP	Usual interstitial pneumonia
USPSTF	United States Preventive Services Task Force

V. Scientific Background

In the United States, over 1.5 million lung nodules are detected annually (Kearney et al., 2017). These pulmonary nodules occur due to a variety of conditions, some malignant (i.e., cancer), and some benign (such as an infection). Since treatment varies widely between malignant and benign nodules, it is crucial to have well-validated and accurate methods to assess risk of malignancy. Traditionally, malignancy has been evaluated using a combination of factors, such as clinical, histological, and radiographic features. Once an initial assessment of malignancy has been performed, further management such as computed tomography (CT) surveillance or biopsy may follow. Low-dose computed tomography (LDCT) is the current standard for lung cancer screening. However, a limitation of the screening is that LDCT shows indeterminate pulmonary nodules which are not clearly defined as benign or cancerous. Assessment of a potentially malignant nodule typically involves invasive biopsy whereas benign nodules may be only placed under surveillance. Clinicians must often weigh the risk of a missed malignant diagnosis against performing an invasive procedure that may ultimately be unnecessary (Weinberger, 2024).

Biomarkers are emerging as clinically useful tools in the management of pulmonary disorders. Validated biomarkers can potentially help improve risk-stratification, facilitate appropriate diagnosis, and may also reduce the number of invasive procedures that patients receive, and the morbidity associated with them.

Proprietary Testing

To assist in the classification and management of indeterminate pulmonary nodules, several proprietary tests have been developed, such as Veracyte's Bronchial Genomic Classifier (Percepta BGC). This test focuses on molecular analysis of the nodules, rather than clinical or radiographic analysis. The Percepta BGC uses cells collected during bronchoscopy to detect genomic changes indicative of a cancerous nodule by analyzing the expression of twenty-three lung cancer associated genes in addition to patient age. Percepta BGC "is designed to reduce the number of invasive biopsies and

other procedures that can follow when suspicious lung nodules are found on computerized tomography (CT) scans" (BU, 2015), and may improve the diagnostic performance of bronchoscopy in detecting lung cancer.

A second-generation risk stratification algorithm called Percepta Genomic Sequencing Classifier (GSC) was described by Choi et al. (2020), and suggested to have broadened utility beyond the BGC for pulmonary nodule management. The GSC considers 1232 gene transcripts coupled with specific clinical factors (gender, age, pack-year, inhaled medication, and specimen collection timing) to calculate the risk of primary lung cancer, and is indicated for use in patients with an inconclusive bronchoscopy result, who are current or former smokers, and have no prior history of cancer (Veracyte, 2024c). A strength of the test is that it may be used in patients across several different pre-test risk categories of cancer, though the clinical validity measurements vary.

Veracyte has developed other tests that are undergoing validation to aid in the management of pulmonary nodules. These include the Percepta Nasal Swab, which is a genomic test that uses a sample from beyond the inferior nasal turbinate to evaluate a lung nodule's risk of malignancy, and the Percepta Genomic Atlas; an NGS-based assay that uses a tissue sample collected through bronchoscopy to identify genomic alterations in 54 genes, to help inform targeted therapy for confirmed malignancies (Babiarz et al., 2021; Veracyte, 2023).

Another condition that is sometimes associated with pulmonary nodules is idiopathic pulmonary fibrosis (IPF). Although the cause of IPF is unknown, by definition, clinical management of this condition may involve assessment of any lung nodules that are present, and further biopsy. Evaluation of nodules associated with IPF includes several of the same procedures discussed above, such as clinical assessment, imaging, and pulmonary function tests. Diagnosis of IPF typically requires "exclusion of other known causes of interstitial lung disease (ILD) and either definite features of usual interstitial pneumonia (UIP) on high resolution computed tomography (HRCT) or certain combinations of HRCT and histopathologic features of UIP." Much debate exists around the role of the lung biopsy in diagnosis of IPF; authorities are conflicted on its importance in IPF assessment (King, 2024).

Veracyte has developed a genomic test named Envisia intended to aid physicians in differentiating between "idiopathic pulmonary fibrosis (IPF) from other interstitial lung diseases (ILD), without the need for invasive, risky, and costly surgery" (Veracyte, 2024b). Envisia uses tissue samples obtained from a transbronchial biopsy and evaluates RNA of 190 genes purported to have common associations with fibrosis and inflammation. The results then report either "positive" or "negative" for usual interstitial

pneumonia, considered to be the signature histopathologic pattern for IPF (Raghu, 2023; Veracyte, 2024a).

There are plasma-based proteomic tests that can be used to screen pulmonary nodules and estimate their risk of malignancy. Nodify XL2 (also known as Xpresys Lung®, Xpresys Lung 2®, and BDX-XL2) is a plasma-based proteomic screening test that measures two proteins (LG3BP and C163A) thought to be important in the development of lung cancer. The test considers their abundance along with five additional factors (age, nodule size, smoking status, edge, and location. It is intended for use after the diagnosis of a pulmonary nodule in patients whose risk category is indeterminate by current risk calculators and may help reclassify a nodule as lower risk (<5%) for malignancy (Biodesix, 2024).

Other proteomic tests include REVEAL Lung Nodule Characterization, which is a proteomic test for classification of pulmonary nodules in current smokers that calculates a risk score between 0 and 100 based on three clinical factors (smoking history, patient age, nodule size) and three blood proteins. REVEAL Lung Nodule Characterization is reported to have a sensitivity of 94% and a negative predictive value of 94% (Arfoosh et al., 2019). Lung Cancer Detector Test (LCDT1) is a proteomic test being developed for stage 1 non-small cell lung cancer detection. LCDT1 is expected to have 95.6% accuracy, 89.1% sensitivity, and 97.7% specificity (Goebel et al., 2020). EarlyCDT-Lung is a serum-based test that measures seven autoantibodies associated with lung cancer to estimate the risk of malignancy in small cell lung cancer and non-small cell lung cancer. EarlyCDT-Lung is reported to have 41% sensitivity and 87% specificity (EarlyCDT, 2024; Ostrin et al., 2020).

Analytical Validity

Hu et al. (2016) conducted studies to evaluate analytical performance of a gene expression profiling test (Percepta) using bronchial brushing specimens. The authors found that "analytical sensitivity studies demonstrated tolerance to variation in RNA input (157 ng to 243 ng). Analytical specificity studies utilizing cancer positive and cancer negative samples mixed with either blood (up to 10 % input mass) or genomic DNA (up to 10 % input mass) demonstrated no assay interference." The authors concluded that "analytical sensitivity, analytical specificity and robustness of the Percepta test were successfully verified, supporting its suitability for clinical use" (Hu et al., 2016).

Pankratz et al. (2017) aimed to develop a genomic classifier to distinguish usual interstitial pneumonia (UIP) from non-UIP in tissue samples obtained by transbronchial biopsy (TBB). The authors stated that this study was performed because UIP was the hallmark symptom of idiopathic pulmonary fibrosis (IPF), and imaging to identify UIP

was frequently inconclusive. A total of 283 samples from TBB were taken from 84 subjects, and "exome-enriched RNA sequencing" was performed on these samples. Then, a machine learning algorithm was created from 53 of these samples. This algorithm was then validated in the remaining 31 samples. The authors found that this algorithm distinguished UIP from non-UIP conditions with an area under curve (AUC) of 0.86 with a single sample. The sensitivity was found to be 63%, and the specificity was found to be 86%. The AUC improved to 0.92 when three to five TBB samples were included. The authors concluded that "genomic analysis and machine learning improves the utility of TBB for the diagnosis of UIP" but acknowledged that "this approach requires validation in an independent cohort of subjects before application in the clinic" (Pankratz et al., 2017).

Roncarati et al. (2020) evaluated the suitability of molecular testing for lung cancer assessment on bronchial washings. A novel droplet digital methylation-specific PCR (ddMSP) test was run on bronchial washings taken during fiber-optic bronchoscopy from 91 lung cancer patients and 31 control patients. The ddMSP assessed the aberrant methylation status of four genes that "display aberrant methylation in more than 50% of cancer samples and no aberrant methylation in normal tissue." The authors confirm that their "methodological approaches, based on either ddMSP or NGS, exhibited an analytical sensitivity of 0.1% or lower, which is adequate to recognize the traces of nucleic acids originating from cancer cells." When used on bronchial washings obtained from patients during fibre-optic bronchoscopy, the ddMSP demonstrated a 97% sensitivity and 74% specificity. Additionally, DNA and RNA analysis of bronchial washings taken from 73 cancer patients and 14 noncancer patients found commonalities among mutations. The authors state that there is predictive value in mutation analysis but "frequent mutation detection in noncancer patients revealed the low specificity of this approach for diagnostic purposes." The authors concluded that molecular testing on bronchial washings "could be performed to support and complete the current clinical diagnostic/predictive strategies" (Roncarati et al., 2020).

Johnson et al. (2021) analyzed the performance of the Percepta Genomic Sequencing Classifier (GSC) in realistic conditions. Bronchial brushing samples were tested from bronchoscopy of patients with "suspicious lung nodules." The authors found no significant difference in Percepta GSC results with varying amounts of RNA input, 10% DNA contamination, and up to 11% blood RNA contamination. Additionally, results were reproducible between runs, within runs, and between laboratories. The authors concluded that "the analytical sensitivity, analytical specificity, and reproducibility of Percepta GSC laboratory results were successfully demonstrated under conditions of expected day to day variation in testing. Percepta GSC test results are analytically robust and suitable for routine clinical use" (Johnson et al., 2021).

Li et al. (2013) first reported on the analytical validity of Nodify XL2. A 371-protein multiplexed multiple reaction monitoring (MRM) assay was developed to identify lung cancer biomarker candidates in blood samples. The authors initially determined that a total of 190 MRM assays were able to detect their target proteins in plasma, reflecting an overall success rate of 51%. This multiplexed MRM assay was then applied to 143 discovery samples and subsequently refined to a 13-protein classifier. The authors established the performance of Nodify XL2 using a set of plasma samples. For this test, negative predictive value (NPV) is the likelihood that a prediction of a benign tumor by the classifier is true. Specificity is defined as "the fraction of the benign nodules that the classifier is able to detect with high confidence." With an assumed cancer prevalence of 15%, the classifier demonstrated a sensitivity of 82%, a specificity of 66%, and an NPV of 95% when run on an initial batch of "discovery" samples. In a follow up analysis on "validation" samples, the classifier demonstrated a sensitivity of 71%, a specificity of 44%, and an NPV of 90% (Li et al., 2013).

Clinical Utility and Validity

Whitney et al. (2015) collected bronchial epithelial cells of 223 cancer-positive and 76 cancer-free subjects undergoing bronchoscopy for suspected lung cancer in a prospective, multi-center study. RNA from these samples was run on gene expression microarrays for training a gene-expression classifier. Out of the 232 genes whose expression levels in the bronchial airway were found to be associated with lung cancer, the authors built a classifier based on the combination of 17 cancer genes, gene expression predictors of smoking status, smoking history, and gender, plus patient age. The authors concluded that their gene classifier "is able to detect lung cancer in current and former smokers who have undergone bronchoscopy for suspicion of lung cancer. Due to the high NPV of the classifier, it could potentially inform clinical decisions regarding the need for further invasive testing in patients whose bronchoscopy is non-diagnostic" (Whitney et al., 2015).

Silvestri et al. (2015) reported on the diagnostic performance of a gene-expression classifier. A total of 639 current or former smokers undergoing bronchoscopy for suspected lung cancer enrolled in two multicenter prospective studies (AEGIS-1 and AEGIS-2) were evaluated. A gene-expression classifier was measured in epithelial cells to assess the probability of lung cancer. In AEGIS-1, the classifier had a sensitivity of 88% and a specificity of 47%. In AEGIS-2, the classifier had a sensitivity of 89% and a specificity of 47%. The combination of the classifier plus bronchoscopy had a sensitivity of 96% in AEGIS-1 and 98% in AEGIS-2. The authors concluded that "the gene-expression classifier improved the diagnostic performance of bronchoscopy for the detection of lung cancer. In intermediate-risk patients with a nondiagnostic

bronchoscopic examination, a negative classifier score provides support for a more conservative diagnostic approach" (Silvestri et al., 2015).

Ferguson et al. (2016) conducted a randomized, prospective decision impact survey study to evaluate pulmonologist recommendations in patients undergoing workup for lung cancer who had an inconclusive bronchoscopy. The authors' goal was to examine if a negative genomic classifier result that down-classifies a patient from intermediate risk to low risk (<10 %) for lung cancer would reduce the rate that physicians recommend more invasive testing among patients with an inconclusive bronchoscopy. The authors found that "invasive procedure recommendations were reduced from 57 % without the classifier result to 18 % with a negative (low risk) classifier result. Invasive procedure recommendations increased from 50 to 65 % with a positive (intermediate risk) classifier result." The authors concluded that their results "support the potential clinical utility of the classifier to improve management of patients undergoing bronchoscopy for suspect lung cancer by reducing additional invasive procedures in the setting of benign disease" (Ferguson et al., 2016).

Lee et al. (2017) published interim results from a large prospective registry of 665 patients undergoing diagnostic bronchoscopy. In a subset of 209 patients with an intermediate pretest risk of malignancy, Advanced bronchoscopic techniques were used in in 68% of cases. The BGC test results reclassified 74 patients as low risk. At 10 months post follow up the patients reclassified as low risk had a 40% relative reduction in the use of invasive procedures. The authors concluded that the BGC improves the sensitivity of diagnostic bronchoscopy for patients undergoing evaluation for lung cancer and can reduce the number of unnecessary invasive procedures (Lee et al., 2017).

The Percepta GSC was validated in a study by Mazzone et al. (2021), in patients with low and intermediate pre-test risk of cancer who were down-classified with Percepta GSC, the test demonstrated a > 99% and 91% NPV in these groups, respectively. The GSC may also up-classify cancer risk; patients with intermediate and high pre-test risk of cancer were up-classified with a 65.4% and 91.5% PPV, respectively. Sensitivity of the classifier was reported as 92.3% among patients with low and intermediate pre-test risk of cancer; however, this value increased to 95.5% when the classifier result was combined with data from bronchoscopy. The authors further concluded that if Percepta GSC were employed in the management of lung nodules, "50% of patients with benign lesions and 29% of patients with malignant lesions undergoing additional invasive procedures could have avoided these procedures" (Mazzone et al., 2021).

The prospective PANOPTIC Trial investigated the accuracy of Nodify XL2 and included a subgroup of 178 patients with a physician-assessed probability for malignancy (pCA)

≤50%. From this study, Silvestri et al. (2018) concluded that Nodify XL2 demonstrated a sensitivity of 97%, specificity of 44%, and an NPV of 98%, in its ability to distinguish benign and malignant nodules. The authors state that 40% fewer procedures would have been performed on benign nodules if the test were used to direct care. Notably however, use of the test would have misclassified three percent of malignant nodules, underscoring the importance of ensuring that all patients reclassified as low-risk using Nodify XL2 receive appropriate follow up care, to continually rule out malignancy (Silvestri et al., 2018).

Tanner et al. (2021) published a follow up to the PANOPTIC trial, observing patients for up to two years. In a cohort of 132 patients with nodules categorized as benign at year one, all remained benign at year two. The authors conclude that the "performance characteristics [of the XL2 classifier] were maintained at year 2." Nodify XL2 was also found to perform equally well in patients with solitary versus multiple nodules (Tanner et al., 2021). This is important because it is common for patients to present with more than one nodule. The authors further conclude that Nodify XL2 was shown to outperform the physician pCA, validated Mayo, Veterans Administration, and Brock models, based on area under curve (AUC) analysis (Tanner et al., 2021).

Feller-Kopman et al. (2017) assessed the cost effectiveness of bronchoscopy plus a genomic classifier versus bronchoscopy alone in the diagnostic work-up of patients at intermediate risk for lung cancer. They found that "use of the genomic classifier reduced invasive procedures by 28% at one month and 18% at two years, respectively. Total costs and QALY gain were similar with classifier use ($27,221 versus $27,183 and 1.512 versus 1.509, respectively), resulting in an incremental cost-effectiveness ratio of $15,052 per QALY." The authors concluded that use of a genomic classifier was associated with meaningful cost reduction in invasive procedures (Feller-Kopman et al., 2017).

Raghu et al. (2019) evaluated the prospective findings for the clinical validity and utility of a machine-learning based molecular test (Envisia). Findings from 90 patients were used to train the classifier, and then the authors attempted to validate the classifier in a set of 49 patients. The authors found that the classifier identified "usual interstitial pneumonia in transbronchial lung biopsy samples" in these 49 patients at 70% sensitivity and 88% specificity. A total of 42 patients were noted to show "possible or inconsistent usual interstitial pneumonia on HRCT", and the classifier identified "underlying biopsy-proven usual interstitial pneumonia" at 81% positive predictive value. Clinical diagnoses based on histopathology data agreed with diagnoses based on classifier results at an 86% rate. The authors also found that diagnostic confidence was improved with addition of classifier results in 18 cases of idiopathic pulmonary fibrosis and all 48 patients with "non-diagnostic pathology or non-classifiable fibrosis

histopathology" (63% vs 42%). The authors concluded that "The molecular test provided an objective method to aid clinicians and multidisciplinary teams in ascertaining a diagnosis of IPF, particularly for patients without a clear radiological diagnosis in samples that can be obtained by a less invasive method", noting that further studies were planned (Raghu et al., 2019).

D'Andrea et al. (2020) evaluated the cost-effectiveness of introducing a bronchial gene-expression classifier (BGC) to "improve the performance of bronchoscopy and the overall diagnostic process for early detection of lung cancer." The authors evaluated a cohort of former and current smokers with indeterminate pulmonary nodules and compared two different strategies: "(i) location-based strategy—integrated the BGC to the bronchoscopy indication; (ii) simplified strategy—extended use of bronchoscopy plus BGC also on small and peripheral lesions." The authors modeled the following outcomes: "rate of invasive procedures, quality adjusted-life-years (QALYs), costs and incremental cost-effectiveness ratios." Both strategies were compared to the standard practice (defined as "bronchoscopy, transthoracic needle aspiration or biopsy (TTNA/B) or surgery, consistent with the current recommendations). " The location-based strategy reduced absolute rate of invasive procedures by 3.3% without increasing costs and resulted in savings when the classifier price was less than $3000. The simplified strategy reduced the absolute rate of invasive procedures by 10% and created an incremental cost-effectiveness ratio of $10109 per QALY. The authors concluded that both strategies reduced "unnecessary invasive procedures at high risk of adverse events" and that "the simplified use of BGC for central and peripheral lesions resulted in larger QALYs gains at acceptable cost." Finally, the authors noted that the location-based strategy is cost-saving if the classifier price declines (D'Andrea et al., 2020).

Lee et al. (2021) assessed the impact that Percepta results has on clinical management decisions. The authors conducted a prospective study on 283 patients with low- and intermediate-risk lung nodules across 35 centers in the US. In 35% of cases with a negative Percepta result, the risk of malignancy was down-classified. A total of 79% of the down-classified cases changed their management plan to avoid an invasive procedure. Percepta down-classification did not significantly delay the time to diagnosis for patients with confirmed lung cancer. The authors concluded that "down-classification of nodule malignancy risk with the Percepta test decreased additional invasive procedures without a delay in time to diagnosis among those with lung cancer" (Lee et al., 2021).

Babiarz et al. (2021) tested the use of Percepta Genomic Atlas for identifying key molecular markers in surgical lung biopsy (SLB) specimens, transbronchial needle aspirates (TBNA), and bronchial brush specimens from an initial bronchoscopy at the

time of diagnosis. DNA and RNA were extracted from Stage I, Stage II, and Stage III lung cancer SLB tissue. "Genomic alterations were observed in 65% of Stage I, 64% of Stage II and 73% of Stage III samples." TBNA and bronchial brush specimens were taken from 25 patients; multiple molecular alterations were detected in all patients. The authors concluded that "Percepta Genomic Atlas detects clinically actionable alterations in both SLB of early stage lung cancer tumors and in specimens collected at the time of diagnostic bronchoscopy or needle aspiration prior to surgery" (Babiarz et al., 2021).

Sethi et al. (2022) performed a study on the impact of the Percepta Genomic Sequencing Classifier (GSC) on decision-making in patients with high-risk lung nodules. In the study, 101 survey participants evaluated 37 cases, resulting in 1341 assessments across three cohorts. The results demonstrated that using Percepta GSC, which up-classes patients from a high (>60%) to a very high risk of malignancy, significantly increased the likelihood of recommending a surgical resection. Specifically, in the independent cohort with a GSC result, the recommendation for surgical resection was 45%, compared to 17% in the cohort without a GSC result ($p<0.001$) after reviewing the GSC result. The authors concluded that the classifier not only heightened the rate of referral for potentially curative therapies but also boosted pulmonologists' confidence in their decision-making following nondiagnostic bronchoscopy (Sethi et al., 2022).

There is a growing body of research investigating the utility of serum biomarker testing for the identification of lung cancer. However, the reported sensitivity of these panels is low and more work will likely be needed before they may be applied clinically. Doseeva et al. (2015) found that a panel of three tumor antigens (CEA, CA-125, and CYFRA 21–1) and one autoantibody marker (NY-ESO-1) discriminated between non-small cell lung cancer and controls with a sensitivity of 74%. P. J. Mazzone et al. (2018) further validated this panel, reporting a sensitivity and specificity of 49% and 96%, respectively. More recently, Fahrmann et al. (2022) developed a blood-based biomarker panel for personalized lung cancer risk assessment called 4MP (four-marker protein panel), that consisted of the precursor form of surfactant protein B, CA-125, CEA, and cytokeratin-19 fragment. In combination with a lung cancer risk prediction model ($PLCO_{m2012}$), the 4MP demonstrated a sensitivity of 88.4% and specificity of 56.2%, at a "≥ 1.0% 6-year risk threshold corresponding to the USPSTF 2021 criteria."

VI. Guidelines and Recommendations

American College of Chest Physicians (ACCP)

In 2013, the ACCP published evidence-based clinical practice guidelines for diagnosis and management of lung cancer (Detterbeck et al., 2013). The guidelines did not mention gene expression profiling as a potential diagnostic or screening tool.

In 2018, the ACCP published guidelines for screening of lung cancer. The guidelines state that "despite their potential promise, evidence that using such biomarkers would improve the efficiency of lung cancer screening is lacking. No applicable studies comparing molecular biomarkers vs NLST or USPSTF criteria were found that could be included in the systematic review for this guideline" (Peter J. Mazzone et al., 2018). The ACCP updated the guidelines for screening of lung cancer in 2021 but did not change the recommendations on the use of biomarkers in lung cancer screening (Mazzone et al., 2021). More generally however, the ACCP does acknowledge the importance that biomarkers will likely play in the evaluation of individuals with pulmonary nodules. They state that "research priorities include developing and validating risk assessment models to estimate the probability of cancer among individuals with small nodules or subsolid nodules, performing studies that compare the benefits and harms of alternative management strategies among individuals stratified by cancer risk, determining the safety of CT scan surveillance by examining outcomes among individuals who choose this strategy, and developing and validating novel noninvasive biomarkers to facilitate diagnosis and determine prognosis" (Gould et al., 2013).

National Comprehensive Cancer Network

The NCCN guidelines for non-small cell lung cancer address the utility of molecular profiling after a cancer diagnosis has been made, "with the goal of identifying rare driver mutations for which effective.
drugs may already be available, or to appropriately counsel patients regarding the availability of clinical trials" (NCCN, 2024b).

The NCCN Guidelines for small cell lung cancer state that "comprehensive molecular profiling can be considered in rare cases –particularly for patients with extensive-stage/relapses SCLC who do not smoke tobacco, lightly smoke, have remote smoking history, or have diagnostic or therapeutic dilemma, or at a time of relapse –if not previously done, because this may change management" (NCCN, 2024c).

The NCCN Guidelines for lung cancer screening did not mention gene expression as a potential diagnostic or screening tool but note that any nodules with the highest risk of lung cancer "should be sufficient to enable histology and molecular testing" (NCCN, 2024a).

European Society for Medical Oncology (ESMO)

The ESMO does not mention gene expression profiling in its guideline on the diagnosis, treatment and follow-up for early and locally advanced non-small cell lung cancer (Postmus et al., 2017). In 2021, they updated a few of the recommendations but did not mention GEP profiling (ESMO, 2021).

The ESMO Guidelines for metastatic non-small cell lung cancer recommend therapy-predictive biomarker testing after morphological diagnosis. Biomarker testing includes testing for *EGFR* mutation, *ALK* rearrangement, *ROS1* rearrangement, *BRAF* mutation, and PD-L1 expression. The guideline states that "this practice will be driven by the availability of treatments and will vary widely between different geopolitical health systems" (Planchard et al., 2018). The guidelines also comment on the utility of blood monitoring for oncogenic driver mutations, noting that the ability to detect such alterations or other factors associated with disease resistance to treatment through blood sampling, improves disease monitoring (Planchard et al., 2018).

An updated ESMO guideline for oncogene-addicted metastatic non-small lung cancer was published in 2023 (Hendriks et al., 2023). In a discussion, they note how essential biomarker testing is to identifying subgroups of NSCLC with oncogenic drivers that can be therapeutically targeted. These drivers are primarily found in lung adenocarcinomas (LUADs). Testing for the specific molecular alteration is vital to being able to predict and utilize the matching therapy (Hendriks et al., 2023).

American Thoracic Society, European Respiratory Society, Japanese Respiratory Society, and Latin American Thoracic Society (ATS/ERS/JRS/ALAT)

This set of joint guidelines remarks that "machine learning using molecular signatures is being developed to make a molecular diagnosis of UIP [usual interstitial pneumonia] in TBBx [transbronchial lung cryobiopsy] specimens but is not yet available in routine clinical practice. The guideline panel acknowledges that recent studies about the utility of molecular diagnostic tools that involve machine learning using TBBx samples are promising." The guidelines also note that further validation studies are pending (Raghu et al., 2018).

A 2022 updated guideline was published that also includes recommendations for progressive pulmonary fibrosis (PPF). In a patient with interstitial lung disease of known or unknown etiology other than IPF, PPF was defined as a patient exhibiting two out of three of the following criteria occurring within the past year with no alternative explanation: worsening primary symptoms, physiological evidence of disease

progression, and radiological evidence of disease progression. The committee made "no recommendation for or against the addition of [Envisia] genomic classifier testing for the purpose of diagnosing UIP in patients with ILD of undetermined type who are undergoing transbronchial forceps biopsy," concluding that "research is also needed to improve the technique's sensitivity, assess the downstream consequences of false-negative results (i.e., incorrectly categorizing a patient with the UIP pattern as not having the UIP pattern), and determine the ability of genomic classifier testing to differentiate UIP related to IPF and UIP related to other types of ILD" (Raghu et al., 2022).

European Paediatric Soft Tissue Sarcoma Study Group

This study group published a report on the clinical significance of indeterminate pulmonary nodules in rhabdomyosarcoma. The group included 316 patients with non-metastatic rhabdomyosarcoma, 67 of which had indeterminate pulmonary nodules, 249 of which didn't have nodules. The authors found event-free survival and overall survival rates to be 77% and 82% respectively for patients with indeterminate nodules, and 73.2% and 80.8% respectively for patients without nodules. The authors concluded that their study "demonstrated that indeterminate pulmonary nodules at diagnosis do not affect outcome in patients with otherwise localized RMS. There is no need to biopsy or upstage patients with RMS who have indeterminate pulmonary nodules at diagnosis" (Vaarwerk et al., 2019).

Another study group convened in 2023 to assess the clinical impact of indeterminate pulmonary nodules in those with diagnosed adult-type non-rhabdomyosarcoma soft tissue sarcoma (NRSTS). The authors examined 206 children/adolescent patients; 109 of these patients (52.9%) were without any nodules, 78 (38%) had at least one indeterminate nodule, and 19 (9.2%) had nodules that met the definition of metastases (considered to misclassified and then excluded from analyses). In the results, "Five-year event-free survival (EFS) was 78.5% (95% CI, 69.4%–85.1%) for patients without nodules and 69.6% (95% CI, 57.9%–78.7%) for patients with indeterminate nodules (p = .135); 5-year overall survival was 87.4% (95% CI, 79.3%–92.5%) and 79.0% (95% CI, 67.5%–86.8%), respectively (p = .086)." The authors concluded that survival did not differ in nonmetastatic patients with indeterminate pulmonary nodules compared to nonmetastatic patients without pulmonary nodules (Giraudo et al., 2024).

Fleischner Society White Paper, Diagnostic Criteria for Idiopathic Pulmonary Fibrosis

This guideline focused on diagnostic criteria for IPF, including discussion on traditional features such as clinical, histopathological, and imaging factors. Under the "Areas of uncertainty" subheading, the Society comments that "we anticipate that molecular diagnosis with machine learning will play an increasing role in the diagnosis of IPF, particularly when integrated with clinical and imaging features" and emphasizes the importance of identifying molecular predictors of IPF (Lynch et al., 2018).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
81554	Pulmonary disease (idiopathic pulmonary fibrosis [IPF]), mRNA, gene expression analysis of 190 genes, utilizing transbronchial biopsies, diagnostic algorithm reported as categorical result (eg, positive or negative for high probability of usual interstitial pneumonia [UIP]) Proprietary test: Envisia® Genomic Classifier Lab/Manufacturer: Veracyte, Inc
0080U	Oncology (lung), mass spectrometric analysis of galectin-3-binding protein and scavenger receptor cysteine-rich type 1 protein M130, with five clinical risk factors (age, smoking status, nodule diameter, nodule-spiculation status and nodule location), utilizing plasma, algorithm reported as a categorical probability of malignancy

CPT	Code Description
	Proprietary test: BDX-XL2 Lab/Manufacturer: Biodesix®, Inc
0360U	Oncology (lung), enzyme-linked immunosorbent assay (ELISA) of 7 autoantibodies (p53, NY-ESO-1, CAGE, GBU4-5, SOX2, MAGE A4, and HuD), plasma, algorithm reported as a categorical result for risk of malignancy Proprietary test: Nodify CDT® Lab/Manufacturer: Biodesix, Inc
0406U	Oncology (lung), flow cytometry, sputum, 5 markers (meso-tetra [4-carboxyphenyl] porphyrin [TCPP], CD206, CD66b, CD3, CD19), algorithm reported as likelihood of lung cancer Proprietary test: CyPath® Lung Lab/Manufacturer: Precision Pathology Services

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Mutation Analysis in Myeloproliferative Neoplasms

Policy Number: AHS – M2101 – Mutation Analysis in Myeloproliferative Neoplasms	Prior Policy Name and Number, as applicable: • AHS-M2101-20180316-*JAK2*, CALR or MPL Mutation Analysis in Myeloproliferative Neoplasms
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Myeloproliferative neoplasms (MPN) are a heterogeneous group of clonal disorders characterized by overproduction of one or more differentiated myeloid lineages (Grinfeld et al., 2017). These include polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF). The majority of MPN result from somatic mutations in the three driver genes, *JAK2*, *CALR*, and *MPL*, which represent major diagnostic criteria in combination with hematologic and morphological abnormalities (Rumi & Cazzola, 2017).

Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS-M2182	Genomic Testing for Hematopoietic Neoplasms

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For the diagnosis of individuals presenting with clinical, laboratory, or pathological findings suggesting classic forms of myeloproliferative neoplasms (MPN)(e.g., polycythemia vera [PV], essential thrombocythemia [ET], or primary myelofibrosis [PMF]), *JAK2, CALR* or *MPL* mutation testing **MEETS COVERAGE CRITERIA** in any of the following situations:

   a) For individuals suspected to have PV who meet at least **one** of the following testing criteria:

      i) Hemoglobin greater than 16.5 g/dL in men or greater than 16.0 g/dL in women; **or** hematocrit greater than 49% in men or greater than 48% in women; **or** increased red cell mass (more than 25% above mean normal predicted value), **and** no other known cause of erythrocytosis, when measured on two separate occasions.

      ii) A bone marrow (BM) biopsy showing hypercellularity for age with trilineage hyperplasia including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes (differences in size).

   b) For individuals suspected to have ET who meet at least **one** of the following testing criteria:

      i) Platelet count greater than or equal to 450 × 10^9/L that has persisted for more than three months.

      ii) A BM biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant increase or left shift in neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers.

   c) For individuals suspected to have PMF who meet at least **one** of the following testing criteria:

      i) The individual has demonstrated leukocytosis of greater than or equal to 11 x 10^9/L on two separate occasions in the absence of other conditions that can cause leukocytosis.

      ii) The individual has an enlarged spleen.

      iii) A BM biopsy shows megakaryocytic proliferation and atypia, without reticulin fibrosis >grade 1, accompanied by increased age-adjusted BM cellularity, granulocytic proliferation, and often decreased erythropoiesis.

      iv) A BM biopsy shows presence of megakaryocytic proliferation and atypia, accompanied by either reticulin and/or collagen fibrosis grades 2 or 3.

2) To exclude a diagnosis of chronic myeloid leukemia (CML) for individuals with a suspected MPN, fluorescence in situ hybridization (FISH) or reverse transcriptase polymerase chain reaction (RT-PCR) testing on a peripheral blood sample to detect *BCR::ABL1* transcripts **MEETS COVERAGE CRITERIA**.

3) For individuals with a clinical suspicion of prePMF or overt PMF who have already tested negative for mutations in *JAK2, CALR,* or *MPL* and who do not meet the WHO criteria for BCR-AB1+ CML, PV, ET, myelodysplastic syndromes, or other myeloid neoplasms, screening for mutations in *ASXL1, CBL, DNMT3A, EZH2, IDH1/IDH2, RAS, SRSF2, SFS3B1*, *TET2, TP53,* and *U2AF1* (see Note 1) **MEETS COVERAGE CRITERIA**.

4) For individuals diagnosed with Budd-Chiari Syndrome, *JAK2, CALR,* or *MPL* mutation testing **MEETS COVERAGE CRITERIA**.

5) For individuals with normal blood counts and unexplained splanchnic vein thrombosis, screening for *JAK2* V617F **MEETS COVERAGE CRITERIA**.

6) For individuals suspected to have chronic neutrophilic leukemia, testing for *CSF3R* mutations **MEETS COVERAGE CRITERIA**.

7) For individuals with a clinical suspicion of mastocytosis, screening for *KIT* D816V **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

8) For all other situations not described above, *JAK2* tyrosine kinase, *CALR*, and *MPL* mutation testing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: For 5 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ABL	*Abelson murine leukemia viral oncogene*
aCML	Atypical chronic myeloid leukemia
ARMS	Amplification refractory mutation system

ASXL1	*additional sex combs like 1, transcriptional regulator*
BCR	Breakpoint cluster region
BPGM	*Bisphosphoglycerate mutase*
BSH	British Society for Haematology
CALR	*Calreticulin*
CBL	*Casitas B-lineage lymphoma* proto-oncogene
CELNOS	Chronic eosinophilic leukemia, not otherwise specified
CML	Chronic myeloid leukemia
CMML	Chronic myelomonocytic leukemia
CNL	Chronic neutrophilic leukemia
CSF3R	*Colony stimulating factor 3 receptor*
DNM3TA	*DNA methyltransferase 3 alpha*
EASL	European Association for the Study of the Liver
ELN	European Leukemia Net
ESMO	European Society of Medical Oncology
ET	Essential thrombocythemia
EZH2	*Enhancer of zeste 2 polycomb repressive complex 2 subunit*
FLT3	*Fms related receptor tyrosine kinase 3*
FLT3-ITD	*FLT3*- internal duplications
HBA1	*Hemoglobin subunit alpha 1*
HBA2	*Hemoglobin subunit alpha 2*
HBB	*Hemoglobin subunit beta*
HSC	Hematopoietic stem cell
HTLV	Human T-lymphotropic virus type 1
IDH1	*Isocitrate dehydrogenase (NADP(+)) 1*
IDH2	*Isocitrate dehydrogenase (NADP(+)) 2*
IR	Ionizing radiation
JAK2	*Janus Kinase 2*
JMML	Juvenile myelomonocytic leukemia
LNK	*Lymphocyte adapter protein*
MONU	MPN unclassifiable
MPL	*MPL proto-oncogene, thrombopoietin receptor*
MPN	Myeloproliferative neoplasms
NCCN	National Comprehensive Cancer Network
PCR	Polymerase chain reaction
PMF	Primary myelofibrosis

PV	Polycythemia vera
RAS	*Rat sarcoma virus* gene
SETBP	*SET binding protein*
SF3B1	*Splicing factor 3b subunit 1*
SH2B3	*SH2B adaptor protein 3*
SRSF2	*Serine and arginine rich splicing factor 2*
STAT	Signal transducer and activator of transcription
TET2	*Tet methylcytosine dioxygenase 2*
TP53	*Tumor protein p53*
U2AF1	*U2 small nuclear RNA auxiliary factor 1*
WHO	World Health Organization

V. Scientific Background

Myeloproliferative neoplasms, including polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF), arise from somatic mutation in hematopoietic stem cell (HSC) that clonally expand resulting in single or multilineage hyperplasia (Vainchenker & Kralovics, 2017). They are relatively rare, affecting 0.84 (PV), 1.03 (ET), and 0.47 (PMF) per 100,000 people worldwide; however, these may not be reflective of its true incidence due to the high heterogeneity of MPN (Titmarsh et al., 2014).

Myeloproliferative neoplasms share features of bone marrow hypercellularity, increased incidence of thrombosis or hemorrhage, and an increased rate of progression to acute myeloid leukemia. Abnormalities in cytokine signaling pathways are common and usually lead to increased JAK-STAT signaling (Grinfeld et al., 2017). PV is characterized by erythrocytosis with suppressed endogenous erythropoietin production, bone marrow panmyelosis, and *JAK2* mutation leading to constitutive activation. ET is defined by thrombocytosis; bone marrow megakaryocytic proliferation; and presence of *JAK2*, *CALR*, or *MPL* mutation. PMF is characterized by bone marrow megakaryocytic proliferation; reticulin and/or collagen fibrosis; and presence of *JAK2*, *CALR*, or *MPL* mutation (Rumi & Cazzola, 2017). Mutations in other genes involved in signal transduction (*CBL, LNK/SH2B3*), chromatin modification (*TET2*, *EZH2*, *IDH1/2, ASXL1*, *DNM3TA*), RNA splicing (*SF3B1*, *SRSF2*, *U2AF1*), and tumor suppressor function (*TP53*) have also been reported and are considered "high-risk" (NCCN, 2019, 2023)

The gene *JAK2*, which stands for "Janus Kinase 2," is a gene whose mutation is responsible for a significant amount of MPNs. It is a mutation that causes hypersensitivity of hematopoietic progenitor cells to other cytokines, and this mutation typically appears on red blood cells or bone marrow cells. This mutation is often found

on exon 12 or 14, and the exon 14 mutation results in a cytokine-independent activation of several regulatory pathways. *JAK2* mutations contribute to at least 95% of PV cases, about 50-65% of ET cases, and 60-65% of PMF cases (Tefferi, 2022a, 2023a, 2023b).

The gene *MPL*, which encodes a thrombopoietin receptor, also contributes to MPNs. *MPL* mutations result in a similar phenotype to *JAK2* mutations; both result in cytokine-independent growth of their targets. However, *MPL* mutations are not nearly as common as *JAK2* and *CALR* mutations, casting doubt on the clinical utility for testing. *MPL* mutations comprise up to 4% of ET cases and 5% of PMF cases (Tefferi, 2022a, 2023a, 2023b).

The gene *CALR* encodes calreticulin (or calregulin), which is a Ca^{2+} binding protein. The mutation typically involves the creation of the incorrect Ca^{2+} binding region, thereby not allowing the protein to perform its regular duties such as maintaining calcium homeostasis. This results in a similar phenotype to the *JAK2* mutation, which is the cytokine-independent activation of regulatory pathways. *CALR* mutations contribute to approximately 15-25% of ET cases and 20-25% of PMF cases, and about 70% of ET or PMF patients without a *JAK2* or *MPL* mutation have this mutation (Tefferi, 2022a, 2023a, 2023b).

The significance of *JAK2*, *MPL*, *CALR* and other mutations in the genesis of the MPNs as well as their roles in determining phenotype are unclear (Tefferi, 2022b). However, integrated genomic analyses suggest that regardless of diagnosis or *JAK2* mutational status, MPNs are characterized by upregulation of JAK-STAT target genes, demonstrating the central importance of this pathway in the pathogenesis (Rampal et al., 2014). This may lead to development of novel *JAK2* therapeutics (Silvennoinen & Hubbard, 2015). Thus, mutation analysis at the time of diagnosis has value for determining prognosis as well as individual risk assessment and guide treatment-making decisions (Hussein et al., 2013; Tefferi, 2022b).

Neutrophilia, an increase in peripheral blood neutrophils at least two standard deviations above the mean, can be associated with any the MPNs. In chronic neutrophilic leukemia (CNL), *CSF3R* mutations have been discovered in most patients with CNL (Coates, 2022; Tefferi et al., 2014). A study released in 2013 reported 16 of 27 patients with CNL or atypical chronic myeloid leukemia (aCML) had activating mutations in *CSF3R* (Maxson et al., 2013). *SETBP1* has also been used as a part of comprehensive mutation profiling in distinguishing aCML and chronic myelomonocytic leukemia (CMML). A 2019 NGS study reports significant differences in the profiles of patients with aCML or CMML when comparing *TET2*, *SETBP1*, and *CSF3R*. The researchers conclude, "differential mRNA expression could be detected between both

cohorts in a subset of genes (*FLT3*, *CSF3R*, and *SETBP1* showed the strongest correlation). However, due to high variances in the mRNA expression, the potential utility for the clinic is limited" (Faisal et al., 2019).

Proprietary Testing

In 2017 the FDA approved ipsogen® *JAK2* RGQ PCR Kit (FDA, 2017b) to detect Janus Tyrosine Kinase 2 (*JAK2*) gene mutation G1849T (V617F) with an allele-specific, quantitative, polymerase chain reaction (PCR) using an amplification refractory mutation system (ARMS). The device marketing authorization was based on data from a clinical study of 473 suspected patients with MPNs, 276 with suspected PV, 98 with suspected ET, and 99 with suspected PMF. The study compared results from the ipsogen *JAK2* RGQ PCR Kit to results obtained with independently validated bi-directional sequencing. The study found that the ipsogen *JAK2* RGQ PCR Kit test was in 96.8% agreement with the reference method, 100% in positive agreement, and 95.1% in negative agreement, with 458 samples in agreement out of 473. The concordance with each condition was also high; agreement of 90.8% within the ET samples (89/98), 94.9% agreement within the PMF samples (94/99), and 99.6% within the PV samples (275/276). All three conditions had positive agreements of 100%. The authors went on to note that the 15 samples with disagreeing results had mutation levels under the detection capability of bi-directional sequencing. To validate these 15 samples, an independently validated NGS panel was used to compare results with the kit, and all 15 samples were found to test positive, thereby agreeing with the kit. The authors concluded that the kit was accurate for any mutation levels at or above 1% (FDA, 2017a).

Other proprietary tests are available for mutational analysis in MPN. IntelliGEN® Myeloid is a NGS assay that analyzes fifty genes for somatic mutations that could be useful in providing diagnostic or prognostic information for patients with MDS, AML, or MPN (labcorp, 2023). The LeukoVantage® Myeloid Neoplasm Mutation Panel detects myeloid neoplasm-associated mutations in 48 genes associated with AML, MDS, and MPN. The LeukoVantage AML panel can be used to assess AML subclass and prognosis based on genetic abnormalities in *NPM1, CEBPA*, and *RUNX1* (Quest_Diagnostics, 2020). NeoGenomics offers two tests which include the MPN Reflex Test and NeoTYPE® Myeloid Disorders Profile. The MPN Reflex Test is a sequential testing panel for qualitative detection of *JAK2* V617F*, JAK2 Exon 12-14, CALR exon 9*, and *MPL exon 10 (NeoGenomics, 2022a)*. NeoTYPE® Myeloid Disorders Profile is a 63 gene panel that targets known mutations associated with AML, MPN, MDS, CML, chronic myelomonocytic leukemia (CMML) and juvenile myelomonocytic leukemia (JMML) (NeoGenomics, 2022b). Centogene has released a Myeloid Tumor

Panel which targets 35 genes that are associated with myeloid malignancies which also include AML, MPN, MDS, CML, CMML, and JMML (Centogene, 2022).

Analytical Validity

Poluben et al. (2019) analyzed the characteristics of myeloproliferative neoplasms (MPN) in patients exposed to ionizing radiation (IR) from the 1986 Chernobyl accident. 281 patients (90 exposed to radiation, 181 unexposed) were included. *JAK2*, *MPL*, and *CALR* mutations were identified. IR-exposed patients had several different genetic features compared to the unexposed cohort: lower rate of *JAK2* V617F mutations (58.4% vs 75.4%), higher rate of type 1-like *CALR* mutations (12.2% vs 3.1%), higher rate of triple-negative cases (27.8% vs 16.2%), and higher rate of "potentially pathogenic" sequence variants (4.8 vs 3.1). The authors suggested IR-exposed patients as a cohort with "distinct" genomic characteristics (Poluben et al., 2019).

Rosenthal et al. (2021) studied the analytical validity of a 48-gene NGS panel for detecting mutations in myeloid neoplasms. The panel detects detect single nucleotide variations (SNVs), insertions/deletions, and *FLT3* internal tandem duplications (*FLT3*-ITD). 184 samples were analyzed using the 48-gene panel and compared to those identified by a 35-gene hematologic neoplasms panel using an additional 137 samples. Analytical validation yielded 99.6% sensitivity and 100% specificity. Concordance of variants detected by the 2 tested panels was 100%. "Among patients with suspected myeloid neoplasms, 54.5% patients had at least one clinically significant mutation: 77% in AML patients, 48% in MDS, and 45% in MPN." The authors conclude that "the assay can identify mutations associated with diagnosis, prognosis, and treatment options of myeloid neoplasms even in technically challenging genes" (Rosenthal et al., 2021).

Clinical Utility and Validity

An Argentinean study focusing on establishing the frequency of *JAK2*, *MPL*, and *CALR* mutations and comparing their clinical and hematological features corroborates this importance. Mutations of *JAK2*V617F, *JAK2* exon 12, *MPL* W515L/K and *CALR* were analyzed in 439 patients with *BCR-ABL1*-negative MPN, and it was demonstrated that these mutations were present in 94.9% of the cases of polycythemia vera (PV), 85.5% in patients with essential thrombocythemia (ET), and 85.2% with primary myelofibrosis, leading the researchers to conclude that "the combined genetic tests of these driver mutations are essential for accurate diagnoses of *BCR-ABL1*-negative MPN" (Ojeda et al., 2018).

VI. Guidelines and Recommendations

World Health Organization (WHO)

The 2017 edition of the World Health Organization's classification of myeloid neoplasm and acute leukemia proposed the following criteria for the diagnosis of PV, ET and PMF.

WHO Criteria for PV

Diagnosis of PV requires meeting either all three major criteria, or the first two major criteria and the minor criterion:

Major Criteria

1. Hemoglobin >16.5 g/dL in men; Hemoglobin >16.0 g/dL in women, or Hematocrit >49% in men; Hematocrit >48% in women, or Increased red cell mass (More than 25% above mean normal predicted value)
2. Bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes (differences in size)
3. Presence of *JAK2V617F* or *JAK2* exon 12 mutation

Minor Criteria

Subnormal serum erythropoietin level

WHO Criteria for ET

Diagnosis of ET requires meeting all four major criteria or the first three major criteria and the minor criterion:

Major Criteria

1. Platelet count ≥450 × 10^9/L
2. Bone marrow biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant increase or left shift in neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers
3. Not meeting WHO criteria for BCR-ABL1+ CML, PV, PMF, myelodysplastic syndromes, or other myeloid neoplasms
4. Presence of *JAK2*, *CALR*, or *MPL* mutation

Minor Criteria

Presence of a clonal marker or absence of evidence for reactive thrombocytosis

WHO Criteria for PrePMF

Diagnosis of prePMF requires meeting all three major criteria, and at least one minor criterion:

Major Criteria

1. Megakaryocytic proliferation and atypia, without reticulin fibrosis >grade 1, accompanied by increased age-adjusted BM cellularity, granulocytic proliferation, and often decreased erythropoiesis
2. Not meeting the WHO criteria for BCR-ABL1$^+$ CML, PV, ET, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence of these mutations, presence of another clonal marker (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1/IDH2*, *SRSF2*, *SF3B1*), or absence of minor reactive BM reticulin fibrosis

Minor Criteria (presence of one of the following):

1. Anemia not attributed to a comorbid condition
2. Leukocytosis ≥11 × 10^9/L
3. Palpable splenomegaly
4. LDH increased to above upper normal limit of institutional reference range

The minor criteria must be confirmed in two consecutive determinations.

WHO Criteria for Overt PMF

Diagnosis of overt PMF requires meeting all three major criteria, and at least 1 minor criterion

Major Criteria

1. Presence of megakaryocytic proliferation and atypia, accompanied by either reticulin and/or collagen fibrosis grades 2 or 3
2. Not meeting WHO criteria for ET, PV, BCR-ABL1$^+$ CML, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence of these mutations, presence of another clonal marker (e.g., *ASXL1*, *EZH2*, *TET2*, *IDH1/IDH2*, *SRSF2*, *SF3B1*), or absence of reactive myelofibrosis

Minor Criteria

1. Anemia not attributed to a comorbid condition
2. Leukocytosis ≥11 × 10^9/L
3. Palpable splenomegaly
4. LDH increased to above upper normal limit of institutional reference range

5. Leukoerythroblastosis (Barbui, Thiele, et al., 2018)

These guidelines also list four additional "clinicopathologic entities" for MPNs: "chronic myeloid leukemia (CML), chronic neutrophilic leukemia (CNL), chronic eosinophilic leukemia, not otherwise specified (CELNOS) and MPN, unclassifiable (MPN-U)". The guidelines note that although *CSF3R* mutations are "specific" to WHO-defined CNL, they also remark that "the presence of a membrane proximal *CSF3R* mutation in a patient with neutrophilic granulocytosis should be sufficient for the diagnosis of CNL, regardless of the degree of leukocytosis" (Barbui, Thiele, et al., 2018).

European LeukemiaNet (ELN)

ELN guidelines also recommend "strict adherence" to these guidelines for the three categories of Philadelphia-negative MPNs, (i.e. ET, PV, and MF) (Barbui, Tefferi, et al., 2018).

However, they also recommend "searching" for complementary clonal markers such as *ASXL1*, *EZH2*, *IDH1/2*, and *SRSF2* for patients that tested negative for the three driver mutations and have bone marrow features as well as a clinical phenotype consistent with myelofibrosis (Barbui, Tefferi, et al., 2018).

National Comprehensive Cancer Network (NCCN)

The NCCN Guidelines Version 1.2024 Myeloproliferative Neoplasms recommends molecular testing for *JAK2* V617F mutations as part of an initial workup for all patients. If *JAK2* mutation testing is negative, molecular testing for *CALR* and *MPL* mutations should be performed for patients with suspected ET and MF, and molecular testing for *JAK2* exon 12 should be done for patients who test negative for *JAK2* but are suspected of PV. An NGS panel including *JAK2*, *CALR*, and *MPL* may also be used for the workup of all patients. The NCCN follows the 2017 edition of the WHO diagnostic criteria for all three conditions. The NCCN does state that NGS "may be useful to establish clonality in selected circumstances (e.g., triple negative non-mutated *JAK2*, *MPL*, and *CALR*)". The NCCN includes a list of somatic mutations with prognostic significance in individuals with MPN that includes the *ASXL1*, *EZH2*, *RAS, IDH1/2*, *SRSF2*, *TP53*, *U2AF1* Q157, *DNMT3A,* and *CBL*.

For individuals suspected of MPN, the NCCN recommends excluding a diagnosis of chronic myeloid leukemia: "Fluorescence in situ hybridization (FISH) or a multiplex reverse transcriptase polymerase chain reaction (RT-PCR), if available, on peripheral blood to detect *BCR::ABL1* transcripts and exclude the diagnosis of CML is especially recommended for patients with left-shifted leukocytosis and/or thrombocytosis with basophilia" (NCCN, 2023).

British Society for Haematology (BSH)

The BSH recommends testing for *CALR* for patients suspected of ET and PMR, as *CALR* mutations account for most patients without either a *JAK2* or *MPL* mutation. The authors found that as many as one third of ET and PMF patients had a mutation in exon 9 of the *CALR* gene (Harrison et al., 2014).

The BSH also published guidelines on the diagnosis of polycythaemia vera (PV). In it, they divide PV into *JAK2*-positive and *JAK2*-negative PV. For *JAK2*-positive PV, the only two diagnostic criteria are as follows:

- "High haematocrit (>0·52 in men, >0·48 in women) OR raised red cell mass (>25% above predicted)"
- "Mutation in *JAK2*"

For *JAK2*-negative PV, the diagnostic criteria are as follows (requiring A1-A4, as well as another "A" criteria or two "B" criteria).

- "A1 Raised red cell mass (>25% above predicted) OR haematocrit ≥0·60 in men, ≥0·56 in women"
- "A2 Absence of mutation in *JAK2*"
- "A3 No cause of secondary erythrocytosis"
- "A4 Bone marrow histology consistent with polycythaemia vera"
- "A5 Palpable splenomegaly"
- "A6 Presence of an acquired genetic abnormality (excluding BCR-ABL1) in the haematopoietic cells"
- "B1 Thrombocytosis (platelet count >450 × 10^9 /l)"
- "B2 Neutrophil leucocytosis (neutrophil count >10 × 10^9 /l in non-smokers, ≥12.5 × 10^9 /l in smokers)"
- "B3 Radiological evidence of splenomegaly"
- "B4 Low serum erythropoietin"

The guidelines also note that investigation of erythrocytosis should be undertaken to properly identify the diagnosis. The BSH remarks that EPO receptor mutations may be a primary cause for erythrocytosis and that *EGNL1*, *VHL*, and *EPAS1* mutations may be a secondary cause. Other hemoglobinopathies caused by mutations in genes such as *HBA1*, *HBA2*, *HBB*, or *BPGM* may also be a factor (McMullin et al., 2019).

In 2021, the BSH published guidelines on the use of genetic tests to diagnose and manage patients with myeloproliferative neoplasms. The following recommendations were made:

1. "Molecular screening for *JAK2*, *CALR* and *MPL* variants as appropriate is recommended in patients with persistent erythrocytosis or thrombocytosis (GRADE 1B).
2. Screening for *JAK2* V617F is recommended in cases with normal blood counts and unexplained splanchnic vein thrombosis (GRADE 1B) and may be considered in selected patients with unexplained cerebral vein thrombosis (GRADE 2C).
3. Screening for *CALR* variants may be considered in patients with splanchnic vein thrombosis or cerebral vein thrombosis (GRADE 2C).
4. Screening for *JAK2*, *CALR* and *MPL* variants should be considered for patients with arterial or unprovoked venous thrombosis who have a mildly or variably elevated haematocrit or platelet count that persists for 2–3 months (GRADE 2C).
5. *BCR–ABL1* should be excluded in cases with persistent thrombocytosis negative for *JAK2, CALR* and *MPL* variants or with atypical features (GRADE 1B).
6. Younger patients (e.g., under 60 years) with bone marrow histology typical of ET [or myeloproliferative neoplasm, unclassifiable (MPN-U) or suspected prefibrotic MF] where confirmation of a clonal disorder would be useful in view of the patient's likely long-term disease course and ideally where a broad panel that covers non-canonical variants in *JAK2* and *MPL* and a range of other driver genes is available.
7. Patients with significant thrombocytosis (e.g., platelet count > 600 × 10^9/l), no reactive cause and borderline bone marrow histology, where cytoreduction would be indicated if there was convincing evidence of a clonal disorder. Examples would include those with an unexplained thrombotic event, particularly younger patients. For older patients without thrombosis, testing may be considered but results must be interpreted with caution in view of the possibility of incidental CH.
8. A myeloid gene panel and cytogenetic analysis (or equivalent) is recommended for patients with bone marrow histology and clinical features consistent with PMF (+/− suggestive features of MDS or MDS/MPN) who test negative for *JAK2*/*CALR*/*MPL* (GRADE 1B).
9. A myeloid gene panel and cytogenetic analysis (or equivalent) is not recommended for most patients with *JAK2*/*CALR*/*MPL*-negative erythrocytosis or thrombocytosis but may be considered in individual cases (GRADE 2C).
10. Myeloid gene panel testing is recommended for MPN cases who test positive for *JAK2*/*CALR*/*MPL* mutations and have additional cytopenias(s) at diagnosis, unexplained ring sideroblasts or other dysplasia, increased blasts (including blastic transformation), peripheral-blood monocytosis or atypical clinical features (GRADE 1B).

11. Myeloid gene panel testing and conventional karyotyping are recommended for all patients with PMF, post-PV or post-ET MF who are candidates for allogeneic stem cell transplant (GRADE 1B).
12. Myeloid gene panel testing should be considered for other patients if the additional genomic data will guide clinical management (GRADE 2C).
13. High-sensitivity assays of mutant allele burden are recommended following post-allogeneic stem cell transplant to monitor for residual disease (GRADE 1C).
14. Quantitative assays of mutant allele burden are not recommended for most MPN patients but may be considered where demonstration of molecular response would influence clinical management (GRADE 2C).
15. Patients with persistent eosinophilia should be investigated initially for *FIP1L1–PDGFRA* by FISH and/or nested RT-PCR (GRADE 1B).
16. BM cytogenetics or FISH is recommended to screen for other fusion genes, which must then be confirmed by molecular methods (GRADE 1B).
17. Myeloid gene panel and *KIT* D816V testing should be considered for patients with persistent unexplained eosinophilia who test negative for fusion genes (GRADE 2B).
18. Testing for *CSF3R* variants, preferably as part of wider myeloid panel, is recommended for all patients with suspected CNL (Grade 2B).
19. Sensitive testing for *KIT* D816V is recommended for all patients with a clinical suspicion of mastocytosis (GRADE 1B).
20. If negative for *KIT* D816V, screening for other *KIT* mutations should be considered for adults (but is recommended for children) (GRADE 1B).
21. Myeloid panel analysis is recommended for patients with advanced SM who are candidates for allogeneic stem cell transplantation (GRADE 1B).
22. Myeloid panel analysis may be considered for other SM patients if the apparent aggressiveness of the disease might influence options for therapy (GRADE 2B).
23. Myeloid panel and/or BM cytogenetics should be considered to characterise the AHN component of SM-AHN (GRADE 2B).
24. *BCR–ABL1* should be excluded in all cases of suspected MDS/MPN, and rearrangements associated with MLN-eo should be excluded in cases with eosinophilia (GRADE 1B).
25. Myeloid gene panel analysis and BM cytogenetics or SNP array is recommended for patients diagnosed with MDS/MPN and for cases with suspected MDS/MPN but with indeterminate morphology (GRADE 1B)" (Cross et al., 2021).

European Association for the Study of the Liver (EASL)

For myeloproliferative neoplasms, the EASL recommends testing for *JAK2* V617F mutations in splanchnic vein thrombosis patients, as well as patients with normal peripheral blood cell counts. If the *JAK2* mutation test is negative, a calreticulin

mutation test should be performed, and if both are negative, a bone marrow histology analysis should be performed (EASL, 2016).

European Society of Medical Oncology (ESMO)

The ESMO recommends that anyone with a suspected MPN be tested for the three driver mutations (*JAK2*, *CALR*, *MPL*) and that genotyping should be obtained at diagnosis. However, the ESMO states that it is not recommended to repeat testing in follow-up or assessing response to treatment, except for "allogeneic stem-cell transplantation and possibly interferon treatment". For these two assessments a detection limit of ≤1% is recommended. The ESMO also notes that conventional sequencing methods (PCR, melting analysis) may be used for detecting mutations (Vannucchi et al., 2015).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On July 28, 2017 the FDA approved ipsogen® JAK2 RGQ PCR Kit (FDA, 2017b) to detect Janus Tyrosine Kinase 2 (JAK2) gene mutation G1849T (V617F) with an allele-specific, quantitative, polymerase chain reaction (PCR) using an amplification refractory mutation system (ARMS). This is the first FDA-authorized test intended to help physicians in evaluating patients for suspected Polycythemia Vera (PV). However, the FDA specifically states that this test is not intended for a stand-alone diagnosis of an MPN, nor can it detect less common mutations for MPN such as an exon 12 mutation (FDA, 2017a).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81120	IDH1 (isocitrate dehydrogenase 1 [NADP+], soluble) (eg, glioma), common variants (eg, R132H, R132C)
81121	IDH2 (isocitrate dehydrogenase 2 [NADP+], mitochondrial) (eg, glioma), common variants (eg, R140W, R172M)
81175	ASXL1 (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; full gene sequence
81176	ASXL1 (additional sex combs like 1, transcriptional regulator) (eg, myelodysplastic syndrome, myeloproliferative neoplasms, chronic myelomonocytic leukemia), gene analysis; targeted sequence analysis (eg, exon 12)
81206	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis; major breakpoint, qualitative or quantitative
81207	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis; minor breakpoint, qualitative or quantitative
81208	BCR/ABL1 (t(9;22)) (eg, chronic myelogenous leukemia) translocation analysis; other breakpoint, qualitative or quantitative
81219	CALR (calreticulin) (eg, myeloproliferative disorders), gene analysis, common variants in exon 9
81236	EZH2 (enhancer of zeste 2 polycomb repressive complex 2 subunit) (eg, myelodysplastic syndrome, myeloproliferative neoplasms) gene analysis, full gene sequence
81237	EZH2 (enhancer of zeste 2 polycomb repressive complex 2 subunit) (eg, diffuse large B-cell lymphoma) gene analysis, common variant(s) (eg, codon 646)
81270	JAK2 (Janus kinase 2) (eg, myeloproliferative disorder) gene analysis, p.Val617Phe (V617F) variant
81273	KIT (v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog) (eg, mastocytosis), gene analysis, D816 variant(s)
81275	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; variants in exon 2 (eg, codons 12 and 13)
81276	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; additional variant(s) (eg, codon 61, codon 146)
81279	JAK2 (Janus kinase 2) (eg, myeloproliferative disorder) targeted sequence analysis (eg, exons 12 and 13)
81311	NRAS (neuroblastoma RAS viral [v-ras] oncogene homolog) (eg, colorectal carcinoma), gene analysis, variants in exon 2 (eg, codons 12 and 13) and exon 3 (eg, codon 61)

CPT	CPT Description
81338	MPL (MPL proto-oncogene, thrombopoietin receptor) (eg, myeloproliferative disorder) gene analysis; common variants (eg, W515A, W515K, W515L, W515R)
81339	MPL (MPL proto-oncogene, thrombopoietin receptor) (eg, myeloproliferative disorder) gene analysis; sequence analysis, exon 10
81347	SF3B1 (splicing factor [3b] subunit B1) (eg, myelodysplastic syndrome/acute myeloid leukemia) gene analysis, common variants (eg, A672T, E622D, L833F, R625C, R625L)
81348	SRSF2 (serine and arginine-rich splicing factor 2) (eg, myelodysplastic syndrome, acute myeloid leukemia) gene analysis, common variants (eg, P95H, P95L)
81351	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; full gene sequence
81352	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; targeted sequence analysis (eg, 4 oncology)
81353	TP53 (tumor protein 53) (eg, Li-Fraumeni syndrome) gene analysis; known familial variant
81357	U2AF1 (U2 small nuclear RNA auxiliary factor 1) (eg, myelodysplastic syndrome, acute myeloid leukemia) gene analysis, common variants (eg, S34F, S34Y, Q157R, Q157P)
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >**10** amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81432	Hereditary breast cancer-related disorders (eg, hereditary breast cancer, hereditary ovarian cancer, hereditary endometrial cancer); genomic sequence analysis panel, must include sequencing of at least 10 genes, always including BRCA1, BRCA2, CDH1, MLH1, MSH2, MSH6, PALB2, PTEN, STK11, and TP53
81442	Noonan spectrum disorders (eg, Noonan syndrome, cardio-facio-cutaneous syndrome, Costello syndrome, LEOPARD syndrome, Noonan-like syndrome), genomic sequence analysis panel, must include sequencing of at least 12 genes, including BRAF, CBL, HRAS, KRAS, MAP2K1, MAP2K2, NRAS, PTPN11, RAF1, RIT1, SHOC2, and SOS1
81450	Hematolymphoid neoplasm or disorder, genomic sequence analysis panel, 5-50 genes, interrogation for sequence variants, and copy number variants or

CPT	CPT Description
	rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
81455	Solid organ or hematolymphoid neoplasm or disorder, 51 or greater genes, genomic sequence analysis panel, interrogation for sequence variants and copy number variants or rearrangements, or isoform expression or mRNA expression levels, if performed; DNA analysis or combined DNA and RNA analysis
81479	Unlisted molecular pathology procedure
0017U	Oncology (hematolymphoid neoplasia), JAK2 mutation, DNA, PCR amplification of exons 12-14 and sequence analysis, blood or bone marrow, report of JAK2 mutation not detected or detected. Proprietary test: JAK2 Mutation Lab/Manufacturer: University of Iowa, Department of Pathology
0027U	JAK2 (Janus kinase 2) (e.g., myeloproliferative disorder) gene analysis, targeted sequence analysis exons 12-15 Proprietary test: JAK2 Exons 12 to 15 Sequencing Lab/Manufacturer: Mayo Clinic

Pancreatic Cancer Risk Testing Using Pancreatic Cyst Fluid

Policy Number: AHS – M2114 – Pancreatic Cancer Risk Testing Using Pancreatic Cyst Fluid	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Pancreatic cancer is the fourth leading cause of death among cancers in the United States, and neoplasms frequently arise from pancreatic cysts that require investigation to differentiate benign neoplasms from malignant ones (Suriawinata, 2024). Up to 10% of pancreatic adenocarcinoma instances are "familial" in nature (Stoffel et al., 2018). Pathogenic germline variants in specific genes play a role in a 4% to 40% risk of developing pancreatic cancer over a lifetime (Canto et al., 2013). In such patients who are determined to be at risk, screening and meaningful intervention can make the difference in detecting pancreatic neoplasms early, but the risk of unnecessary and invasive intervention is also high.

First-line tests for pathologic diagnosis of a pancreatic cyst include cytology, imaging, and fluid chemistry. Integrated molecular pathology (IMP) testing combines molecular analysis with first-line test results (cytology, imaging, and fluid chemistry) to assess malignant potential (Al-Haddad et al., 2015). It is currently most commonly used adjunctively as a second-line testing strategy when a definitive pathologic diagnosis cannot be made because of inadequate specimen or equivocal histologic or cytologic findings.

II. Related Policies

Policy Number	Policy Title
AHS-G2124	Serum Tumor Markers for Malignancies
AHS-G2153	Pancreatic Enzyme Testing for Acute Pancreatitis
AHS-M2066	Genetic Cancer Susceptibility Using Next Generation Sequencing
AHS-M2079	Genetic Testing for Hereditary Pancreatitis

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) As a first step analysis of pancreatic cyst fluid, cytology and/or testing of carcinoembryonic antigen (CEA) and/or amylase **MEETS COVERAGE CRITERIA.**

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For all situations, pancreatic cancer risk testing using molecular classifiers (e.g., PancraGEN) to evaluate pancreatic cyst fluid **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ACG	American College of Gastroenterology
ACR	American College of Radiology
AGA	American Gastroenterological Association
ASGE	American Society for Gastrointestinal Endoscopy
CA 19-9	Carbohydrate antigen 19-9
CAPS	International Cancer of The Pancreas Screening
CEA	Carcinoembryonic antigen
CF	Cystic fluid
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid Services
CTNNB1	*Catenin beta 1* gene
DNA	Deoxyribonucleic acid
ESG	European Study Group on Cystic Tumours of the Pancreas
EUS	Endoscopic ultrasound
EUS-FNA	Endoscopic ultrasound fine-needle aspiration
FDA	Food And Drug Administration
FNA	Fine-needle aspirates
GNAS	*Guanine nucleotide binding protein, alpha stimulating* gene
IAP	International Association of Pancreatology
ICG	International Consensus Guideline

IMP	Integrated molecular pathology
indels	Insertions/deletions
IPMN	Intraductal papillary mucinous neoplasm
KRAS	*Kirsten rat sarcoma viral oncogene homolog* gene
LDT	Laboratory-developed test
MCN	Mucinous cystic neoplasm
MRI	Magnetic resonance imaging
MvP	Metastasis versus primary tumors
NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
NT	Neoplastic tissue
PCF	Pancreatic cyst fluid
PCN	Pancreatic cystic neoplasm
POLD1	*DNA polymerase delta 1, catalytic subunit* gene
PTPRD	*Protein tyrosine phosphatase receptor type D* gene
QALY	Quality-adjusted life-years
RAF	*Rapidly accelerated fibrosarcoma* gene
RNF43	*Ring finger protein 4* gene
SCA	Serous cystadenoma
SNV	Single nucleotide variant
SPN	Solid pseudopapillary neoplasm
TG	Topographic genotyping
TP53	Tumor protein p53
WGO	World Gastroenterology Organization

V. Scientific Background

Discovery of pancreatic cysts is becoming increasingly common as imaging technologies such as computed tomography and magnetic resonance imaging scans have become widespread in use. Though data suggests that malignant transformation of cysts is rare, due to the overall poor prognosis of pancreatic cancer, an incidental finding of a cyst can lead to an aggressive clinical workup. Cysts may be neoplastic with malignant potential, whereas non-neoplastic cysts only require treatment if they are symptomatic. Pancreatic cysts are divided pathologically into three different categories: inflammatory fluid collections, non-neoplastic pancreatic cysts, and pancreatic cystic neoplasms (PCNs) (Khalid & McGrath, 2023). Non-neoplastic cysts are often only identified after a surgical resection (Khalid & McGrath, 2023).

Pancreatic cystic neoplasms are further categorized into four subtypes with varying degrees of potential towards malignancy:

- Serous neoplasms
- Mucinous cystic neoplasms (MCNs)
- Intraductal papillary mucinous neoplasms (IPMNs)
- Solid pseudopapillary neoplasms (SPNs)

Evaluating tissues samples pathologically is a critical component of diagnosing patients with malignancy. Many cysts are first surveilled by imaging technology. The management of PCNs focuses on preventing progression of malignancy, while also avoiding unnecessary and invasive surgical intervention. If imaging is inconclusive, an evaluation is usually performed by endoscopic, ultra-sound guided fine needle aspiration sampling of fluid and the cyst wall using cytologic examination and analysis. Generally, before a diagnosis is made, the patient may have undergone any or all of the following diagnostic procedures: computed tomography, magnetic resonance imaging/magnetic resonance cholangiopancreatography, and/or endoscopic ultrasound (with or without fine needle aspiration) (Scholten et al., 2018). Additional tests may include amylase, lipase, and carcinoembryonic antigen (CEA) levels on cyst fluid, but these may still leave uncertainty as to a diagnosis.

Combining pathological study with molecular analysis and/or serum biomarkers is proposed to enhance the ability for greater diagnostic confirmation. One method used to ascertain subtypes of PCN and to identify malignancy is the use of biomarkers in peripheral blood such as serum carbohydrate antigen (CA) 19-9. Serum CA 19-9 levels that exceed 37 U/ml, may provide information on potential malignancy or invasive IPMN.

Cystic fluid analysis is also purported as useful to further analyze PCN by subtype. Analyses of pancreatic cystic fluid for this purpose may include CEA, CA 19-9, amylase and lipase, viscosity, mucin stain, and cytology (Khalid & McGrath, 2023).

Molecular analysis of DNA has been suggested as another way to gather important diagnostic information on pancreatic cysts. DNA markers such as *GNAS* and *KRAS* have evidenced specificity and sensitivity for diagnosis of whether a cyst is an IPMN (Scholten et al., 2018).

Proprietary tests are available that propose that they can estimate the chances of pancreatic cancer with pancreatic cyst fluid and integrated molecular pathology or molecular anatomic pathology.

Proprietary Testing

RedPath Integrated Pathology developed and patented a proprietary platform, PathFinderTG®, based on topographic genotyping (TG), which integrates microscopic

analysis (anatomic pathology) with molecular tissue analysis (RedPath Integrated Pathology, 2001). RedPath developed five different Pathfinder GT tests (Pancreas, Biliary, Barrett, Glioma, and Metastasis versus Primary Tumors (MvP) before the company was purchased by Interpace Diagnostics. Interpace Diagnostics has continued development of these molecular pathology panels and markets them separately as PancraGEN (Interpace, 2023b).

PancraGEN is a DNA-based, integrated molecular pathology test that helps to assess the cancer risk in aspirated pancreatic cyst fluid. This test uses extracted DNA from aspirated pancreatic cyst fluid to test tumor suppressor genes (such as *PTEN* and *TP53*) and oncogenes (such as *KRAS* and *NRAS*). PancraGEN is intended as a supplement to other diagnostic tools such as cytology and imaging, and is proposed to enhance assessments of malignancy risk (Interpace, 2023a). The DNA abnormalities identified by this technology include tumor suppressor gene panel (Loss of Heterozygosity) analysis of *VHL, OGG1; PTEN, MXI1; TP53; SMAD4, DCC; CDKN2A; RNF43, NME1; PSEN2, TFF1; CMM1v; MCC, APC; NF2*. Oncogene point mutations provided by this test are those in KRAS and GNAS. The report provides summary of specific molecular results and details of each result with the possible clinical meanings of those results. Interpace also offers PanDNA, which provides molecular-only results to enhance risk stratification of pancreatic cysts. DNA abnormalities are identified by PanDNA technology from aspirated pancreatic cyst fluid without the integration with first-line testing results (Interpace, 2023b).

PancraSeq, from UPMC, is a test that detects "74 pancreatic cyst- and pancreatic cancer-related genes for main classes of molecular alterations, including mutations, gene fusions, copy number alterations, and gene expression alterations." The test also detects *CEA* gene expression. The test identifies the following mutations (SNVs/indels): *KRAS, GNAS, BRAF, VHL, TP53, PIK3CA, PTEN, CTNNB1, MEN1, AKT1, APC, HRAS, NRAS, IDH1, IDH2, MET, NF2, STK11, TERT, TSC2*; the following copy number alterations: *RNF43* (17q), *SMAD4* (18q), *TP53* (17p), *VHL* (3p*), NF2* (22q), and *PTEN* (10q) tumor suppressor genes and 13 other chromosomal regions; the following gene expression alterations: *KRT7, KRT20, CHGA, CEACAM5, PGK*; and over 170 types of gene fusions, including *PRKACA/B* fusions for detection of IOPN, and *ALK, NTRK1/3, BRAF, RET* gene fusions as potential therapeutic targets for PDAC. The test reports alterations in any of its genes, its allele frequency, and whether the variant is of clinical or "potential" clinical significance. PancraSeq reports the test to have a "95% sensitivity and 100% specificity for detection of cystic precursor neoplasms (IPMN, MCN, IOPN), and the 82% sensitivity and 100% specificity for detection of advanced neoplasia" (Pancreaseq, 2024).

PanreaSeq has a sensitivity of 82% - 98%, specificity of 94% - 100%, positive predictive value of 84% - 100%, and negative predictive value of 62% - 98% (Nikiforova et al., 2023; Paniccia et al., 2023). PancraGen/PanDNA has a sensitivity: 70% - 100%, and a specificity of 77% - 99%. The positive predictive value and negative predictive value of PancraGen/PanDNA is not explicitly identified (Bell et al., 2022; Rahal et al., 2022; Simpson et al., 2018, 2019).

Clinical Utility and Validity

Malhotra et al. (2014) evaluated the supporting role that mutational profiling of DNA may play in the diagnosis of malignancy in fine-needle aspirates (FNA) and biliary brushing specimens from patients with pancreaticobiliary masses. The study included 30 patients who presented with pancreaticobiliary masses were evaluated and had minimum follow-up of three months. PathFinderTG® mutational profiling was done and analyzed in 26 patients with atypical, negative, or indeterminate cytology. Cytology correctly diagnosed four of 21 malignant cases (sensitivity, 19%), and identified seven of nine patients with non-aggressive disease (specificity, 78%). PathFinderTG® correctly diagnosed eight of 17 malignant cases (sensitivity, 47%) and identified all nine patients with non-aggressive disease (specificity, 100%). When first-line malignant cytology results were combined with positive second-line mutational profiling results, sensitivity improved to 57% (12/21 cases of aggressive disease were identified). The investigators concluded that mutational profiling provided additional information regarding the presence of aggressive disease. When used in conjunction with first-line cytology, mutational profiling increased detection of aggressive disease without compromising specificity in patients that were difficult to diagnose by cytology alone (Malhotra et al., 2014)

Al-Haddad et al. (2015) published a study that examined the diagnostic accuracy of IMP for pancreatic adenocarcinoma. A total of 492 samples were assessed, and out of the benign or indolent IMP diagnoses, 97% had a benign follow-up for up to seven years, eight months after IMP testing. Statistically higher risk and aggressive diagnoses had hazard ratios for malignancy of 30.8 and 76.3, respectively. The Sendai surveillance criteria had identical chances of benign follow-up over the same timeframe, but the Sendai surgical criteria only had a hazard ratio of 9.0. The authors concluded, “IMP more accurately determined the malignant potential of pancreatic cysts than a Sendai 2012 guideline management criteria model. IMP may improve patient management by justifying more relaxed observation in patients meeting Sendai surveillance criteria. IMP can more accurately differentiate between the need for surveillance or surgery in patients meeting Sendai surgical criteria” (Al-Haddad et al., 2015).

Loren et al. (2016) performed a study evaluating the impact of IMP testing on clinical management decisions. A total of 491 patients were examined, and 66 had a malignant outcome (425 benign). The IMP testing was compared to the 2012 International Consensus Guideline (ICG) recommendations. When the two methods agreed, surveillance and surgery was undertaken in 83% and 88% of the cases, respectively. However, when the methods disagreed, the clinicians tended to agree with the IMP method. Eighty eight percent of patients had an intervention when ICG recommended surveillance, but IMP indicated "high-risk," and 55% of patients underwent surveillance when the ICG recommended surgery, but IMP indicated low risk. The authors concluded that "DNA-based IMP diagnoses were predictive of real-world management decisions. Importantly, when International Consensus Guidelines and IMP were discordant, IMP influence benefitted patients by increasing confidence in surveillance and surgery decisions and reducing the number of unnecessary surgeries in patients with benign disease" (Loren et al., 2016).

Springer et al. (2015) evaluated "whether a combination of molecular markers and clinical information could improve the classification of pancreatic cysts and management of patients." A total of 130 patients with resected pancreatic cystic neoplasms were enrolled. The cyst fluid was evaluated for the following genetic alterations: "*BRAF, CDKN2A, CTNNB1, GNAS, KRAS, NRAS, PIK3CA, RNF43, SMAD4, TP53* and *VHL*); loss of heterozygosity at *CDKN2A, RNF43, SMAD4, TP53*, and *VHL* tumor suppressor loci; and aneuploidy." The authors found this panel to identify 67 of the 74 patients who did not require surgery and estimated the sensitivity to be 90-100% and the specificity to be 92-98% (Springer et al., 2015).

Singhi et al. (2016) assessed the accuracy of the AGA guidelines in detecting advanced neoplasia and presented an alternative approach to pancreatic cysts. The clinical findings and molecular testing of pancreatic cyst fluid of 225 patients who underwent EUS-guided FNA for pancreatic cysts were reviewed. The authors found that "Diagnostic pathology results were available for 41 patients with 13 harboring advanced neoplasia. Among these cases, the AGA guidelines identified advanced neoplasia with 62% sensitivity, 79% specificity, 57% positive predictive value, and 82% negative predictive value. Moreover, the AGA guidelines missed 45% of intraductal papillary mucinous neoplasms with adenocarcinoma or high-grade dysplasia. For cases without confirmatory pathology, 27 of 184 patients (15%) with serous cystadenomas (SCAs) based on EUS findings and/or VHL alterations would continue magnetic resonance imaging (MRI) surveillance. In comparison, a novel algorithmic pathway using molecular testing of pancreatic cyst fluid detected advanced neoplasias with 100% sensitivity, 90% specificity, 79% positive predictive value, and 100% negative predictive value" (Singhi et al., 2016).

Singhi et al. (2018) also evaluated the accuracy of pancreatic cyst fluid (PCF) DNA testing. A total of 626 PCF samples were taken from 595 patients. *KRAS/GNAS* mutations were identified in 308 samples (49%), and *PIK3CA/PTEN/TP53* mutations were identified in 35 samples (6%). A total of 102 patients had a surgical follow-up, and *KRAS/GNAS* mutations were detected in 56 intraductal papillary mucinous neoplasms (IPMNs) and three mucinous cystic neoplasms (MCNs), which corresponded to an 89% sensitivity and 100% specificity for a mucinous pancreatic cyst. Next generation sequencing identified the combination of *KRAS/GNAS* mutations and *TP53/PTEN/PIK3CA* alterations at an 89% sensitivity and 100% specificity. The authors concluded, "In contrast to Sanger sequencing, preoperative NGS of PCF for *KRAS/GNA*S mutations is highly sensitive for IPMNs and specific for mucinous PCs. In addition, the combination of *TP53/PIK3CA/PTEN* alterations is a useful preoperative marker for advanced neoplasia" (Singhi et al., 2018).

Das et al. (2015) investigated the cost efficiency of IMP in a "third-party-payer perspective Markov decision model" of a hypothetical cohort of 1000 asymptomatic patients with a three cm solitary pancreatic cyst. They used four different strategies to evaluate the cost efficiency in terms of quality-adjusted life-years (QALY): "Strategy I used cross-sectional imaging, recommended surgery only if symptoms or risk factors emerged. Strategy II considered patients for resection without initial EUS. Strategy III (EUS + CEA + Cytology) referred only those with mucinous cysts (CEA > 192 ng/mL) for resection. Strategy IV implemented IMP; a commercially available panel provided a 'Benign,' 'Mucinous,' or 'Aggressive' classification based on the level of mutational change in cyst fluid. 'Benign' and 'Mucinous' patients were followed with surveillance; 'Aggressive' patients were referred for resection." The authors report that the IMP-based Strategy IV provided the greatest increase in QALY at approximately the same cost as the "cheapest approach," concluding that "use of IMP was the most cost-effective strategy, supporting its routine clinical use" (Das et al., 2015). It should be noted, however, that two of the authors listed on the study were employed by RedPath Integrated Pathology, the developer of the IMP test.

Laquiere et al. (2019) investigated the concordance of mutation analysis between pancreatic cyst fluid and neoplastic tissue. The authors used next-generation sequencing to compare DNA collected from both cystic fluid (CF) and neoplastic tissue (NT). A total of 17 patients were included, and concordant CF-NT genotypes were found in 15 of 17 patients. A higher proportion of mutated alleles were found in CF compared to NT. The authors also noted that "the sensitivity and specificity of *KRAS/GNAS* mutations in CF to predict an appropriate indication for surgical resection were 0.78 and 0.62, respectively. The sensitivity and specificity of *RAF/PTPRD/CTNNB1 /RNF43/POLD1/TP53* mutations in CF were 0.55 and 1.0, respectively." Although the authors remarked that mutational analysis between both media were highly

concordant, they also stated that the results "need to be confirmed on a larger scale" (Laquiere et al., 2019).

Volckmar et al. (2019) published preliminary results from the "prospective ZYSTEUS biomarker study." This study is intended to investigate "(i) whether detection of driver mutations in IPMN [intraductal papillary mucinous neoplasm] by liquid biopsy is technically feasible, (ii) which compartment of IPMN is most suitable for analysis, and (iii) implications for clinical diagnostics." A total of 15 patients with pancreatic cysts larger than 10 mm were included, 12 of which had an IPMN and three acute pancreatitis controls. All 12 IPMN cases were found to harbor at least one mutation in either KRAS (n = 11) or GNAS (n = 4), with three cases harboring both mutations. In three cases with "pseudocysts," no alterations were identified. The authors also found that DNA yields were higher and showed higher mutation diversity in the cellular fraction and concluded that "mutation detection in pancreatic cyst fluid is technically feasible with more robust results in the cellular than in the liquid fraction." The authors also suggested that their results, "targeted sequencing supports discrimination of IPMN from pseudocysts" when combined with imaging (Volckmar et al., 2019).

Pérez et al. (2021) studied the impact of molecular analysis on the detection of mucinous cysts and malignancy. Currently, recommendations suggest endoscopic ultrasound fine-needle aspiration (EUS-FNA) with molecular analysis to improve the diagnosis of pancreatic cysts. EUS-FNA and next-generation sequencing was performed in 36 pancreatic cysts, which were classified as mucinous, non-mucinous, and malignant. Of the 36 lesions, 28 (82.4%) were classified as mucinous, six (17.6%) were classified as non-mucinous, and five (13.9%) were classified as malignant lesions. *KRAS* and *GNAS* genes were analyzed for mutations. Analysis of *KRAS* and *GNAS* showed 83.33% sensitivity, 60% specificity, 88.24% positive predictive value, and 50% negative predictive value for the diagnosis of mucinous cystic lesions. Mutations in *KRAS* and *GNAS* were found in two of five (40%) of the lesions classified as non-mucinous, so they were recategorized as mucinous neoplasms. These led to a modification of the follow up plan in 8% of the cysts. Additionally, one indeterminate cyst showed a mutation in both *KRAS* and *GNAS*, so it could also be classified as mucinous. Therefore, performing molecular analysis in cases of uncertain diagnosis improved categorization of the cyst. One hundred percent of the malignant cysts had mutations in *KRAS* and/or *GNAS*. However, the presence of a mutation was not related to malignancy. Overall, the authors conclude that "molecular analysis can improve the classification of pancreatic cysts as mucinous or non-mucinous. This is important as mucinous cysts are premalignant lesions and have a higher risk of concomitant pancreatic adenocarcinoma, thus implying long-term follow-up" (Pérez et al., 2021).

Buerlein and Shami (2021) published an overview of current guidelines for gastroenterologists as part of recommendations for pancreatic cysts. The prevalence of pancreatic cysts has increased as technology has improved. However, incidental identification of asymptomatic pancreatic cysts causes patient concern as malignancy varies greatly and surgical resection is an invasive technique. Pancreatic cystic neoplasms (PCNs) fall into one of two categories: mucinous PCNs, which create mucus and have a greater potential for malignancy, as compared to non-mucinous PCNs. Regarding biomarker identification, EUS-guided fluid samples taken from PCNs combined with ways of acquiring tissue to analyze PCN malignancy "could improve our ability to accurately diagnose PCNs and understand their risk of malignant transformation." However, "these are not currently recommended for usage by any of the guidelines." The authors briefly discussed several methods of risk-stratifying pancreatic cysts through identifying mucinous versus non-mucinous cysts: (1) next-generation sequencing of PCN fluid (2) cyst fluid glucose level (3) microbiopsy, and (4) confocal laser endomicroscopy. All four methods were described as requiring further clinical validation (Buerlein & Shami, 2021).

Nagula et al. (2010) evaluated the use of cyst fluid CEA analysis in the diagnosis of mucinous cysts of the pancreas. A group of 267 patients was identified by pathological diagnosis. Mucinous cysts were identified in 66 of 97 patient cases (68%) by CEA value. A CEA greater than 192 ng/mL had a sensitivity of 73% and specificity of 65% when it came to identifying mucinous cysts. However, cyst fluid CEA was not found to be associated with malignancy. A non-surgical strategy was used to manage the 178 patients identified to have mucinous cysts. Eight of these patients later had radiographic developments that required surgery. Results from pathology indicated seven benign mucinous cysts and one retention cyst. The conclusion of the study was that "cyst fluid CEA is a useful test for identifying mucinous cysts, including MCN and IPMN. In mucinous cysts, cyst fluid CEA is not associated with malignancy or radiographic progression" (Nagula et al., 2010).

Oh et al. (2014) used a pancreatic cyst database containing the profiles of 78 patients with histologically proven cysts to study the differential diagnosis of pancreatic cysts using cyst fluid amylase and CEA. The median age of the 78 patients was 60.4 years. Cyst fluid amylase levels showed a significant difference between pseudocysts (PP) and mucinous cystic neoplasms (MCNs) but did not aid in distinguishing between MCNs and IPMN. The cyst fluid CEA showed a significant difference between pseudocysts and mucinous cystic neoplasms (median: 26.00 versus 627.50 ng/mL respectively, $p < 0.001$) and between pseudocysts (26.00 ng/mL) and IPMN (356.50 ng/mL). Overall, the established optimal cut-off values from the study were 6,800 U/mL for amylase and 50 ng/mL for CEA. These correlated with the "crossover of the sensitivity and specificity

curves for differentiating PP and mucinous neoplasms. The overall accuracies of cyst fluid amylase and CEA were 69% and 85%, respectively" (Oh et al., 2014).

Smith et al. (2016) performed a retrospective study on cytology, amylase, and CEA in the preoperative diagnosis of pancreatic cysts. The goal of the study was to reclassify and analyze malignancy risk in cysts that were already histologically proven to be pancreatic neoplastic mucinous cysts using Pap Center guidelines, ancillary testing through amylase and CEA values, and cytology. First, a database search was conducted. Pancreatic neoplastic mucinous cyst resections using EUS-FNA technique in the prior year were identified. One hundred and thirty-eight cases of pancreatic neoplastic mucinous cysts were retrieved. Eleven cases were excluded for missing slides. Of the remaining 127 cases, there were 81 IPMNs and 86 MCNs. Cysts that were atypical, suspicious, or positive were re-reviewed, blinded to the previous diagnosis and categorization. The authors concluded that the sensitivity of cytology for diagnosis of neoplastic mucinous cysts (with ancillary information from amylase and CEA values) was 76.4%. Diagnosis of malignancy using cytology had a sensitivity of 48.3%, specificity of 94.9% and accuracy of 84.3%. The authors concluded that a "purely cytologic approach is inferior to an integrated approach of cytology with ancillary testing in diagnosing a neoplastic mucinous cyst of the pancreas" (Smith et al., 2016).

Gorris et al. (2023) studied the value of combined carcinoembryonic antigen (CEA) and glucose testing in pancreatic cyst fluid when differentiating mucinous from non-mucinous pancreatic cystic neoplasms. Pancreatic cyst fluid was collected from 63 patients. Histopathology, cytopathology, clinical, and/or radiological diagnosis was used as a reference standard; 33 (52%) participants had mucinous pancreatic cystic neoplasms and 30 (48%) had non-mucinous pancreatic cystic neoplasms. The authors performed laboratory measurements of CEA and used a hand glucometer to measure glucose. Combined CEA and glucose results had 92% specificity and 48% sensitivity. Either a positive CEA or glucose result alone had 97% sensitivity and 50% specificity. The authors conclude that "combined CEA and glucose testing in PCF reached high specificity and sensitivity for differentiating mucinous from non-mucinous PCN" and note that changing the CEA cut-off levels could increase sensitivity (Gorris et al., 2023).

Pflüger et al. (2023) conducted a systematic review of 42 studies to analyze the predictive ability of pancreatic cyst fluid biomarkers. The authors included studies that evaluated the diagnostic performance of cyst fluid, particularly those that emphasized DNA-based biomarkers. "Mutations in *KRAS* and/or *GNAS* allowed identification of mucinous cysts with a sensitivity of 79% and specificity of 98%," which "exceeded the performance of the traditional biomarker carcinoembryonic antigen (CEA; sensitivity 58%, specificity 87%)." Additionally, mutations in *VHL* were specific to serous cystadenomas, and mutations of *CDKN2A, PIK3CA, SMAD4,* and *TP53* all had high

specificities to high-grade dysplasia or pancreatic ductal adenocarcinoma. The authors concluded that the results "support the use of DNA-based cyst fluid biomarkers in the multidisciplinary diagnostic work-up of pancreatic cysts" (Pflüger et al., 2023).

Cui et al. (2023) studied potential cyst fluid biomarkers to be used for the diagnosis of PCN. The authors analyzed the glycoproteomic and proteomic characteristics of pancreatic cyst fluid samples from PCN patients using mass spectrometry-based glycosite- and glycoform-specific glycoproteomics and proteomics. N-glycosylated PHKB (Asn-935, H5N2F0S0; Asn-935, H4N4F0S0; Asn-935, H5N4F0S0), CEACAM5 (Asn-197, H5N4F0S0) and ATP6V0A4 (Asn-367, H6N4F0S0) were confirmed as "promising diagnostic biomarkers for distinguishing malignant PCNs" with an area under the curve ranging from 0.771 to 0.943. The authors concluded that the results "hold significant clinical implications, providing valuable insights for PCN decision-making, and potentially offering therapeutic targets for PCN treatment" (Cui et al., 2023).

VI. Guidelines and Recommendations

American Gastroenterological Association (AGA)

In 2015, the AGA published guidelines on the diagnosis and management of asymptomatic neoplastic pancreatic cysts. These guidelines only state, "Molecular techniques to evaluate pancreatic cysts remain an emerging area of research, and the diagnostic utility of these tests is uncertain" (Vege et al., 2015).

American College of Gastroenterology (ACG)

In 2018, the ACG updated its recommendations (Elta et al., 2018) on the diagnosis and management of pancreatic cysts, stating that "Molecular markers may help identify IPMNs and MCNs. Their use may be considered in cases in which the diagnosis is unclear and the results are likely to change management (Conditional recommendation, very low quality of evidence)."

The ACG also acknowledges the cost of cyst analysis, noting that "The cost of cyst analysis and cyst surveillance is high, and the benefit in terms of cancer prevention is unproven. There have been no dedicated cost effectiveness analyses about surveillance of incidental pancreatic cysts" (Elta et al., 2018).

American Society for Gastrointestinal Endoscopy (ASGE)

The ASGE states that "additional research is needed to determine the precise role molecular analysis of cyst fluid will play in evaluating pancreatic cystic lesions." However, the ASGE suggests that "molecular testing of the cyst be considered when

initial ancillary testing of cytology and CEA is inconclusive and when test results may alter management" (Muthusamy et al., 2016).

National Comprehensive Cancer Network (NCCN)

The current NCCN clinical practice guidelines for pancreatic adenocarcinoma do not include recommendations for assessment of pancreatic cyst fluid (NCCN, 2024).

International Consensus Fukuoka Guidelines

The International Association of Pancreatology (IAP) (Tanaka et al., 2017) held a consensus symposium to examine the guidelines regarding prediction of invasive carcinoma and high-grade dysplasia, surveillance, and postoperative follow-up of IPMN. They found that "At present, EUS-FNA with cytological and molecular analyses is still considered investigational and should be performed only in centers with expertise in performing EUS-FNA and interpreting the results. More data are needed to accurately determine the sensitivity, specificity, and safety of this procedure and if results can be generalized." Overall, the guideline remarked that molecular analysis of cyst fluid is "still evolving" (Tanaka et al., 2017).

European Study Group on Cystic Tumours of the Pancreas

This guideline is considered "a joint initiative of the European Study Group on Cystic Tumors of the Pancreas, United European Gastroenterology, European Pancreatic Club, European-African Hepato-Pancreato-Biliary Association, European Digestive Surgery, and the European Society of Gastrointestinal Endoscopy."

The guidelines state that "DNA markers, in particular, mutations in *GNAS* and *KRAS*, have shown promise in identifying mucin-producing cysts. In cases in which the diagnosis is unclear, and a change in diagnosis will alter management, analysis of these mutations using highly sensitive techniques, such as next-generation sequencing (NGS), may be considered." This recommendation was given a grade of "2C." The guidelines also remarked that there is "insufficient evidence" to support the use of RNA or non-carcinoembryonic antigen protein markers in pancreatic cysts. This recommendation was given a grade of "1B" (The European Study Group on Cystic Tumours of the Pancreas, 2018).

International Cancer of the Pancreas Screening (CAPS) Consortium

The CAPS Consortium was convened to update the consensus recommendations for "management of individuals with increased risk of pancreatic cancer based on family history or germline mutation status (high-risk individuals)." In this Consortium, the authors state that "In some cases, evidence of pancreatic neoplasia can be inferred by

the presence of mutations detected in secretin-stimulated pancreatic fluid samples…but further investigation is needed to determine the value of these tests for patients under pancreatic surveillance" (Goggins et al., 2020).

World Gastroenterology Organization (WGO)

The WGO Global Guidelines provided key guidelines in diagnosis and management of pancreatic cystic lesions. The following recommendations were made.

1. "At the initial cyst fluid aspiration: carry out carcinoembryonic antigen (CEA), amylase, and cytology testing.
2. Molecular testing is not routinely done because of limited data and the expense, but it does hold promise for the future.
3. When fluid is aspirated, the following tests are recommended in the sequence described, depending on the volume of the aspirate:
    - Cytology: glycogen-rich cells (SCNs) or mucin-containing cells (MCNs and IPMNs), but the sensitivity is low.
    - Tumor markers: CEA level, an accurate tumor marker for diagnosing a mucinous PCN (the accuracy and cut-off level vary among laboratories).
    - Diagnostic molecular markers: KRAS, GNAS, VHL, CTNNB1.
    - Prognostic molecular markers: TP53, PIK3CA, PTEN.
    - Mucins: assessment of cyst mucin is complementary to cyst CEA levels and cytology
    - Viscosity: the "string sign" concept is an indirect, inexpensive, but subjective measurement of viscosity, assessed by placing a sample of aspirated fluid between the thumb and index finger and measuring the length of stretch prior to disruption.
    - Amylase (or lipase)" (Malagelada et al., 2019).

The guidelines also state that "molecular testing is not routinely done because of limited data and the expense, but it does hold promise for the future" (Malagelada et al., 2019).

American College of Radiology (ACR)

The Expert Panel on Gastrointestinal Imaging of the American College of Radiology created guidelines to determine the appropriate initial imaging study to further evaluate a pancreatic cyst that was incidentally detected on a nondedicated imaging study. ACR mentions that molecular assays for markers such as *K-ras, GNAS, PTEN, VHL, TP53*, and *PIK3CA* "may also assist in differentiating neoplastic cystic lesions and predicting cyst behavior. When performed in centers with expertise in EUS-FNA,

cytological evaluation can identify atypia, dysplasia, or neoplasia" (Fábrega-Foster et al., 2020).

American Society of Clinical Oncology (ASCO)

In 2019, ASCO published a guideline on the susceptibility to pancreatic cancer. The authors note the importance of emerging data despite very few clinical trials. In a disclaimer, they note: "This PCO should be read with the understanding that randomized clinical trial data are not available for these guidance statements, but it is the opinion of the Expert Panel that the statements made represent the state of the data available." Generally, they note that there are "currently no approved biomarkers for screening or surveillance" (Stoffel et al., 2018).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
82150	Amylase
82378	Carcinoembryonic antigen (CEA)
84999	Unlisted chemistry procedure
88108	Cytopathology, concentration technique, smears and interpretation (eg, Saccomanno technique)

88112	Cytopathology, selective cellular enhancement technique with interpretation (eg, liquid based slide preparation method), except cervical or vaginal
88173	Cytopathology, evaluation of fine needle aspirate; interpretation and report
0313U	Oncology (pancreas), DNA and mRNA next-generation sequencing analysis of 74 genes and analysis of CEA (CEACAM5) gene expression, pancreatic cyst fluid, algorithm reported as a categorical result (ie, negative, low probability of neoplasia or positive, high probability of neoplasia) Proprietary test: PancreaSeq® Genomic Classifier Lab/Manufacturer: Molecular and Genomic Pathology Laboratory/University of Pittsburgh Medical Center

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Pharmacogenetic Testing

Policy Number: AHS – M2021 – Pharmacogenetic Testing	Prior Policy Name and Number, as applicable: • M2021 – Cytochrome P450
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Pharmacogenetics aims to study the influence of genetic variation on drug response and drug toxicity, which allows physicians to select a more targeted therapeutic strategy to suit each patient's genetic profile (Aka et al., 2017). Genetic variations in human proteins, such as, cytochrome P450 enzymes, Thiopurine methyltransferase (*TPMT*), dihydropyrimidine dehydrogenase (*DPD*), and cell surface proteins, highlights the clinical importance of pharmacogenetic testing.

Cytochrome (CYP) P450 enzymes are a class of enzymes essential in the synthesis and breakdown metabolism of various molecules and chemicals. Found primarily in the liver, these enzymes are also essential for the metabolism of many medications. CYP P450 enzymes, approximately 58 CYP human genes, are essential to produce many biochemical building blocks, such as cholesterol, fatty acids, and bile acids. Additional cytochrome P450 are involved in the metabolism of drugs, carcinogens, and internal substances, such as toxins formed within cells. Mutations in CYP P450 genes can result in the inability to properly metabolize medications and other substances, leading to increased levels of toxic substances in the body (Bains, 2013; Tantisira & Weiss, 2023).

Thiopurine methyltransferase (*TPMT*) is an enzyme that methylates azathioprine, mercaptopurine and thioguanine into active thioguanine nucleotide metabolites. Azathioprine and mercaptopurine are used for treatment of nonmalignant immunologic disorders; mercaptopurine is used for treatment of lymphoid malignancies; and thioguanine is used for treatment of myeloid leukemias (Relling et al., 2013).

Dihydropyrimidine dehydrogenase (DPD), encoded by the gene *DPYD*, is a rate-limiting enzyme responsible for fluoropyrimidine catabolism. The fluoropyrimidines (5-fluorouracil and capecitabine) are drugs used in the treatment of solid tumors, such as colorectal, breast, and aerodigestive tract tumors (Amstutz et al., 2018).

A variety of cell surface proteins, such as antigen-presenting molecules and other proteins, are encoded by the human leukocyte antigen genes (*HLA*s). HLAs are also known as major histocompatibility complex (MHC) (Viatte, 2023).

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with any of the medications listed below, testing for the *CYP2D6* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:
    a) Amphetamine
    b) Aripiprazole
    c) Aripiprazole Lauroxil
    d) Atomoxetine
    e) Brexpiprazole
    f) Carvedilol
    g) Cevimeline
    h) Clozapine

i) Codeine
j) Desipramine
k) Deutetrabenazine
l) Eliglustat
m) Fluvoxamine
n) Gefitinib
o) Iloperidone
p) Lofexidine
q) Meclizine
r) Metoclopramide
s) Nortriptyline
t) Oliceridine
u) Ondansetron
v) Paroxetine
w) Perphenazine
x) Pimozide
y) Pitolisant
z) Propafenone
aa) Tamoxifen
bb) Tetrabenazine
cc) Thioridazine
dd) Tolterodine
ee) Tramadol
ff) Tropisetron
gg) Valbenazine
hh) Venlafaxine
ii) Vortioxetine

2) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with any of the medications listed

below, testing for the *CYP2D6* and *CYP2C19* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA:**

a) Amitriptyline
b) Clomipramine
c) Doxepin
d) Imipramine
e) Trimipramine

3) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy, testing for the *CYP2C19* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:

a) Abrocitinib
b) Brivaracetam
c) Citalopram
d) Clobazam
e) Clopidogrel
f) Dexlansoprazole (see Note 2)
g) Escitalopram
h) Flibanserin
i) Lansoprazole (see Note 2)
j) Mavacamten
k) Omeprazole (see Note 2)
l) Pantoprazole (in pediatric individuals) (see Note 2)
m) Sertraline
n) Voriconazole (see Note 2)

4) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with any of the medications listed below, testing for the *CYP2C9* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:

a) Celecoxib
b) Dronabinol

c) Erdafitinib
d) Flurbiprofen
e) Lornoxicam
f) Meloxicam
g) Nateglinide
h) Piroxicam
i) Siponimod
j) Tenoxicam

5) For individuals being considered for warfarin therapy, testing for the *CYP2C9*, *CYP4F2*, *VKORC1*, and rs12777823 genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**.

6) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with the below medications, testing for the *TPMT* and *NUDT15* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:
   a) Azathioprine
   b) Mercaptopurine
   c) Thioguanine

7) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with the below medications, testing for the *DPYD* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:
   a) Capecitabine
   b) Flucytosine
   c) Fluorouracil
   d) Tegafur

8) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with the below medications, testing for the following human leukocyte antigens (HLAs) genotypes once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:
   a) *HLA-B*57:01* before treatment with Abacavir
   b) *HLA-B*58:01* before treatment with Allopurinol

c) *HLA-B*15:02* for treatment with Oxcarbazepine

d) *HLA-B*15:02* and *HLA-A*31:01* for treatment with Carbamazepine

9) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with phenytoin/fosphenytoin, testing for the *CYP2C9* and *HLA-B*15:02* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**.

10) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with the medications listed below, testing for the *G6PD* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:

a) Pegloticase

b) Primaquine

c) Rasburicase

d) Tafenoquine

11) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with the below medications, testing for the following genotypes once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**:

a) *BCHE* for treatment with mivacurium or succinylcholine.

b) *CFTR* for treatment with ivacaftor, elexacaftor and tezacaftor, ivacaftor and lumacaftor, or ivacaftor and tezacaftor.

c) *CYP2B6* for treatment with efavirenz.

d) *CYP3A5* for treatment with tacrolimus.

e) *IFNL3* treatment with peginterferon alfa-2a, peginterferon alfa-2b or ribavirin.

f) *NAT2* for treatment with amifampridine or amifampridine phosphate.

g) *UGT1A1* for treatment with atazanavir, belinostat, irinotecan, nilotinib, pazopanib, or sacituzumab govitecan-hziy.

12) To aid in therapy selection and/or dosing for individuals being considered for therapy or who are in their course of therapy with belzutifan, testing for the *CYP2C19* and *UGT2B17* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**.

13) For individuals being considered for the use of halogenated volatile anesthetics or depolarizing muscle relaxants, testing for the *RYR1* and *CACNA1S* genotype once per lifetime (see Note 1) **MEETS COVERAGE CRITERIA**.

14) When formulary coverage allows a pharmacotherapy that is dependent on a known genetic status (e.g., *APOE* testing prior to lecanemab-irmb treatment), gene specific testing **MEETS COVERAGE CRITERIA.**

15) To identify patients at risk of statin-induced myopathy, genetic testing for the presence of variants in the *SLCO1B1* gene **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

16) The following pharmacogenetic testing **DOES NOT MEET COVERAGE CRITERIA**:

a) Genotyping more than once per lifetime (see Note 1) for any medication therapy.

b) Genotyping of the general population.

c) Pharmacogenetic testing (e.g., single nucleotide polymorphism [SNP] testing or SNP panel testing; single gene or multi-gene panel testing [see Note 3]) for all other situations not addressed above.

NOTES:

Note 1: Any gene may only be tested **once** per lifetime, regardless of the indication (an exception would be for *HLA* where a specific variant is tested for the medication). For example, if *CYP2C19* was tested for therapy with citalopram, additional testing for *CYP2C19* for treatment with clopidogrel is not needed and **DOES NOT MEET COVERAGE CRITERIA**. Testing in a patient post-liver transplant is not indicated.

Note 2: Pharmacogenetic testing for proton pump inhibitor therapies (PPIs) ***ONLY MEETS COVERAGE CRITERIA*** if the patient has an active *H. pylori* infection.

Note 3: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162-Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AACAP	American Academy of Child and Adolescent Psychiatry

AACC	American Association for Clinical Chemistry
AACF	American College of Cardiology Foundation
AAFP	American Family Physician
AAN	American Academy of Neurology
ACMG	American College of Medical Genetics and Genomics
AHA	American Heart Association
AMP	Association For Molecular Pathology
APOE	*Apolipoprotein E*
ARIA	Amyloid related imaging abnormalities
AS	Activity score
ASCPT	American Society for Clinical Pharmacology and Therapeutics
ASHP	American Society of Health System Pharmacists
BCHE	*Butyrylcholinesterase*
BDI	Beck's Depression Inventory
CACNA1S	*Calcium voltage-gated channel subunit alpha1 S*
CFTR	*Cystic fibrosis transmembrane conductance regulator*
COMT	*Catechol-O-methyltransferase*
CPIC	Clinical Pharmacogenetics Implementation Consortium
CYP	Cytochrome
CYP1A2	*Cytochrome P450 family 1 subfamily A member 2*
CYP2B6	*Cytochrome P450 family 2 subfamily B member 6*
CYP2C9	*Cytochrome P450 family 2 subfamily C member 9*
CYP2C19	*Cytochrome P450 family 2 subfamily C member 19*
CYP2D6	*Cytochrome P450 family 2 subfamily D member 6*
CYP3A4	*Cytochrome P450 family 3 subfamily A member 4*
CYP3A5	*Cytochrome P450 family 3 subfamily A member 5*
CYP4F2	*Cytochrome P450 family 4 subfamily F member 2*
DAT1	Former gene name of *solute carrier family 6 member 3*
DBH	*Dopamine beta-hydroxylase*
DPD	Dihydropyrimidine dehydrogenase
DPWG	Dutch Pharmacogenetics Working Group
DPYD	*Dihydropyrimidine dehydrogenase gene*
DRD1/2/4	*Dopamine receptor gene 1/2/4*
EMA	European Medicines Agency
FDA	Food and Drug Administration

G6PD	*Glucose-6-phosphate dehydrogenase gene*
HLA	Human leukocyte antigen
HLA-A	*Major histocompatibility complex, class I, A*
HLA-B	*Major histocompatibility complex, class I, B*
IFNL3	*Interferon lambda 3*
IM	Intermediate metabolizer
ISPG	The International Society of Psychiatric Genetics
MDD	Major depressive disorder
MHC	Major histocompatibility complex
MP	Mercaptopurine
MTHFR	*Methylenetetrahydrofolate reductase*
NAT2	*N-acetyltransferase 2*
NM	Normal metabolizer
NUDT15	*Nudix hydrolase 15*
OPRK1	*Opioid receptor kappa 1*
OPRM1	*Opioid receptor mu 1*
PM	Poor metabolizer
PPIs	Proton pump inhibitor therapies
RM	Rapid metabolizer
rs12777823	SNP that can affect warfarin sensitivity
RYR1	*Ryanodine receptor 1 gene*
SJS	Stevens Johnson Syndrome
SLC6A3	*Solute carrier family 6 member 3*
SLC6A4	*Solute carrier family 6 member 4*
SLCO1B1	*Solute carrier organic anion transporter family member 1B1*
SNP	Single nucleotide polymorphism
TAU	Treatment as usual
TCAs	Tricyclic antidepressants
TEN	Toxic epidermal necrolysis
TG	Thioguanine
TPMT	*Thiopurine methyltransferase*
TYMS	*Thymidylate synthetase*
UGT1A1	*UDP glucuronosyltransferase family 1 member A1*
UGT2B15	*Uridine diphosphate glycosyltransferase 2 family, member 15*
UGT2B17	*UDP glucuronosyltransferase family 2 member B17*
URM	Ultra-rapid metabolizer
VKORC1	*Vitamin K epoxide reductase complex subunit 1*

V. Scientific Background

Genetic variations play a potentially large role in an individual's response to medications. However, drug metabolism and responses are affected by many other factors, including age, sex, interactions with other drugs, and disease states (Tantisira & Weiss, 2023). Nonetheless, inherited differences in the metabolism and disposition of drugs and genetic polymorphisms in the targets of drug therapy can have a significant influence on the efficacy and toxicity of medications potentially even more so than clinical variables such as age and organ function (Kapur et al., 2014; Ting & Schug, 2016). Genetic variation can influence pharmacodynamic factors through variations affecting drug target receptors and downstream signal transduction, or pharmacokinetic factors, affecting drug metabolism and/or elimination (Tantisira & Weiss, 2023).

The Cytochrome P450 (CYP 450) system is a group of enzymes responsible for the metabolism of many endogenous and exogenous substances, including many pharmaceutical agents. This system may serve to "activate" an inactive form of a drug, as well as inactivate and/or clear a drug from circulation. The CYP 450 enzymes are responsible for the clearance of over half of all drugs, and their activity can be affected by diet, age, and other medications. The genes encoding for the CYP 450 enzymes are highly variable with multiple alleles that confer various levels of metabolic activity for specific substrates. In some cases, alleles can be highly correlated with ethnic background. Generally, there are three categories of metabolizer; ultra-rapid metabolizers, normal metabolizers, and poor metabolizers (Tantisira & Weiss, 2023).

Due to the variations in enzyme activity conferred by allelic differences, some CYP 450 alleles are associated with an increased risk for certain conditions or adverse outcomes with certain drugs. Knowledge of the allele type may assist in the selection of a drug, or in drug dosing. Three CYP 450 enzymes are most often considered regarding clinical use for drug selection and/or dosing. Phenotypes, such as CYP2D6, CYP2C9 and CYP2C19, have been associated with the metabolism of several therapeutic drugs, and various alleles of the *CYP450* gene confer differences in metabolic function. For these CYP 450 enzymes, it is thought that "poor metabolizers" could have less efficient elimination of a drug, and therefore may be at risk for side effects due to drug accumulation. For drugs that require activation by a specific CYP 450 enzyme, lower activity may yield less of the biologically active drug, which could result in lower drug efficacy. Individuals considered as "ultra-rapid metabolizers" may clear the drug more quickly than normal, and therefore may require higher doses to yield the desired therapeutic effect. Likewise, for drugs that require activation, these individuals may produce higher levels of the active drug, potentially causing unwanted side effects.

Due to these differences in enzyme activity, some alleles are associated with a higher risk of adverse outcomes depending on the drug prescribed (Tantisira & Weiss, 2023).

ApoE

Apolipoprotein E (*APOE*) is the gene most strongly associated as a genetic risk factor for late-onset Alzheimer disease. *APOE* can have three alleles: ε1, ε2, and ε4 (Sherva & Kowall, 2022). *APOE ε4* is a susceptibility gene, meaning it is associated with increased risk but does not cause Alzheimer disease, and not all patients with Alzheimer disease will carry *APOE ε4*. In one study of 1303 patients, 55% of those homozygous for *ε4* developed Alzheimer disease, while 27% of those heterozygous and 9% with no *ε4* allele also developed Alzheimer disease (Myers et al., 1996). *APOE*, as well as *CYP2D6,* carrier status may have an effect on a patient's response to drugs, "with *CYP2D6*-PMs [poor metabolizers], *CYP2D6*-Ums [ultrarapid metabalizers], and *APOE-4/4* carriers acting as the worst responders" (Cacabelos et al., 2012).

In 2023, the FDA approved Lecanemab (brand name Leqembi), an amyloid beta-directed antibody, for the treatment of Alzheimer disease in adult patients (FDA, 2023). One potential side effect of Leqembi is amyloid related imaging abnormalities (ARIA), which may be more likely to occur in people who are homozygous *APOE ε4* carries (Leqembi, 2024). The FDA includes that "the prescribing information states that testing for ApoE ε4 status should be performed before starting treatment with Leqembi to inform the risk of developing ARIA" (FDA, 2023).

CYP2C9

Warfarin (brand name Coumadin) is widely used as an anticoagulant in the treatment and prevention of thrombotic disorders. *CYP2C9* participates in warfarin metabolism, and several *CYP2C9* alleles have reduced activity, resulting in a higher circulating drug concentration. *CYP2C9**2 and *CYP2C9**3 are the most common variants with reduced activity. Variations in a second gene, *VKORC1*, also can impact warfarin's effectiveness. This gene codes for the enzyme that is the target for warfarin. Genotypes resulting in reduced metabolism may need a higher dose to achieve the desired efficacy (Tantisira & Weiss, 2023).

CYP2C19

Clopidogrel (brand name Plavix) is used to inhibit platelet aggregation and is given as a pro-drug that is metabolized to its active form by *CYP2C19*. Alleles *CYP2C19**2 and *CYP2C19**3 are associated with reduced metabolism of clopidogrel. Individuals with

the "poor metabolizer" alleles may not benefit from clopidogrel treatment at standard doses (Tantry et al., 2021). Tuteja et al. (2020) studied *CYP2C19* genotyping to guide antiplatelet therapy. A total of 504 participants contributed to this study, with only 249 participants genotyped. The authors noted that genotyping results "significantly influenced antiplatelet drug prescribing; however, almost half of *CYP2C19* LOF [loss-of-function] carriers continued to receive clopidogrel. Interventional cardiologists consider both clinical and genetic factors when selecting antiplatelet therapy following PCI [percutaneous coronary intervention]" (Tuteja et al., 2020).

CYP2D6

Tetrabenazine (brand name Xenazine) is used in the treatment of chorea associated with Huntington disease. This drug is metabolized for clearance primarily by *CYP2D6*. Poor metabolizers are considered to be those individuals with impaired *CYP2D6* function, and dosing is often influenced by how well a patient metabolizes the drug. For example, a poor metabolizer will often have a maximum dose of 50 mg daily whereas an extensive metabolizer has a maximum dose of 100 mg daily (Suchowersky, 2023).

Tamoxifen, a drug commonly used for the treatment and prevention of recurrence of estrogen receptor positive breast cancer, is metabolized by *CYP2D6*. Polymorphisms of *CYP2D6* have been noted to affect the efficacy of tamoxifen by affecting the amount of active metabolite produced. Endoxifen, which is the primary active metabolite of tamoxifen, has a 100-fold affinity for the estrogen receptor compared to tamoxifen, but poor metabolizers have been demonstrated to show lower than expected levels of plasma endoxifen (Ahern et al., 2017).

Codeine, which is commonly used to treat mild to moderate pain, is metabolized to morphine, a much more powerful opioid, by *CYP2D6*. Individuals with varying CYP2D6 activity may see negative side effects or a shorter duration of pain relief. The effect is significant enough to have caused fatalities in unusual metabolizers; for instance, an ultra-rapid metabolizing toddler was reported to have passed away after being given codeine for a routine dental operation (Kelly et al., 2012; Tantisira & Weiss, 2023).

TPMT

Thiopurine methyltransferase (TPMT) is an enzyme that methylates thiopurines into active thioguanine nucleotides. The *TPMT* gene is inherited as a monogenic co-dominant trait with ethnic differences in the frequencies of low-activity variant alleles. Individuals who inherit two inactive *TPMT* alleles will develop severe myelosuppression. Individuals that inherit only one inactive *TPMT* allele will develop moderate to severe myelosuppression, and those individuals who inherit both active *TPMT* alleles will have

a lower risk of myelosuppression. Therefore, genotyping for *TPMT* is critical before starting therapy with thiopurine drugs (Relling et al., 2013).

DPYD

The dihydropyrimidine dehydrogenase (*DPYD*) gene encodes for the rate-limiting enzyme dihydropyrimidine dehydrogenase, which is involved in catabolism of fluoropyrimidine drugs used in the treatment of solid tumors. Decreased DPD activity increases the risk for severe or even fatal drug toxicity when patients are being treated with fluoropyrimidine drugs. Numerous genetic variants in the *DPYD* gene have been identified that alter the protein sequence or mRNA splicing; however, some of these variants have no effect on DPD enzyme activity. The most studied causal variant of *DPYD* haplotype (HapB3) spans intron 5 to exon 11 and affects protein function. The most common variant in Europeans is HapB3 with a c.1129–5923C>G *DPYD* variant which demonstrates decreased function with carrier frequency of 4.7%, followed by c.190511G>A (carrier frequency: 1.6%) and c.2846A>T (carrier frequency: 0.7%). Approximately 7% of Europeans carry at least one decreased function *DPYD* variant. In people with African ancestry, the most common variant is c.557A>G (rs115232898, p.Y186C) and is relatively common (3–5% carrier frequency). Other *DPYD* decreased function variants are rare. Therefore, most available genetic tests focus on identifying the most common variants with well-established risk: (c.190511G>A, c.1679T>G, c.2846A>T, c.1129– 5923C>G) (Amstutz et al., 2018).

TYMS

TYMS (thymidylate synthetase) encodes an enzyme necessary for thymidine production. As with *DPYD*, *TYMS* is thought to be involved with the toxicity of fluoropyrimidines. Fluorouracil (FU)'s primary metabolite inhibits thymidylate synthetase by forming a stable complex with thymidylate synthetase and folate, thereby blocking activity of the enzyme. Polymorphisms in the *TYMS* gene further affect the interaction between *TYMS* and FU, potentially increasing the toxicity of FU. Genotyping of *TYMS* prior to treatment with FU or capecitabine has been suggested for clinical practice, but data has been varied (Krishnamurthi & Kamath, 2024).

Castro-Rojas et al. (2017) evaluated *TYMS* genotypes as predictors of both clinical response and toxicity to fluoropyrimidine-based treatment for colorectal cancer. A total of 105 patients were genotyped. The authors noted that while the 2R/2R genotype was associated with clinical response (odds ratio = 3.45), the genotype was also associated with severe toxicity (odds ratio = 5.21). The genotype was thought to be associated with low *TYMS* expression. The authors further identified the rs2853542

and rs151264360 alleles to be independent predictors of response failure to chemotherapy (Castro-Rojas et al., 2017).

HLAs

Human Leukocyte antigens (HLAs) are divided into three regions, such as class I, class II and class III. Each class has many gene loci, expressed genes and pseudogenes. The class I encodes HLA-A, HLA-B, HLA-C and other antigens. The class II encodes HLA-DP, DQ and DR. The class III region is located between class I and class II and does not encode any HLAs, but other immune response proteins (Viatte, 2023).

An article published by van der Wouden et al. (2019) reports on the development of the new PGx-Passport panel (pre-emptive pharmacogenetics-passport panel), which is able to test "58 germline variant alleles, located within 14 genes (*CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP3A5, DPYD, F5, HLA-A, HLA-B, NUDT15, SLCO1B1, TPMT, UGT1A1*, and *VKORC1*)"; this standardized panel is based on the Dutch Pharmacogenetics Working Group (DPWG) guidelines and will help physicians to optimize drug prescription in 49 common drugs. It is recommended by the authors that commercial and hospital laboratories utilize this panel for personalized medicinal purposes. Drug optimization in the 49 commonly prescribed drugs includes ten antidepressants, five immunosuppressants, five anti-cancer drugs, four anti-infectives, four anticoagulants, four antiepileptics, four antipsychotics, three proton pump inhibitors, two anti-arrhythmics, two analgesics, two antilipidemics, one antihypertensive, one psychostimulant, one anticontraceptive and one Gaucher disease drug (van der Wouden et al., 2019).

Proprietary Testing

Due to the increase in pharmacogenetic genotyping, proprietary gene panels have become commercially available. Panels encompassing the most common genes that influence drug metabolism have increased in usage. For example, Myriad's new proprietary panel "GeneSight" proposes it can "predict poorer antidepressant outcomes and to help guide healthcare providers to more genetically optimal medications," thereby leading to better patient outcomes. The test assesses every known metabolic pathway (CYP450 or otherwise) for a given drug and their metabolites, as well as the pharmacodynamic activity of the compound and its metabolites, any FDA information on that drug, and other validated research on the relevant alleles; this information is then integrated with the genetic test results. This allows the test to categorize the 64 medications into three categories: "green (use as directed), yellow (some moderate gene-drug interaction) and red (significant gene-

drug interaction)." Myriad states that this allows every metabolic pathway of a drug to be evaluated instead of the "one gene, one drug" view. Other GeneSight variations, such as GeneSight Psychotropic used for psychotropic medications, exist as well (Myriad, 2016, 2019, 2022). Still, other companies such as Mayo Clinic and Sema4 have developed their own pharmacogenetic panels, each with individually chosen analytes (Mayo, 2023; Sema4, 2022).

Benitez et al. (2018) assessed the cost-effectiveness of pharmacogenomics in treating psychiatric disorders. The authors compared 205 members that received guidance from GeneSight's Psychotropic to 478 members that received "treatment-as-usual" (TAU). Reimbursement costs were calculated over the 12 months pre- and post-index event periods. The authors found a total post-index cost savings of $5505, which was equivalent to a savings of $0.07 per-member-per-month (PMPM). The authors also evaluated the savings at different adoption rates of the GeneSight test. At 5% adoption, commercial payer savings was calculated at $0.02 PMPM and at 40% adoption, savings was $0.15 PMPM (Benitez et al., 2018).

The AmpliChip® (Roche Molecular Systems, Inc.) is the FDA-cleared test for CYP450 genotyping. This test genotypes *CYP2D6* and *CYP2C19*. From the FDA website: "The AmpliChip CYP4502C19 Test is designed to identify specific nucleic acid sequences and query for the presence of certain known sequence polymorphisms through analysis of the pattern of hybridization to a series of probes that are specifically complementary either to wild-type or mutant sequences" (FDA, 2005). The analytical accuracy was evaluated at 99.6%, or 806 of 809 samples identified correctly. This test assesses a total of 30 alleles, three for CYP219 and 27 for *CYP2D6* (FDA, 2005).

The OneOme RightMed Pharmacogenomic Test analyzes more than 100 variants in 27 genes to study how a patient may respond to certain medications. The test covers *CYP1A2, CYP2B6, CYP2C Cluster, CYP2C9, CYP2C19, CYP2D6, CYP3A4, CYP3A5, CYP4F2, COMT, DPYD, DRD2, F2, F5, GRIK4, HLA-A, HLA-B, HTR2A, HTR2C, IL28B (IFNL4), MTHFR*, NUDT15, OPRM1, SLC6A4, SLCO1B1, TPMT, UGT1A1*, and *VKORC1* (OneOme, 2021). Analytical validity of the test was assessed by comparing RightMed test results with bi-directional Sanger sequencing results, which resulted in 100% concordance. The RightMed test detects *CYP2D6* deletions, duplications, and hybrid alleles, but cannot differentiate duplications in the presence of a deletion (GTR, 2017).

Clinical Utility and Validity

A study evaluating GeneSight Psychotropic's clinical utility was performed by Greden et al. (2019); a total of 1167 patients with major depressive disorder were split into two randomized groups: treatment as usual (TAU) and pharmacogenetic-guided. Medications were classified as "congruent" (use as directed' or 'use with caution' test

categories) or "incongruent" ('use with increased caution and with more frequent monitoring' test category) with test results. After eight weeks, the authors found a statistically significant improvement in response and remission; 26% for the pharmacogenetic arm compared 19.9% for TAU and 15.3% for remission compared to 10.1% for TAU (Greden et al., 2019). The authors concluded that pharmacogenetic testing did not improve results, but significantly improved response and remission rates for "difficult-to-treat depression patients over standard of care" (Greden et al., 2019).

Kekic et al. (2020) studied genetic variants that commonly affect supportive care medications, which include, antidepressants, antiemetics, and analgesics, used in oncology practice. A total of 196 cancer patients were genotyped using a multi-gene panel, OneOme RightMed. The panel assessed 27 genes, including *CYP2C9, CYP2C19, CYP2D6, CYP3A4, COMT, OPRM1, GRIK4, HTR2A, SLC6A4,* associated with pain medications, antidepressants, and antiemetics. Of the 196 patients, 19.9% had prostate cancer, 17.9% had colorectal cancer, 14.8% had melanoma, and 47.4% had other cancer types. All 196 patients had at least one actionable polymorphism related to these supportive care medications, specifically, in *CYP2C19* and *CYP2D6*. Specifically, 67.3% of the patients had other than normal *CYP2D6* metabolizer phenotype and 57.1% had other than normal *CYP2C19* metabolizer phenotype. Based on the results, 37 patients were recommended an alternative analgesic, nine were recommended an alternative antiemetic, and 51 were recommended an alternative anti-depressant (Kekic et al., 2020).

Plumpton et al. (2019) evaluated the cost-effectiveness of panel tests with various pharmacogenes. The constructed multigene panel included *HLA-A*31:01, HLA-B*15:02, HLA-B*57:01, HLA-B*58:01, HLA-B (158T), and HLA-DQB1 (126Q)*, which are involved with various treatments (abacavir, carbamazepine, et al). The constructed multigene panel was found to provide a cost savings of $491 if all findings for all alleles were acted on, regardless of an allele's individual cost-effectiveness. Testing for patients eligible for abacavir (*HLA-B*57:01*) and clozapine (*HLA-B (158T*) and *HLA-DQB1 (126Q*)) was found to be cost-effective. However, testing for patients eligible for allopurinol (*HLA-B*58:01*) was not found to be cost-effective. Furthermore, testing for *HLA-A*31:01* for carbamazepine was found to be cost-effective, but not testing for *HLA-B*15:02* (Plumpton et al., 2019).

Braten et al. (2020) researched the impact of *CYP2C19* genotyping on the antidepressant drug sertraline, which is metabolized by the polymorphic *CYP2C19* enzyme. A total of 1202 patients participated and submitted 2190 sertraline serum samples. All patients were categorized based on *CYP2C19* genotype-predicted phenotype subgroups; these groups include normal (NM), ultra-rapid (UM),

intermediate (IM), and poor metabolizer (PM). Serum samples showed that *CYP2C19* IM and PM patients had significantly higher sertraline concentrations compared to NMs; "Based on the relative differences in serum concentrations compared to NMs, dose reductions of 60% and 25% should be considered in PMs and IMs, respectively, to reduce the risk of sertraline overexposure in these patients" (Braten et al., 2020).

Roscizewski et al. (2021) conducted a retrospective observational study to determine what effect pharmacogenomic testing had on "treatment decisions in patients with depressive symptoms in an interprofessional primary care setting." From April 2019 to March 2021, they identified 78 patients who underwent pharmacogenomic testing for psychotropic medications. They found that 53.8% of patients "experienced a change to their antidepressant regiment after [pharmacogenomic] testing," with the most cited change being addition of another antidepressant, followed by switching the antidepressant, then increased dose. This demonstrated how pharmacogenomic testing could be useful in informing clinical decision making at the beginning of treatment or "in those who experience an inadequate response to their prescribed regimen" and ensuring optimal patient recovery.

Stevenson et al. (2021) aimed to assess the potential impact of multigene pharmacogenomic testing among those hospitalized with COVID-19 in the United States. Through a cross-sectional analysis with electronic health records, researchers "characterized medication orders, focusing on medications with actionable guidance related to 14 commonly assayed genes (*CYP2C19, CYP2C9, CYP2D6, CYP3A5, DPYD, G6PD, HLA-A, HLA-B, IFNL3, NUDT15, SLCO1B1, TPMT, UGT1A1, and VKORC1*)." From their cohort, they found that 64 unique medications with pharmacogenomic guidance were ordered at least once, and about 89.7% of patients "had at least one order for a medication with PGx guidance and… (23.1%) had orders for 4 or more actionable medications." Through a simulation analysis, they estimated that "17 treatment modifications per 100 patients would be enabled if [pharmacogenomic] results were available," and that the genes *CYP2D6* and *CYP2C19* were responsible for most of the treatment modifications. Medications most affected included ondansetron, oxycodone, and clopidogrel. With additional investigations that support these findings, pharmacogenomic testing would better inform the curation of individualized treatment plans for patients suffering from severe COVID-19.

Galli et al. (2021) studied the use of guided selection of antiplatelet therapy for patients undergoing percutaneous coronary intervention. The authors conducted a meta-analysis that included 3656 relevant articles with 20743 patients. Overall, "guided selection of antiplatelet therapy was associated with a reduction in major adverse cardiovascular events and reduced bleeding, although not statistically significant." Additionally, cardiovascular death, myocardial infraction, stent thrombosis, and minor

bleeding were all reduced with guided therapy compared to standard therapy, but the risks of all-cause death and major bleeding did not differ. The authors concluded that "guided selection of antiplatelet therapy improved both composite and individual efficacy outcomes with a favourable safety profile, driven by a reduction in minor bleeding, supporting the use of platelet function or genetic testing to optimise the choice of agent in patients undergoing PCI" (Galli et al., 2021).

Oslin et al. (2022) conducted a randomized clinical trial that compared treatment guided by pharmacogenomic testing vs. usual care "to determine whether pharmacogenomic testing affects antidepressant medication selection and whether such testing leads to better clinical outcomes". Participants of this clinical trial included 676 clinicians and 1944 patients. Criteria for patient enrollment were those with major depressive disorder who were initiating or switching treatment with a single antidepressant and exclusion included those who have active substance use disorder, mania, psychosis, or concurrent treatment with a specified list of medications. Results of this study determined "remission rates over 24 weeks were higher among patients whose care was guided by pharmacogenomic testing than those in usual care (OR, 1.28 [95% CI, 1.05 to 1.57]; P = .02; risk difference, 2.8% [95% CI, 0.6% to 5.1%]) but were not significantly higher at week 24 when 130 patients in the pharmacogenomic-guided group and 126 patients in the usual care group were in remission (estimated risk difference, 1.5% [95%CI, -2.4% to 5.3%]; P = .45)". In conclusion, in provision of pharmacogenomic testing for drug-gene interaction amongst patients with major depressive disorder, pharmacogenomic testing "reduced prescription of medications with predicted drug-gene interactions compared to usual care. Provision test results had small nonpersistent effects on symptom remission" (Oslin et al., 2022).

Ghanbarian et al. (2023) studied the cost-effectiveness of pharmacogenetic testing used to guide prescription of antidepressants. The authors looked at data from patients with major depressive disorder in British Columbia, Canada. The data included unique patient characteristics, including metabolizer phenotypes, incremental costs, life-years, and quality-adjusted life-years. "Pharmacogenomic-guided care was associated with 37% fewer patients with refractory depression over 20 years." The costs of pharmacogenetic testing were estimated to be offset within about two years of use, with an overall saving of 956 million Canadian dollars (4926 Canadian dollars per patient) (Ghanbarian et al., 2023).

The 2023 PREPARE (preemptive pharmacogenomic testing for preventing adverse drug reactions) trial investigated the effects of pre-emptive genotyping using a pharmacogenetic panel on adverse drug reactions. Swen et al. (2023) conducted an "open-label, multicentre, controlled, cluster-randomised, crossover implementation

study of a 12-gene pharmacogenetic panel in 18 hospitals, nine community health centres, and 28 community pharmacies in seven European countries." A total of 6944 patients receiving their first prescription for a clinically recommended drug were included in the study. The participants were divided into a study group, which received genotyping and recommended treatment adjustments, and a control group, which received standard care. The primary outcome measured was the occurrence of clinically relevant adverse drug reactions within 12-weeks. A clinically relevant adverse drug reactions occurred in 21.5% of patients in the study group (N=2923), and 28.6% of patients in the control group (N=3270). The authors concluded that "genotype-guided treatment using a 12-gene pharmacogenetic panel significantly reduced the incidence of clinically relevant adverse drug reactions and was feasible across diverse European health-care system organisations and settings" (Swen et al., 2023)

VI. Guidelines and Recommendations

Clinical Pharmacogenetics Implementation Consortium (CPIC)

CPIC guidelines provide guidance to physicians on how to use genetic testing to help them to optimize drug therapy. The guidelines and projects were endorsed by several professional societies including The Association for Molecular Pathology (AMP), The American Society for Clinical Pharmacology and Therapeutics (ASCPT) and The American Society of Health-System Pharmacists (ASHP) (CPIC, 2023b).

In their list of guidelines, CPIC provides specific therapeutic recommendations for drugs metabolized by Cytochrome P450 enzymes and other important metabolic enzymes.

CYP2C9 Genotypes

Drug	***CYP2C9*/ Phenotype**	**Summary of CPIC Therapeutic Recommendations**	**Level of Recommendations**	**Reference**
Phenytoin/ fosphenytoin based on *HLA-B*15:02*	HLA-B*15:02 Positive- Normal Metabolizer (NM), Intermediate Metabolizer	If patient is phenytoin-naïve, do not use phenytoin/fosphenytoin. Avoid carbamazepine and oxcarbazepine. If the patient has previously used phenytoin continuously for longer than three months	Strong	(Caudle et al., 2014; Karnes et al., 2021)

	(EM), and Poor Metabolism (M)	without incidence of cutaneous adverse reactions, cautiously consider use of phenytoin in the future.		
	HLA-B*15:02 Negative-Normal Metabolizer (NM)	No adjustments needed from typical dosing strategies. Subsequent doses should be adjusted according to therapeutic drug monitoring, response, and side effects. An HLA-B*15:02 negative test does not eliminate the risk of phenytoin-induced SJS/TEN, and patients should be carefully monitored according to standard practice.	Strong	
	HLA-B*15:02 Negative-Intermediate Metabolizer (IM)	No adjustments needed from typical dosing strategies. Subsequent doses should be adjusted according to therapeutic drug monitoring, response and side effects. An HLA-B*15:02 negative test does not eliminate the risk of phenytoin-induced SJS/TEN, and patients should be carefully monitored according to standard practice. For first dose, use typical initial or loading dose. For subsequent doses, use approximately 25% less than typical maintenance dose. Subsequent doses should be adjusted according to therapeutic drug monitoring, response and side effects.	Moderate	

	HLA-B*15:02 Negative-Poor Metabolizer (PM)	For first dose, use typical initial or loading dose. For subsequent doses use approximately 50% less than typical maintenance dose. Subsequent doses should be adjusted according to therapeutic drug monitoring, response, and side effects. An HLA-B*15:02 negative test does not eliminate the risk of phenytoin-induced SJS/TEN, and patients should be carefully monitored according to standard practice.	Strong	
Warfarin	Various phenotypes	Genotype-guided warfarin dosing is very complex and involves a combination of *CYP2C9*, *VKORC1*, *CYP4F2* and rs12777823 as well as an algorithm including ancestry information.	Multiple	(Johnson et al., 2017)
Celecoxib, flurbiprofen, ibuprofen, lornoxicam	NM	"In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals"	Strong	(Theken et al., 2020)
	IM (Activity Score [AS] = 1.5)	"Initiate therapy with recommended starting dose. In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals."	Moderate	
	IM (AS = 1)	"Initiate therapy with lowest	Moderate	

		recommended starting dose. Titrate dose upward to clinical effect or maximum recommended dose with caution. In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals. Carefully monitor adverse events, such as blood pressure and kidney function during course of therapy."		
	PM	"Initiate therapy with 25–50% of the lowest recommended starting dose. Titrate dose upward to clinical effect or 25–50% of the maximum recommended dose with caution. In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals. Upward dose titration should not occur until after steady-state is reached (at least 8 days for celecoxib and 5 days for ibuprofen, flurbiprofen, and lornoxicam after first dose in PMs). Carefully monitor adverse events such as blood pressure and kidney function during	Moderate	

		course of therapy. Alternatively, consider an alternate therapy not metabolized by CYP2C9 or not significantly impacted by CYP2C9 genetic variants in vivo"		
Meloxicam	NM	"Initiate therapy with recommended starting dose. In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals"	Strong	(Theken et al., 2020)

Alternatively, consider alternative therapy. Choose an alternative therapy not metabolized by CYP2C9 or not significantly impacted by	Moderate	

		CYP2C9 genetic variants in vivo or choose an NSAID metabolized by CYP2C9 but with a shorter half-life"		
	PM	"Choose an alternative therapy not metabolized by CYP2C9 or not significantly impacted by CYP2C9 genetic variants in vivo or choose an NSAID metabolized by CYP2C9 but with a shorter half-life"	Moderate	
Piroxicam/ Tenoxicam	NM	"Initiate therapy with recommended starting dose. In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals."	Strong	(Theken et al., 2020)
	IM AS 1.5	"Initiate therapy with recommended starting dose. In accordance with the prescribing information, use the lowest effective dosage for shortest duration consistent with individual patient treatment goals."	Moderate	
	IM AS 1	"Choose an alternative therapy not metabolized by CYP2C9 or not significantly impacted by CYP2C9 genetic variants in vivo or choose an NSAID metabolized by CYP2C9 but with a shorter half-life"	Moderate (Optional for Tenoxicam)	

	PM	"Choose an alternative therapy not metabolized by CYP2C9 or not significantly impacted by CYP2C9 genetic variants in vivo or choose an NSAID metabolized by CYP2C9 but with a shorter half-life"	Moderate (Optional for Tenoxicam)	

***CYP2D6* Genotype**

Drug	***CYP2D6* Phenotype**	**Summary of CPIC Therapeutic Recommendations**	**Level of Recommendations**	**Reference**
Amitriptyline and Nortripylin e Other TCAs (tricyclic antidepressants): clomipramine, desipramine, doxepin, imipramine, and trimipramine	Ultra-rapid Metabolizer (URM)	Avoid tricyclic use due to potential lack of efficacy. Consider alternative drug not metabolized by *CYP2D6*. If a TCA is warranted, consider titrating to a higher target dose (compared to normal metabolizers). Utilize therapeutic drug monitoring to guide dose adjustments.	Strong (recommendation for other TCAs is Optional)	(Hicks et al., 2016)
	Normal Metabolizer (NM)	Initiate therapy with recommended starting dose.	Strong (recommendation for other TCAs is Strong)	
	IM	Consider a 25% reduction of recommended starting dose. Utilize therapeutic drug monitoring to guide dose adjustments.	Moderate (recommendation for other TCAs is Optional)	
	PM	Avoid tricyclic use due to potential for side effects.	Strong	

Drug	*CYP2D6* Phenotype	Summary of CPIC Therapeutic Recommendations	Level of Recommendations	Reference
		Consider alternative drug not metabolized by *CYP2D6*. If a TCA is warranted, consider a 50% reduction of recommended starting dose. Utilize therapeutic drug monitoring to guide dose adjustments.	(recommendation for other TCAs is Optional)	
Codeine	URM	Avoid codeine use due to potential for toxicity.	Strong	(Crews et al., 2021)
	EM	Use label-recommended age or weight-specific dosing.	Strong	
	IM	Use label-recommended age or weight-specific dosing. If no response, consider alternative analgesics such as morphine or a nonopioid.	Moderate	
	PM	Avoid codeine use because of possibility of diminished analgesia	Strong	
Paroxetine	URM	Select alternative drug not predominantly metabolized by *CYP2D6*	Moderate	(Bousman et al., 2023)
	M	Initiate therapy with recommended starting dose.	Strong	
	IM	Consider a lower starting dose and slower titration schedule as compared with normal metabolizers	Optional	
	PM	Consider a 50% reduction in recommended starting dose, slower titration schedule, and	Moderate	

Drug	*CYP2D6* Phenotype	Summary of CPIC Therapeutic Recommendations	Level of Recommendations	Reference
		a 50% lower maintenance dose as compared with normal metabolizers.		
Fluvoxamine	URM	No recommendation due to lack of evidence.	No recommendation	(Bousman et al., 2023)
	EM	Initiate therapy with recommended starting dose.	Strong	
	IM	Initiate therapy with recommended starting dose.	Moderate	
	PM	Consider a 25–50% lower starting dose and slower titration schedule as compared with normal metabolizers or consider a clinically appropriate alternative antidepressant not predominantly metabolized by *CYP2D6*	Optional	
Ondansetron and Tropisetron	URM	Select alternative drug not predominantly metabolized by *CYP2D6* (i.e., granisetron).	Moderate	(Bell et al., 2016)
	NM	Initiate therapy with recommended starting dose.	Strong	
	IM	Insufficient evidence demonstrating clinical impact based on *CYP2D6* genotype. Initiate therapy with recommended starting dose.	No recommendation	
	PM	Insufficient evidence demonstrating clinical impact based on *CYP2D6* genotype.	No recommendation	

Drug	*CYP2D6* Phenotype	Summary of CPIC Therapeutic Recommendations	Level of Recommendations	Reference
		Initiate therapy with recommended starting dose.		
Tamoxifen	URM	Avoid moderate and strong *CYP2D6* inhibitors. Initiate therapy with recommended standard of care dosing (tamoxifen 20 mg/day).	Strong	(Goetz et al., 2018)
	NM	Avoid moderate and strong *CYP2D6* inhibitors. Initiate therapy with recommended standard of care dosing (tamoxifen 20 mg/day).	Strong	
	NM/IM	Consider hormonal therapy such as an aromatase inhibitor for postmenopausal [individuals] or aromatase inhibitor along with ovarian function suppression in premenopausal [individuals], given that these approaches are superior to tamoxifen regardless of *CYP2D6* genotype. If aromatase inhibitor use is contraindicated, consideration should be given to use a higher but FDA approved tamoxifen dose (40 mg/day).45 Avoid *CYP2D6* strong to weak inhibitors.	Optional (Controversy remains)	
	IM	Consider hormonal therapy such as an aromatase inhibitor for postmenopausal	Moderate	

Drug	*CYP2D6* Phenotype	Summary of CPIC Therapeutic Recommendations	Level of Recommendations	Reference
		[individuals] or aromatase inhibitor along with ovarian function suppression in premenopausal [individuals], given that these approaches are superior to tamoxifen regardless of *CYP2D6* genotype. If aromatase inhibitor use is contraindicated, consideration should be given to use a higher but FDA approved tamoxifen dose (40 mg/day). Avoid *CYP2D6* strong to weak inhibitors.		
	PM	Recommend alternative hormonal therapy such as an aromatase inhibitor for postmenopausal [individuals] or aromatase inhibitor along with ovarian function suppression in premenopausal [individuals] given that these approaches are superior to tamoxifen regardless of *CYP2D6* genotype and based on knowledge that *CYP2D6* poor metabolizers switched from tamoxifen to anastrozole do not have an increased risk of recurrence. Note, higher dose tamoxifen (40 mg/day)	Strong	

Drug	*CYP2D6* Phenotype	Summary of CPIC Therapeutic Recommendations	Level of Recommendations	Reference
		increases but does not normalize endoxifen concentrations and can be considered if there are contraindications to aromatase inhibitor therapy.		
Atomoxetine (for children)	URM	Initiate with a dose of 0.5 mg/kg/day and increase to 1.2 mg/kg/day after 3 days. If no clinical response and in the absence of adverse events after 2 weeks, consider obtaining a peak plasma concentration (1–2 hours after dose administered). If < 200 ng/mL, consider a proportional increase in dose to approach 400 ng/mL	Moderate	(Brown et al., 2019)
	NM	Initiate with a dose of 0.5 mg/kg and increase to 1.2 mg/kg/day after 3 days. If no clinical response and in the absence of adverse events after 2 weeks, consider obtaining a peak plasma concentration (1–2 hours after dose administered). If < 200 ng/mL, consider a proportional increase in dose to approach 400 ng/mL.	Moderate

		(> 12 weeks) and efficacy achieved, consider 50% reduction in daily dose and monitor for continued efficacy"		

***CYP2D6* and *CYP2C19* Genotypes (Caudle et al., 2020; Hicks et al., 2016) for Amitriptyline, Clomipramine, Doxepin, Imipramine, and Trimipramine**

Phenotype	***CYP2D6***	***CYP2D6***	***CYP2D6***	***CYP2D6***
CYP2C19	**UM**	**NM**	**IM**	**PM**
URM	Avoid amitriptyline use Recommendation: Optional	Consider alternative drug not metabolized by *CYP2C19*. Recommendation: Optional	Consider alternative drug not metabolized by *CYP2C19*. Recommendation: Optional	Avoid amitriptyline use Recommendation: Optional
NM	Avoid amitriptyline use. If amitriptyline is warranted, consider titrating to a higher target dose (compared to normal metabolizers) Recommendation: Strong	Initiate therapy with recommended starting dose. Recommendation: Strong	Consider a 25% reduction of recommended starting dose. Recommendation: Moderate	Avoid amitriptyline use. If Amitriptyline is warranted, consider a 50% reduction of recommended starting dose. Recommendation: Strong

IM	Avoid amitriptyline use Recommendation: Optional	Initiate therapy with recommended starting dose. Recommendation: Strong	Consider a 25% reduction of recommended starting dose. Recommendation: Optional This recommendation may also be considered for diplotypes with an activity score of 1.	Avoid amitriptyline use. If Amitriptyline is warranted, consider a 50% reduction of recommended starting dose. Recommendation: Optional
PM	Avoid amitriptyline use Recommendation: Optional	Avoid amitriptyline use. If Amitriptyline is warranted, consider a 50% reduction of recommended starting dose. Recommendation: Moderate	Avoid amitriptyline use Recommendation: Optional	Avoid amitriptyline use Recommendation: Optional

***TPMT* Genotype**

Drug	***TPMT* Phenotype**	**Summary of CPIC Therapeutic Recommendations**	**Level of Recommendations**	**Reference**
Mercaptopurine (MP)	NM	Start with normal starting dose (e.g., 75 mg/m^2/d or 1.5 mg/kg/d) and adjust doses of MP (and of any other myelosuppressive therapy) without any special emphasis on MP compared to other agents.	Strong	(Relling et al., 2018)

		Allow 2 weeks to reach steady state after each dose adjustment. Consider evaluating TPMT erythrocyte activity to assess TPMT phenotype. If thiopurines are required and either TPMT or NUDT15 status is unknown, monitor closely for toxicity.		
	IM	Start with reduced doses (start at 30–70% of full dose: e.g., at 50 mg/m^2/d or 0.75 mg/kg/d) and adjust doses of MP based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment. In those who require a dosage reduction based on myelosuppression, the median dose may be ~40% lower (44 mg/m^2) than that tolerated in wild-type patients (75 mg/m^2). In setting of myelosuppression, and depending on other therapy, emphasis should be on reducing MP over other agents. Consider evaluating TPMT erythrocyte activity to assess TPMT phenotype. If thiopurines are required and either TPMT or NUDT15 status is unknown, monitor closely for toxicity.	Strong	
	PM	For malignancy, start with drastically reduced doses (reduce daily dose by 10-fold and reduce frequency to thrice weekly	Strong	

		instead of daily, e.g., 10 mg/m^2/d given just 3 days/week) and adjust doses of MP based on degree of myelosuppression and disease-specific guidelines. Allow 4–6 weeks to reach steady state after each dose adjustment. In setting of myelosuppression, emphasis should be on reducing MP over other agents. For nonmalignant conditions, consider alternative nonthiopurine immunosuppressant therapy. Consider evaluating TPMT erythrocyte activity to assess TPMT phenotype. If thiopurines are required and either TPMT or NUDT15 status is unknown, monitor closely for toxicity.		
Azathioprine	NM	Start with normal starting dose (e.g., 2–3 mg/kg/d) and adjust doses of azathioprine based on disease-specific guidelines. Allow 2 weeks to reach steady state after each dose adjustment. Consider evaluating erythrocyte TPMT activity to assess TPMT phenotype. If thiopurines are required and TPMT status is unknown, monitor closely for toxicity.	Strong	(Relling et al., 2018)
	IM	Start with reduced starting doses (30%-80% of normal dose) if normal starting dose is 2-3 mg/kg/day, (e.g. 0.6 – 2.4 mg/kg/day), and adjust doses of azathioprine based on degree of	Strong	

		myelosuppression and disease-specific guidelines. Allow 2-4 weeks to reach steady-state after each dose adjustment. Consider evaluating erythrocyte TPMT activity to assess TPMT phenotype. If thiopurines are required and TPMT status is unknown, monitor closely for toxicity.		
	PM	For non-malignant conditions, consider alternative-nonthiopurine immunosuppressant therapy or malignancy, start with drastically reduced doses (reduce daily dose by 10-fold and dose thrice weekly instead of daily) and adjust doses of azathioprine based on degree of myelosuppression and disease specific guidelines. Allow 4-6 weeks to reach steady state after each dose adjustment. Consider evaluating erythrocyte TPMT activity to assess TPMT phenotype. If thiopurines are required and TPMT status is unknown, monitor closely for toxicity.	Strong	
Thioguanine	NM	Start with normal starting dose (e.g. 40-60 mg/m2 /day). Adjust doses of thioguanine (TG) and of other myelosuppressive therapy without any special emphasis on TG. Allow 2 weeks to reach steady state after each dose adjustment. Consider evaluating erythrocyte TPMT activity to	Strong	(Relling et al., 2013; Relling et al., 2018)

		assess TPMT phenotype. If thiopurines are required and TPMT status is unknown, monitor closely for toxicity.		
	IM	Start with reduced doses (50% to 80% of normal dose) if normal starting dose is ≥40-60 mg/m2 /day (e.g. 20-48 mg/m2 /day) and adjust doses of TG based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment. In setting of myelosuppression, and depending on other therapy, emphasis should be on reducing TG over other agents. Consider evaluating erythrocyte TPMT activity to assess TPMT phenotype. If thiopurines are required and TPMT status is unknown, monitor closely for toxicity.	Moderate	
	PM	Start with drastically reduced doses (reduce daily dose by 10-fold and dose thrice weekly instead of daily) and adjust doses of TG based on degree of myelosuppression and disease-specific guidelines. Allow 4–6 weeks to reach steady state after each dose adjustment. In setting of myelosuppression, emphasis should be on reducing TG over other agents. For nonmalignant conditions, consider alternative	Strong	

		nonthiopurine immunosuppressant therapy. Consider evaluating erythrocyte TPMT activity to assess TPMT phenotype. If thiopurines are required and TPMT status is unknown, monitor closely for toxicity.		

***NUDT15* Genotype**

Drug	***NUDT15* Phenotype**	**Summary of CPIC Therapeutic Recommendations**	**Level of Recommendations**	**Reference**
Mercaptopurine	NM	Start with normal starting dose (e.g., 75 mg/m^2/d or 1.5 mg/kg/d) and adjust doses of MP (and of any other myelosuppressive therapy) without any special emphasis on MP compared to other agents. Allow 2 weeks to reach steady state after each dose adjustment.	Strong	(Relling et al., 2018)
	IM	Start with reduced doses (start at 30–80% of normal dose: if normal starting dose is ≥75 mg/m2 /day or ≥ 1.5 mg/kg/day (e.g. start at 25-60 mg/m2 /day or 0.45-1.2 mg/kg/day) and adjust doses of MP based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment. If myelosuppression occurs, and	Strong	

Drug	*NUDT15* Phenotype	Summary of CPIC Therapeutic Recommendations	Level of Recommendations	Reference
		depending on other therapy, emphasis should be on reducing mercaptopurine over other agents. If normal starting dose is already < 1.5mg/kg/day, dose reduction may not be recommended.		
	PM	For malignancy, initiate dose at 10 mg/m2 /day and adjust dose based on myelosuppression and disease specific guidelines. Allow 4-6 weeks to reach steady state after each dose adjustment. If myelosuppression occurs, emphasis should be on reducing mercaptopurine over other agents. For nonmalignant conditions, consider alternative nonthiopurine immunosuppressant therapy.	Strong	
Azathioprine	NM	Start with normal starting dose (e.g., 2–3 mg/kg/day) and adjust doses of azathioprine based on disease-specific guidelines. Allow 2 weeks to reach steady state after each dose adjustment.	Strong	(Relling et al., 2018)
	IM	Start with reduced doses (start at 30–80% of normal dose: if normal starting dose is 2-3 mg/kg/day, (e.g. 0.6 – 2.4 mg/kg/day) and adjust doses of MP based on degree of	Strong

		available and effective in patients with MHS		
	Uncertain susceptibility	Clinical findings, family history, further genetic testing and other laboratory data should guide use of halogenated volatile anesthetics or depolarizing muscle relaxants.	Strong	

CPIC notes that evidence for *TYMS* testing is unclear or weak and have assigned *TYMS* a "D" level recommendation. CPIC does not recommend any change in prescription based on *TYMS* genotype (CPIC, 2023a).

American College of Medical Genetics and Genomics (ACMG)

ACMG notes that *CYP2C9* and *VKORC1* testing may be useful for assessing unusual responses to warfarin, but cannot recommend for or against routine genotyping (ACMG, 2007).

American College of Cardiology Foundation (AACF) and the American Heart Association (AHA) Joint Guidelines

A report by the ACCF and the AHA on genetic testing for selection and dosing of clopidogrel provided the following recommendations for practice:

- "Clinicians must be aware that genetic variability in CYP enzymes alter clopidogrel metabolism, which in turn can affect its inhibition of platelet function. Diminished responsiveness to clopidogrel has been associated with adverse patient outcomes in registry experiences and clinical trials."
- "The specific impact of the individual genetic polymorphisms on clinical outcome remains to be determined (e.g., the importance of *CYP2C19**2 versus *3 or *4 for a specific patient), and the frequency of genetic variability differs among ethnic groups."
- "Information regarding the predictive value of pharmacogenomic testing is very limited at this time; resolution of this issue is the focus of multiple ongoing studies."

- "The evidence base is insufficient to recommend either routine genetic or platelet function testing at the present time. There is no information that routine testing improves outcome in large subgroups of patients. In addition, the clinical course of the majority of patients treated with clopidogrel without either genetic testing or functional testing is excellent. Clinical judgment is required to assess clinical risk and variability in patients considered to be at increased risk. Genetic testing to determine if a patient is predisposed to poor clopidogrel metabolism ("poor metabolizers") may be considered before starting clopidogrel therapy in patients believed to be at moderate or high risk for poor outcomes. This might include, among others, patients undergoing elective high-risk PCI procedures (e.g., treatment of extensive and/or very complex disease). If such testing identifies a potential poor metabolizer, other therapies, particularly prasugrel for coronary patients, should be considered. (Holmes et al., 2010).

American Academy of Neurology (AAN)

The AAN published a position paper on the use of opioids for chronic non-cancer pain. Regarding pharmacogenetic testing, the guidelines state "genotyping to determine whether response to opioid therapy can/should be more individualized will require critical original research to determine effectiveness and appropriateness of use" (Franklin, 2014).

American Association for Clinical Chemistry (AACC) Academy Laboratory Medicine Practice Guidelines

AACC Academy issued laboratory medicine practice guidelines on using clinical laboratory tests to monitor drug therapy in pain management. Their guidelines have a total of 26 recommendations and seven expert opinions. Regarding pharmacogenetic testing for pain management, they stated in the recommendation #20 (Level A, II) that: "While the current evidence in the literature doesn't support routine genetic testing for all pain management patients, it should be considered to predict or explain variant pharmacokinetics, and/ or pharmacodynamics of specific drugs as evidenced by repeated treatment failures, and/or adverse drug reactions/toxicity" (AACC, 2017).

American Family Physician (AAFP)

The AAFP has published guidelines on pharmacogenetics: using genetic information to guide drug therapy. CPIC guidelines are cited for many medication/allele combinations in this article. The recommendations by the AAFP are listed in the table below taken from Chang et al. (2015):

Allele	Medications	Test Results and Clinical Implications	Comments
CYP2D6	Codeine, hydrocodone, oxycodone, tramadol	Ultrarapid metabolizer: Avoid codeine because of potential for toxicity Poor metabolizer: Avoid codeine and possibly tramadol because of possible lack of effectiveness	CPIC guidance limits genotype-guided dosing recommendations to codeine. Alternative analgesics not affected by *CYP2D6* variability include morphine, oxymorphone, and nonopioid analgesics. Oxycodone may also have reduced effectiveness in poor *CYP2D6* metabolizers.
CYP2C19	Clopidogrel (Plavix)	Intermediate metabolizer: Use alternative antiplatelet therapy if no contraindications Poor metabolizer: Use alternative antiplatelet therapy if no contraindications	Clopidogrel prescribing information states that *CYP2C19* tests can be used as an aid to determine therapeutic strategy in patients with acute coronary syndromes who are undergoing percutaneous coronary intervention. CPIC guidance limits genotype-guided dosing recommendations to patients undergoing percutaneous coronary intervention for acute coronary syndromes (excluding medical management of acute coronary syndromes, stroke, and peripheral artery disease). ACCF/AHA guidelines state that genotyping may be considered in patients with unstable angina/non-ST segment elevation myocardial infarction (or after percutaneous coronary intervention for acute coronary syndromes) if test results could alter management. Alternative antiplatelet therapy not affected by *CYP2C19* variability

Allele	Medications	Test Results and Clinical Implications	Comments
			includes prasugrel (Effient) and ticagrelor (Brilinta).
CYP2C19	Amitriptyline	Poor metabolizer: Consider 50% reduction in recommended starting dose	CPIC guidance is available for *CYP2D6*- and *CYP2C19*-genotype guided tricyclic antidepressant therapy. Although limited data exist for other tricyclic antidepressants, most supporting evidence of clinically relevant gene-drug effects is for amitriptyline and nortriptyline (Pamelor).
CYP2C19	Citalopram (Celexa), escitalopram (Lexapro)	Ultrarapid metabolizer: Consider alternative Poor metabolizer: Consider 50% starting dose reduction and titrate to response, or use alternative	CPIC guidance is available for *CYP2C19*-genotype guided citalopram and escitalopram therapy. FDA label for citalopram states that 20 mg per day is the maximum recommended dosage for patients older than 60 years, patients with hepatic impairment, and *CYP2C19* poor metabolizers or patients taking cimetidine (Tagamet) or another *CYP2C19* inhibitor.
CYP2C19	Sertraline (Zoloft)	Ultrarapid metabolizer: If patient does not respond to recommended dose, consider alternative Poor metabolizer: Consider 50% dose reduction or alternative	CPIC guidance is available for *CYP2C19*-genotype guided sertraline therapy.
CYP2D6	Amitriptyline, nortriptyline	Ultrarapid metabolizer: Avoid	CPIC guidance is available for CYP2D6- and CYP2C19-genotype

Allele	Medications	Test Results and Clinical Implications	Comments
		because of possible lack of effectiveness Poor metabolizer: Avoid because of possible adverse effects; if use is warranted, consider 50% reduction in recommended starting dose	guided tricyclic antidepressant therapy. Although limited data exist for other tricyclic antidepressants, most supporting evidence of clinically relevant gene-drug effects is for amitriptyline and nortriptyline.
CYP2D6	Aripiprazole (Abilify)	Poor metabolizer: Decrease dose	Quality of supporting evidence is classified as low by PharmGKB FDA label for aripiprazole states that in poor metabolizers, the usual dose should initially be reduced to 50% and then adjusted to achieve a favorable clinical response; in poor metabolizers receiving a strong CYP3A4 inhibitor, the usual dose should be reduced to 25%.
CYP2D6	Atomoxetine (Strattera)	Poor metabolizer: Adjust dose	Quality of supporting evidence is classified as moderate (Level 2a) by PharmGKB. FDA label for atomoxetine states that in poor metabolizers, the initial dosage should be 0.5 mg per kg per day and then increased to the the usual target dosage of 1.2 mg per kg per day only if symptoms do not improve after 4 weeks and the initial dose is well tolerated.
CYP2D6	Paroxetine (Paxil)	Ultrarapid metabolizer: Select alternative because of possible lack of effectiveness.	CPIC guidance is available for CYP2D6-genotype guided paroxetine therapy.

Allele	Medications	Test Results and Clinical Implications	Comments
		Poor metabolizer: Select alternative or if use is warranted, consider 50% starting dose reduction	

Dutch Pharmacogenetics Working Group (DPWG)

The DPWG has published guidelines for the gene-drug interaction of *DPYD* and fluoropyrimidines. Conclusions state that "four variants have sufficient evidence to be implemented into clinical care: DPYD*2A (c.1905+1G>A, IVS14+1G>A), DPYD*13 (c.1679T>G), c.2846A>T and c.1236G>A (in linkage disequilibrium with c.1129–5923C>G). The current guideline only reports recommendations for these four variants; no recommendations are provided for other variants in *DPYD* or other genes" (Lunenburg et al., 2020).

Food and Drug Administration

The FDA published several tables of pharmacogenetic associations with "sufficient scientific evidence to suggest that subgroups of patients with certain genetic variants, or genetic variant-inferred phenotypes (i.e., affected subgroup in the table below), are likely to have altered drug metabolism, and in certain cases, differential therapeutic effects, including differences in risks of adverse events".

The table below lists associations "for which the data support therapeutic management recommendations" (FDA, 2022).

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Abacavir	*HLA-B*	*57:01 allele positive	Results in higher adverse reaction risk (hypersensitivity reactions). Do not use abacavir in patients positive for HLA-B*57:01.
Abrocitinib	*CYP2C19*	poor metabolizers	Results in higher systemic concentrations and may result in higher adverse reaction risk. Dosage adjustment is recommended. Refer

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			to FDA labeling for specific dosing recommendations.
Amifampridine	*NAT2*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Use lowest recommended starting dosage and monitor for adverse reactions. Refer to FDA labeling for specific dosing recommendations.
Amifampridine Phosphate	*NAT2*	poor metabolizers	Results in higher systemic concentrations. Use lowest recommended starting dosage (15 mg/day) and monitor for adverse reactions.
Amphetamine	*CYP2D6*	poor metabolizers	May affect systemic concentrations and adverse reaction risk. Consider lower starting dosage or use alternative agent.
Aripiprazole	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Dosage adjustment is recommended. Refer to FDA labeling for specific dosing recommendations.
Aripiprazole Lauroxil	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations. Dosage adjustment is recommended. Refer to FDA labeling for specific dosing recommendations.
Atomoxetine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Adjust titration interval and increase dosage if tolerated. Refer to FDA labeling for specific dosing recommendations.

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Azathioprine	*TPMT* and/or *NUDT15*	intermediate or poor metabolizers	Alters systemic active metabolite concentration and dosage requirements. Results in higher adverse reaction risk (myelosuppression). Consider alternative therapy in poor metabolizers. Dosage reduction is recommended in intermediate metabolizers for NUDT15 or TPMT. Intermediate metabolizers for both genes may require more substantial dosage reductions. Refer to FDA labeling for specific dosing recommendations.
Belinostat	*UGT1A1*	*28/*28 (poor metabolizers)	May result in higher systemic concentrations and higher adverse reaction risk. Reduce starting dose to 750 mg/m2 in poor metabolizers.
Belzutifan	*CYP2C19 and/or UGT2B17*	Poor metabolizers	Results in higher systemic concentrations and may result in higher adverse reaction risk (anemia, hypoxia). Monitor patients who are poor metabolizers for both genes for adverse reactions.
Brexpiprazole	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations. Dosage adjustment is recommended. Refer to FDA labeling for specific dosing recommendations.
Brivaracetam	*CYP2C19*	intermediate or poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Consider dosage reductions in poor metabolizers.
Capecitabine	*DPYD*	intermediate or poor metabolizers	Results in higher adverse reaction risk (severe, life-threatening, or fatal toxicities). No dosage has proven safe in poor metabolizers, and

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			insufficient data are available to recommend a dosage in intermediate metabolizers. Withhold or discontinue in the presence of early-onset or unusually severe toxicity.
Carbamazepine	*HLA-B*	*15:02 allele positive	Results in higher adverse reaction risk (severe skin reactions). Avoid use unless potential benefits outweigh risks and consider risks of alternative therapies. Patients positive for HLA-B*15:02 may be at increased risk of severe skin reactions with other drugs that are associated with a risk of Stevens Johnson Syndrome/Toxic Epidermal necrolysis (SJS/TEN). Genotyping is not a substitute for clinical vigilance.
Celecoxib	*CYP2C9*	poor metabolizers	Results in higher systemic concentrations. Reduce starting dose to half of the lowest recommended dose in poor metabolizers. Consider alternative therapy in patients with juvenile rheumatoid arthritis.
Citalopram	*CYP2C19*	poor metabolizers	Results in higher systemic concentrations and adverse reaction risk (QT prolongation). The maximum recommended dose is 20 mg.
Clobazam	*CYP2C19*	intermediate or poor metabolizers	Results in higher systemic active metabolite concentrations. Poor metabolism results in higher adverse reaction risk. Dosage adjustment is recommended. Refer to FDA labeling for specific dosing recommendations.

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Clopidogrel	*CYP2C19*	intermediate or poor metabolizers	Results in lower systemic active metabolite concentrations, lower antiplatelet response, and may result in higher cardiovascular risk. Consider use of another platelet P2Y12 inhibitor.
Clozapine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations. Dosage reductions may be necessary.
Codeine	*CYP2D6*	ultrarapid metabolizers	Results in higher systemic active metabolite concentrations and higher adverse reaction risk (life-threatening respiratory depression and death). Codeine is contraindicated in children under 12 years of age.
Deutetrabenazine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and adverse reaction risk (QT prolongation). The maximum recommended dosage should not exceed 36 mg (maximum single dose of 18 mg).
Dronabinol	*CYP2C9*	intermediate or poor metabolizers	May result in higher systemic concentrations and higher adverse reaction risk. Monitor for adverse reactions.
Eliglustat	*CYP2D6*	ultrarapid, normal, intermediate, or poor metabolizers	Alters systemic concentrations, effectiveness, and adverse reaction risk (QT prolongation). Indicated for normal, intermediate, and poor metabolizer patients. Ultrarapid metabolizers may not achieve adequate concentrations to achieve a therapeutic effect. The recommended dosages are based on CYP2D6 metabolizer status. Coadministration with strong CYP3A

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			inhibitors is contraindicated in intermediate and poor CYP2D6 metabolizers. Refer to FDA labeling for specific dosing recommendations.
Erdafitinib	*CYP2C9*	*3/*3 (poor metabolizers)	May result in higher systemic concentrations and higher adverse reaction risk. Monitor for adverse reactions.
Flibanserin	*CYP2C19*	poor metabolizers	May result in higher systemic concentrations and higher adverse reaction risk. Monitor patients for adverse reactions.
Flurbiprofen	*CYP2C9*	poor metabolizers	Results in higher systemic concentrations. Use a reduced dosage.
Fluorouracil	*DPYD*	intermediate or poor metabolizer	Results in higher adverse reaction risk (severe, life-threatening, or fatal toxicities). No dosage has proven safe in poor metabolizers and insufficient data are available to recommend a dosage in intermediate metabolizers. Withhold or discontinue in the presence of early-onset or unusually severe toxicity.
Fosphenytoin	*CYP2C9*	Intermediate or poor metabolizers	May result in higher systemic concentrations and higher adverse reaction risk (central nervous system toxicity). Consider starting at the lower end of the dosage range and monitor serum concentrations. Refer to FDA labeling for specific dosing recommendations. Carriers of CYP2C9*3 alleles may be at increased risk of severe cutaneous adverse reactions. Consider avoiding

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			fosphenytoin as an alternative to carbamazepine in patients who are CYP2C9*3 carriers. Genotyping is not a substitute for clinical vigilance and patient management.
Fosphenytoin	*HLA-B*	*15:02 allele positive	May result in higher adverse reaction risk (severe cutaneous reactions). Patients positive for HLA-B*15:02 may be at increased risk of Stevens Johnson Syndrome/Toxic Epidermal necrolysis (SJS/TEN). Consider avoiding fosphenytoin as an alternative to carbamazepine in patients who are positive for HLA-B*15:02. Genotyping is not a substitute for clinical vigilance and patient management.
Gefitinib	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Monitor for adverse reactions.
Iloperidone	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (QT prolongation). Reduce dosage by 50%.
Irinotecan	*UGT1A1*	*28/*28 (poor metabolizers)	Results in higher systemic active metabolite concentrations and higher adverse reaction risk (severe neutropenia). Consider reducing the starting dosage by one level and modify the dosage based on individual patient tolerance.
Lofexidine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. Monitor for orthostatic hypotension and bradycardia.

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Meclizine	*CYP2D6*	ultrarapid, intermediate, or poor metabolizers	May affect systemic concentrations. Monitor for adverse reactions and clinical effect.
Meloxicam	*CYP2C9*	Poor metabolizers or *3 carriers	Results in higher systemic concentrations. Consider dose reductions in poor metabolizers. Monitor patients for adverse reactions.
Metoclopramide	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk. The recommended dosage is lower. Refer to FDA labeling for specific dosing recommendations.
Mercaptopurine	*TPMT* and/or *NUDT15*	intermediate or poor metabolizers	Alters systemic active metabolite concentration and dosage requirements. Results in higher adverse reaction risk (myelosuppression). Initial dosages should be reduced in poor metabolizers; poor metabolizers generally tolerate 10% or less of the recommended dosage. Intermediate metabolizers may require dosage reductions based on tolerability. Intermediate metabolizers for both genes may require more substantial dosage reductions. Refer to FDA labeling for specific dosing recommendations.
Mivacurium	*BCHE*	intermediate or poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (prolonged neuromuscular blockade). Avoid use in poor metabolizers.

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Nateglinide	*CYP2C9*	Poor metabolizers	Results in higher systemic concentrations and may result in higher adverse reaction risk (hypoglycemia). Dosage reduction is recommended. Increase monitoring frequency for adverse reactions. Refer to FDA labeling for specific dosing recommendations.
Oliceridine	*CYP2D6*	Poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (respiratory depression and sedation). May require less frequent dosing.
Pantoprazole	*CYP2C19*	poor metabolizers	Results in higher systemic concentrations. Consider dosage reduction in children who are poor metabolizers. No dosage adjustment is needed for adult patients who are poor metabolizers.
Phenytoin	*CYP2C9*	Intermediate or poor metabolizers	May result in higher systemic concentrations and higher adverse reaction risk (central nervous system toxicity). Refer to FDA labeling for specific dosing recommendations. Carriers of CYP2C9*3 alleles may be at increased risk of severe cutaneous adverse reactions. Consider avoiding phenytoin as an alternative to carbamazepine in patients who are CYP2C9*3 carriers. Genotyping is not a substitute for clinical vigilance and patient management.
Phenytoin	*HLA-B*	*15:02 allele positive	May result in higher adverse reaction risk (severe cutaneous reactions). Patients positive for HLA-B*15:02 may be at increased risk of Stevens Johnson Syndrome/Toxic Epidermal

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			necrolysis (SJS/TEN). Consider avoiding phenytoin as an alternative to carbamazepine in patients who are positive for HLA-B*15:02. Genotyping is not a substitute for clinical vigilance and patient management.
Pimozide	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations. Dosages should not exceed 0.05 mg/kg in children or 4 mg/day in adults who are poor metabolizers and dosages should not be increased earlier than 14 days.
Piroxicam	*CYP2C9*	intermediate or poor metabolizers	Results in higher systemic concentrations. Consider reducing dosage in poor metabolizers.
Pitolisant	*CYP2D6*	Poor metabolizers	Results in higher systemic concentrations. Use lowest recommended starting dosage. Refer to FDA labeling for specific dosing recommendations.
Propafenone	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (arrhythmia). Avoid use in poor metabolizers taking a CYP3A4 inhibitor.
Sacituzumab Govitecan-hziy	*UGT1A1*	*28/*28 (poor metabolizers)	May result in higher systemic concentrations and adverse reaction risk (neutropenia). Monitor for adverse reactions and tolerance to treatment.
Siponimod	*CYP2C9*	intermediate or poor metabolizers	Results in higher systemic concentrations. Adjust dosage based on genotype. Do not use in patients with CYP2C9 *3/*3 genotype. Refer to FDA labeling for specific dosing recommendations.

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Succinylcholine	*BCHE*	intermediate or poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (prolonged neuromuscular blockade). Avoid use in poor metabolizers. May administer test dose to assess sensitivity and administer cautiously via slow infusion.
Tacrolimus	*CYP3A5*	intermediate or normal metabolizers	Results in lower systemic concentrations and lower probability of achieving target concentrations. Measure drug concentrations and adjust dosage based on trough whole blood tacrolimus concentrations.
Tetrabenazine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations. The maximum recommended single dose is 25 mg and should not exceed 50 mg/day.
Thioguanine	*TPMT* and/or *NUDT15*	intermediate or poor metabolizers	Alters systemic active metabolite concentration and dosage requirements. Results in higher adverse reaction risk (myelosuppression). Initial dosages should be reduced in poor metabolizers; poor metabolizers generally tolerate 10% or less of the recommended dosage. Intermediate metabolizers may require dosage reductions based on tolerability. Intermediate metabolizers for both genes may require more substantial dosage reductions. Refer to FDA labeling for specific dosing recommendations.
Thioridazine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			reaction risk (QT prolongation). Predicted effect based on experience with CYP2D6 inhibitors. Contraindicated in poor metabolizers.
Tramadol	*CYP2D6*	Ultrarapid metabolizers	Results in higher systemic and breast milk active metabolite concentrations, which may result in respiratory depression and death. Contraindicated in children under 12 and in adolescents following tonsillectomy/adenoidectomy. Breastfeeding is not recommended during treatment.
Valbenazine	*CYP2D6*	poor metabolizers	Results in higher systemic active metabolite concentrations and higher adverse reaction risk (QT prolongation). Dosage reductions may be necessary.
Venlafaxine	*CYP2D6*	poor metabolizers	Alters systemic parent drug and metabolite concentrations. Consider dosage reductions.
Vortioxetine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations. The maximum recommended dose is 10 mg.
Warfarin	*CYP2C9*	intermediate or poor metabolizers	Alters systemic concentrations and dosage requirements. Select initial dosage, taking into account clinical and genetic factors. Monitor and adjust dosages based on INR.
Warfarin	*CYP4F2*	V433M variant carriers	May affect dosage requirements. Monitor and adjust doses based on INR.
Warfarin	*VKORC1*	-1639G>A variant carriers	Alters dosage requirements. Select initial dosage, taking into account clinical and genetic factors. Monitor and adjust dosages based on INR.

The table below lists associations "for which the data indicate a potential impact on safety or response" (FDA, 2022).

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
Allopurinol	*HLA-B*	*58:01 allele positive	Results in higher adverse reaction risk (severe skin reactions).
Carbamazepine	*HLA-A*	*31:01 allele positive	Results in higher adverse reaction risk (severe skin reactions). Consider risk and benefit of carbamazepine use in patients positive for HLA-A*31:01. Genotyping is not a substitute for clinical vigilance.
Carvedilol	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (dizziness).
Cevimeline	*CYP2D6*	poor metabolizers	May result in higher adverse reaction risk. Use with caution.
Codeine	*CYP2D6*	poor metabolizers	Results in lower systemic active metabolite concentrations and may result in reduced efficacy.
Efavirenz	*CYP2B6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (QT prolongation).
Isoniazid	Nonspecific (NAT)	poor metabolizers	May result in higher systemic concentrations and adverse reaction risk.
Lapatinib	*HLA-DRB1*	*07:01 allele positive	Results in higher adverse reaction risk (hepatotoxicity). Monitor liver function tests regardless of genotype.
Lapatinib	*HLA-DQA1*	*02:01 allele positive	Results in higher adverse reaction risk (hepatotoxicity). Monitor liver function tests regardless of genotype.
Mavacamten	*CYP2C19*	Intermediate or poor metabolizers	Results in higher systemic concentrations and may have higher adverse reaction risk (heart

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
			failure). Dosage is based on individual response. The dose titration and monitoring schedule accounts for differences due to CYP2C19 genetic variation, so adjustments based on CYP2C19 genotype are not necessary. Refer to FDA labeling for specific dosing recommendations and monitoring.
Nilotinib	*UGT1A1*	*28/*28 (poor metabolizers)	Results in higher adverse reaction risk (hyperbilirubinemia).
Oxcarbazepine	*HLA-B*	*15:02 allele positive	Results in higher adverse reaction risk (severe skin reactions). Patients positive for HLA-B*15:02 may be at increased risk of severe skin reactions with other drugs that are associated with a risk of Stevens Johnson Syndrome/Toxic Epidermal necrolysis (SJS/TEN). Genotyping is not a substitute for clinical vigilance.
Pazopanib	*HLA-B*	*57:01 allele positive	May result in higher adverse reaction risk (liver enzyme elevations). Monitor liver function tests regardless of genotype.
Pazopanib	*UGT1A1*	*28/*28 (poor metabolizers)	Results in higher adverse reaction risk (hyperbilirubinemia).
Perphenazine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk.
Procainamide	Nonspecific (NAT)	poor metabolizers	Alters systemic parent drug and metabolite concentrations. May result in higher adverse reaction risk.
Simvastatin	*SLCO1B1*	521 TC or 521 CC (intermediate	Results in higher systemic concentrations and higher adverse reaction risk (myopathy). The risk

Drug	Gene	Affected Subgroups	Description of Gene-Drug Interaction
		or poor function transporters)	of adverse reaction (myopathy) is higher for patients on 80 mg than for those on lower doses.
Sulfamethoxazole and Trimethoprim	Nonspecific (NAT)	poor metabolizers	May result in higher adverse reaction risk.
Sulfasalazine	Nonspecific (NAT)	poor metabolizers	Results in higher systemic metabolite concentrations and higher adverse reaction risk.
Tolterodine	*CYP2D6*	poor metabolizers	Results in higher systemic concentrations and higher adverse reaction risk (QT prolongation).
Tramadol	*CYP2D6*	poor metabolizers	Results in lower systemic active metabolite concentrations and may result in reduced efficacy.
Voriconazole	*CYP2C19*	Intermediate or poor metabolizers	Results in higher systemic concentrations and may result in higher adverse reaction risk.

The International Society of Psychiatric Genetics

The International Society of Psychiatric Genetics (ISPG) released recommendations on the use of pharmacogenetic testing to guide psychiatric treatment. ISPG recommends that pharmacogenetic testing should be used as a decision-support tool. *HLA-A* and *HLA-B* testing is recommended before the use of carbamazepine and oxcarbazepine. *CYP2C19* and *CYP2D6* testing would be beneficial for those who experienced an inadequate response or adverse reaction to a previous antidepressant or antipsychotic medication (ISPG, 2019).

The American Academy of Child and Adolescent Psychiatry

AACAP does not recommend the use of pharmacogenetic testing to select psychotropic medications for children and adolescents (AACAP, 2020)

Association for Molecular Pathology PGx Working Group (AMP)

AMP released clinical practice guidelines to define a minimum set of *CYP2C19* allele variants that should be included in the pharmacogenomic genotyping assay. Tier 1 represents alleles that have been shown to affect drug response and should be included, while Tier 2 represents alleles which meet at least one but not all the criteria

for inclusion in Tier 1 and are considered optional for inclusion in expanded clinical genotyping panels. Those in Tier 1 include alleles *2, *3, and *17. The following *CYP2C19* alleles were recommended as Tier 2: *4A, *4B, *5, *6, *7, *8, *9, *10, and *35 (Pratt et al., 2018). Regarding *CYP2C9* variant alleles, Tier 1 alleles include *CYP2C9* *2, *3, *5, *6, *8, and *11. The following *CYP2C9* alleles are recommended for inclusion in Tier 2: CYP2C9*12, *13, and *15 (Pratt et al., 2019). For testing genes and alleles specific to warfarin, AMP recommends including *VKORC1* c.-1639G>A in Tier 1 and *VKORC1* c.196G>A and c.106G>A in Tier 2 (Pratt et al., 2020). In a joint recommendation endorsed by the AMP, College of American Pathologists, Dutch Pharmacogenetics Working Group of the Royal Dutch Pharmacists Association, and the European Society for Pharmacogenomics and Personalized Therapy, *CYP2D6* variant alleles were elucidated. Tier 1 alleles include *CYP2D6* *2 to *6, *9, *10, *17, *29, and *41. Tier 2 *CYP2D6* alleles include *CYP2D6* *7, *8, *12, *14, *15, *21, *31, *40, *42, *49, *56, and *59, and hybrid genes containing portions of *CYP2D6* and *CYP2D7* (Pratt et al., 2021). These recommendations should help to standardize testing and genotyping concordance among laboratories.

European Medicines Agency

EMA released recommendations on *DPD* testing before treatment with fluorouracil, capecitabine, tegafur, and flucytosine. EMA recommends testing for the lack of *DPD* before starting cancer treatment with fluorouracil, capecitabine, or tegafur. Patients who completely lack *DPD* should not be given these medications. For patients with partial deficiency, the physician may consider beginning treatment at a lower dose and terminating treatment if severe side effects occur. These recommendations do not apply to fluorouracil medications used for skin conditions or flucytosine used for fungal infection (EMA, 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Diagnostic genotyping tests for certain drug metabolizing enzymes are FDA-approved. Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). As an LDT, the U. S. Food and Drug Administration has not approved or cleared this test; however, FDA clearance or approval is not currently required for clinical use.

Currently, there are over 14 other FDA-approved tests for the drug metabolizing enzymes that are nucleic acid-based tests including xTAG *CYP2D6* Kit v3 and XTAG *CYP2C19* KIT V3 (Luminex Molecular Diagnostics, Inc), Spartan RX *CYP2C19* Test System (Spartan Bioscience, Inc), Verigene *CYP2C19* Nucleic Acid Test (Nanosphere, Inc), INFINITI *CYP2C19* Assay (AutoGenomics, Inc), Invader *UGT1A1* (Third Wave Technologies Inc.), eSensor Warfarin Sensitivity Saliva Test (GenMark Diagnostics), eQ-PCR LC Warfarin Genotyping kit (TrimGen Corporation), eSensor Warfarin Sensitivity Test and XT-8 Instrument (Osmetech Molecular Diagnostics), Gentris Rapid Genotyping Assay-*CYP2C9*&VKORCI (ParagonDx, LLC), INFINITI 2C9 & *VKORC1* Multiplex Assay for Warfarin (AutoGenomics, Inc), Verigene Warfarin Metabolism Nucleic Acid Test and Verigene System (Nanosphere, Inc), TruDiagnosis System (Akonni Systems, Inc), Roche AmpliChip CYP450 microassay (Roche Molecular Systems, Inc) (FDA, 2021a).

FDA Notes

The Office of Clinical Pharmacology within FDA includes The Genomics and Targeted Therapy Group responsible for applying pharmacogenomics and other biomarkers in drug development and clinical practice. The FDA scientists review current pharmacogenomic information and ensure that pharmacogenomic strategies are utilized appropriately in all phases of drug development (FDA, 2022).

The current list of pharmacogenomic biomarkers in drug labeling by FDA contain numerous medications that have genotypes related to metabolism dosage recommendations or warnings. These medications are involved in different therapeutic areas and the list includes the following genes and medications:

CYP1A2: Rucaparib

CYP2B6: Efavirenz, Prasugrel, Ospemifene

CYP2C19 contains 22 different medications: Clopidogrel, Prasugrel, Ticagrelor, Lansoprazole, Omeprazole, Esomeprazole, Rabeprazole, Pantoprazole, Dexlansoprazole, Flibanserin, Drospirenone and Ethinyl Estradiol, Voriconazole, Lacosamide, Brivaracetam, Clobazam, Phenytoin, Diazepam, Citalopram, Escitalopram, Doxepin, Formoterol, Carisoprodol

CYP2C9 contains 15 different medications: Prasugrel, Dronabinol, Flibanserin, Warfarin, Phenytoin, Celecoxib, Piroxicam, Flurbiprofen, Lesinurad, Avatrombopag, Erdafitinib, Ospemifene, Siponimod, Meloxicam, Rimegepant

CYP2D6 contains 70 different medications: Tramadol, Metoprolol, Nebivolol, Propafenone, Propranolol, Ondansetron, Palonosetron, Flibanserin, Eliglustat, Deutetrabenazine, Dextromethorphan and Quinidine, Galantamine, Tetrabenazine, Valbenazine, Rucaparib, Aripiprazole, Aripiprazole Lauroxil, Atomoxetine, Brexpiprazole, Cariprazine, Citalopram, Clozapine, Desvenlafaxine, Doxepin, Escitalopram, Fluoxetine, Fluvoxamine, Iloperidone, Modafinil, Paroxetine, Perphenazine, Risperidone, Venlafaxine, Vortioxetine, Arformoterol, Formoterol, Umeclidinium, Darifenacin, Mirabegron, Tolterodine, Amphetamine, Donepezil, Fesoterodine, Gefitinib, Metoclopramide, Paliperidone, Tamoxifen, Carvedilol, Amitriptyline, Amoxapine, Clomipramine, Codeine, Desipramine, Duloxetine, Imipramine, Meclizine, Metoclopramide, Nefazodone, Nortriptyline, Pimozide, Protriptyline, Quinine Sulfate, Tamsulosin, Thioridazine, Trimipramine, Pitolisant, Upadacitinib, Bupropion.

CYP3A5: Prasugrel

TPMT: Thioguanine, Azathioprine, Mercaptopurine, Cisplatin

NUDT15: Thioguanine, Azathioprine, Mercaptopurine

UGT1A1: Arformoterol, Belinostat, Binimetinib, Dolutegravir, Indacaterol, Irinotecan, Nilotinib, Pazopanib, Raltegravir, Sacituzumab Govitecan-hziy (FDA, 2021b).

FDA Recommendations

The FDA package insert for Plavix (clopidogrel) carries the following "Black Box" warning: "The effectiveness of Plavix results from its antiplatelet activity which is dependent on its conversion to an active metabolite by the cytochrome P450 (CYP) system, principally *CYP2C19*. Plavix at recommended doses forms less of the active metabolite and so has a reduced effect on platelet activity in patients who are homozygous for nonfunctional alleles of the *CYP2C19* gene, (termed "*CYP2C19* poor metabolizers"). Tests are available to identify patients who are *CYP2C19* poor metabolizers. Consider another platelet P2Y12 inhibitor in patients identified as *CYP2C19* poor metabolizers." (FDA, 2016)

The FDA package insert for Xenazine (tetrabenazine) indicates, "Patients who require doses of Xenazine greater than 50 mg per day should be first tested and genotyped to determine if they are poor metabolizers (PMs) or extensive metabolizers (EMs) by their ability to express the drug metabolizing enzyme, *CYP2D6*. The dose of XENAZINE should then be individualized accordingly to their status as PMs or EMs. (FDA, 2008)

The Coumadin (warfarin) highlights of prescription information notes that "The appropriate initial dosing of COUMADIN varies widely for different patients. Not all factors responsible for warfarin dose variability are known, and the initial dose is influenced by: Genetic factors (*CYP2C9* and *VKORC1* genotypes)." Although dosage suggestions based on *CYP2C9* and *VKORC1* genotypes are provided in the package insert, the requirement for genetic testing is not included (FDA)

The eligibility and dosing of Eliglustat is dependent on cytochrome P450 *CYP2D6* genotype as eliglustat is extensively metabolized by *CYP2D6*. The FDA contraindicates this medication in the following patients due "to the risk of cardiac arrhythmias from prolongation of the PR, QTc, and/or QRS cardiac Intervals":

EMs of *CYP2D6*

- Taking a strong or moderate CYP2D6 inhibitor concomitantly with a strong or moderate CYP3A inhibitor
- Moderate or severe hepatic impairment
- Mild hepatic impairment and taking a strong or moderate CYP2D6 inhibitor

IMs

- Taking a strong or moderate CYP2D6 inhibitor concomitantly with a strong or moderate CYP3A inhibitor
- Taking a strong CYP3A inhibitor
- Any degree of hepatic impairment

PMs

- Taking a strong CYP3A inhibitor
- Any degree of hepatic impairment (FDA, 2014)

The FDA also includes a warning for irinotecan's interaction with *UGT1A1*, stating "When administered in combination with other agents, or as a single-agent, a reduction in the starting dose by at least one level of CAMPTOSAR [irinotecan] should be considered for patients known to be homozygous for the *UGT1A1**28 allele" (FDA, 2021b).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81220	CFTR (cystic fibrosis transmembrane conductance regulator) (eg, cystic fibrosis) gene analysis; common variants (eg, ACMG/ACOG guidelines)
81225	CYP2C19 (cytochrome P450, family 2, subfamily C, polypeptide 19) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *8, *17)
81226	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *5, *6, *9, *10, *17, *19, *29, *35, *41, *1XN, *2XN, *4XN)
81227	CYP2C9 (cytochrome P450, family 2, subfamily C, polypeptide 9) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *5, *6)
81230	CYP3A4 (cytochrome P450 family 3 subfamily A member 4) (eg, drug metabolism), gene analysis, common variant(s) (eg, *2, *22)
81231	CYP3A5 (cytochrome P450 family 3 subfamily A member 5) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3, *4, *5, *6, *7)
81232	DPYD (dihydropyrimidine dehydrogenase) (eg, 5-fluorouracil/5-FU and capecitabine drug metabolism), gene analysis, common variant(s) (eg, *2A, *4, *5, *6)
81247	G6PD (glucose-6-phosphate dehydrogenase) (eg, hemolytic anemia, jaundice), gene analysis; common variant(s) (eg, A, A-)
81283	IFNL3 (interferon, lambda 3) (eg, drug response), gene analysis, rs12979860 variant
81291	MTHFR (5,10-methylenetetrahydrofolate reductase) (eg, hereditary hypercoagulability) gene analysis, common variants (eg, 677T, 1298C)
81306	NUDT15 (nudix hydrolase 15) (eg, drug metabolism) gene analysis, common variant(s) (eg, *2, *3, *4, *5, *6)
81328	SLCO1B1 (solute carrier organic anion transporter family, member 1B1) (eg, adverse drug reaction), gene analysis, common variant(s) (eg, *5)
81335	TPMT (thiopurine S-methyltransferase) (eg, drug metabolism), gene analysis, common variants (eg, *2, *3)
81346	TYMS (thymidylate synthetase) (eg, 5-fluorouracil/5-FU drug metabolism), gene analysis, common variant(s) (eg, tandem repeat variant)
81350	UGT1A1 (UDP glucuronosyltransferase 1 family, polypeptide A1) (eg, drug metabolism, hereditary unconjugated hyperbilirubinemia [Gilbert syndrome]) gene analysis, common variants (eg, *28, *36, *37)
81355	VKORC1 (vitamin K epoxide reductase complex, subunit 1) (eg, warfarin metabolism), gene analysis, common variant(s) (eg, -1639G>A, c.173+1000C>T)

CPT	Code Description
81381	HLA Class I typing, high resolution (ie, alleles or allele groups); one allele or allele group (eg, B*57:01P), each
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81418	Drug metabolism (eg, pharmacogenomics) genomic sequence analysis panel, must include testing of at least 6 genes, including CYP2C19, CYP2D6, and CYP2D6 duplication/deletion analysis
81479	Unlisted molecular pathology procedure
0029U	Drug metabolism (adverse drug reactions and drug response), targeted sequence analysis (ie, CYP1A2, CYP2C19, CYP2C9, CYP2D6, CYP3A4, CYP3A5, CYP4F2, SLCO1B1, VKORC1 and rs12777823) Proprietary test: Focused Pharmacogenomics Panel Lab/Manufacturer: Mayo Clinic
0030U	Drug metabolism (warfarin drug response), targeted sequence analysis (ie, CYP2C9, CYP4F2, VKORC1, rs12777823) Proprietary test: Warfarin Response Genotype Lab/Manufacturer: Mayo Clinic
0031U	CYP1A2 (cytochrome P450 family 1, subfamily A, member 2) (eg, drug metabolism) gene analysis, common variants (ie, *1F, *1K, *6, *7) Proprietary test: Cytochrome P450 1A2 Genotype Lab/Manufacturer: Mayo Clinic
0032U	COMT (catechol-O-methyltransferase)(eg, drug metabolism) gene analysis, c.472G>A (rs4680) variant Proprietary test: Catechol-O-Methyltransferase (COMT) Genotype Lab/Manufacturer: Mayo Clinic
0033U	HTR2A (5-hydroxytryptamine receptor 2A), HTR2C (5-hydroxytryptamine receptor 2C) (eg, citalopram metabolism) gene analysis, common variants (ie, HTR2A rs7997012 [c.614-2211T>C], HTR2C rs3813929 [c.-759C>T] and rs1414334 [c.551-3008C>G]) Proprietary test: Serotonin Receptor Genotype (HTR2A and HTR2C) Lab/Manufacturer: Mayo Clinic
0034U	TPMT (thiopurine S-methyltransferase), NUDT15 (nudix hydroxylase **15**)(eg, thiopurine metabolism) gene analysis, common variants (ie, TPMT *2, *3A, *3B, *3C, *4, *5, *6, *8, ***12**; NUDT15 *3, *4, *5)

CPT	Code Description
	Proprietary test: Thiopurine Methyltransferase (TPMT) and Nudix Hydrolase (NUDT15) Genotyping Lab/Manufacturer: Mayo Clinic
0070U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, common and select rare variants (ie, *2, *3, *4, *4N, *5, *6, *7, *8, *9, *10, *11, *12, *13, *14A, *14B, *15, *17, *29, *35, *36, *41, *57, *61, *63, *68, *83, *xN) Proprietary test: CYP2D6 Common Variants and Copy Number Lab/Manufacturer: Mayo Clinic
0071U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, full gene sequence (List separately in addition to code for primary procedure) Proprietary test: CYP2D6 Full Gene Sequencing Lab/Manufacturer: Mayo Clinic
0072U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, CYP2D6-2D7 hybrid gene) (List separately in addition to code for primary procedure) Proprietary test: CYP2D6-2D7 Hybrid Gene Targeted Sequence Analysis Lab/Manufacturer: Mayo Clinic
0073U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, CYP2D7-2D6 hybrid gene) (List separately in addition to code for primary procedure) Proprietary test: CYP2D7-2D6 Hybrid Gene Targeted Sequence Analysis Lab/Manufacturer: Mayo Clinic
0074U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, non-duplicated gene when duplication/multiplication is trans) (List separately in addition to code for primary procedure) Proprietary test: CYP2D6 trans-duplication/multiplication non-duplicated gene targeted sequence analysis Lab/Manufacturer: Mayo Clinic
0075U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, 5' gene

CPT	Code Description
	duplication/multiplication) (List separately in addition to code for primary procedure) Proprietary test: CYP2D6 5′ gene duplication/multiplication targeted sequence analysis Lab/Manufacturer: Mayo Clinic
0076U	CYP2D6 (cytochrome P450, family 2, subfamily D, polypeptide 6) (eg, drug metabolism) gene analysis, targeted sequence analysis (ie, 3′ gene duplication/ multiplication) (List separately in addition to code for primary procedure) Proprietary test: CYP2D6 3′ gene duplication/multiplication targeted sequence analysis Lab/Manufacturer: Mayo Clinic
0169U	NUDT15 (nudix hydrolase 15) and TPMT (thiopurine S-methyltransferase) (eg, drug metabolism) gene analysis, common variants Proprietary test: NT (NUDT15 and TPMT) genotyping panel Lab/Manufacturer: RPRD Diagnostics
0286U	CEP72 (centrosomal protein, 72-KDa), NUDT15 (nudix hydrolase 15) and TPMT (thiopurine S-methyltransferase) (eg, drug metabolism) gene analysis, common variants Proprietary test: CNT (CEP72, TPMT and NUDT15) genotyping panel Lab/Manufacturer: RPRD Diagnostics
0345U	Psychiatry (eg, depression, anxiety, attention deficit hyperactivity disorder [ADHD]), genomic analysis panel, variant analysis of 15 genes, including deletion/duplication analysis of CYP2D6 Proprietary test: GeneSight® Psychotropic Lab/Manufacturer: Assurex Health, Inc
0347U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 16 gene report, with variant analysis and reported phenotypes Proprietary test: RightMed® PGx16 Test Lab/Manufacturer: OneOme®
0348U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 25 gene report, with variant analysis and reported phenotypes

CPT	Code Description
	Proprietary test: RightMed® Comprehensive Test Exclude F2 and F5 Lab/Manufacturer: OneOme®
0349U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 27 gene report, with variant analysis, including reported phenotypes and impacted gene-drug interactions Proprietary test: RightMed® Comprehensive Test Lab/Manufacturer: OneOme®
0350U	Drug metabolism or processing (multiple conditions), whole blood or buccal specimen, DNA analysis, 27 gene report, with variant analysis and reported phenotypes Proprietary test: RightMed® Gene Report Lab/Manufacturer: OneOme®
0380U	Drug metabolism (adverse drug reactions and drug response), targeted sequence analysis, 20 gene variants and CYP2D6 deletion or duplication analysis with reported genotype and phenotype Proprietary test: PersonalisedRX Lab/Manufacturer: Lab Genomics LLC
0392U	Drug metabolism (depression, anxiety, attention deficit hyperactivity disorder [ADHD]), gene-drug interactions, variant analysis of 16 genes, including deletion/duplication analysis of CYP2D6, reported as impact of gene-drug interaction for each drug Proprietary test: Medication Management Neuropsychiatric Panel Lab/Manufacturer: RCA Laboratory Services LLC d/b/a GENETWORx
0411U	Psychiatry (eg, depression, anxiety, attention deficit hyperactivity disorder [ADHD]), genomic analysis panel, variant analysis of 15 genes, including deletion/duplication analysis of CYP2D6 Proprietary test: IDgenetix® Lab/Manufacturer: Castle Biosciences, Inc
0419U	Neuropsychiatry (eg, depression, anxiety), genomic sequence analysis panel, variant analysis of 13 genes, saliva or buccal swab, report of each gene phenotype Proprietary test: Tempus nP Lab/Manufacturer: Tempus Labs, Inc

CPT	Code Description
0423U	Psychiatry (eg, depression, anxiety), genomic analysis panel, including variant analysis of 26 genes, buccal swab, report including metabolizer status and risk of drug toxicity by condition. Proprietary test: Genomind® Pharmacogenetics Report - Full Lab/Manufacturer: Genomind®, Inc
0434U	Drug metabolism (adverse drug reactions and drug response), genomic analysis panel, variant analysis of 25 genes with reported phenotypes. Proprietary test: RightMed® Gene Test Exclude F2 and F5 Lab/Manufacturer: OneOme® LLC
0437U	Psychiatry (anxiety disorders), mRNA, gene expression profiling by RNA sequencing of 15 biomarkers, whole blood, algorithm reported as predictive risk score. Proprietary test: MindX One™ Blood Test – Anxiety Lab/Manufacturer: MindX Sciences
0438U	Drug metabolism (adverse drug reactions and drug response), buccal specimen, gene-drug interactions, variant analysis of 33 genes, including deletion/duplication analysis of CYP2D6, including reported phenotypes and impacted gene- drug interactions. Proprietary test: EffectiveRX™ Comprehensive Panel Lab/Manufacturer: RCA Laboratory Services LLC d/b/a GENETWORx
0460U	Oncology, whole blood or buccal, DNA single-nucleotide polymorphism (SNP) genotyping by real-time PCR of 24 genes, with variant analysis and reported phenotypes Proprietary test: RightMed® Oncology Gene Report Lab/Manufacturer: OneOme® LLC
0461U	Oncology, pharmacogenomic analysis of single-nucleotide polymorphism (SNP) genotyping by real-time PCR of 24 genes, whole blood or buccal swab, with variant analysis, including impacted gene-drug interactions and reported phenotypes Proprietary test: RightMed® Oncology Medication Report Lab/Manufacturer: OneOme® LLC
G9143	Warfarin responsiveness testing by genetic technique using any method, any number of specimen(s)

Precision Genetic Test Management Reimbursement Policy

Policy Number: AHS – R2183 – Precision Genetic Test Management Reimbursement Policy	Initial Policy Effective Date: 01/01/2026

POLICY SPECIFIC DEFINITIONS | REIMBURSEMENT GUIDELINES | CLAIM SUBMISSION REQUIREMENTS | OBTAINING A PALMETTO DEX Z-CODE® |

I. Policy Specific Definitions

Molecular Pathology: Molecular pathology procedures are medical laboratory procedures that involve the analysis of nucleic acids or proteins in the tissue, blood, or other bodily fluids. These molecular pathology procedures can detect genetic, genomic, or other molecular abnormalities, with results being used to assist with diagnosis and/or prognosis or to help guide treatment.

Molecular Diagnostic Test (MDT): MDTs involve the detection or identification of nucleic acid(s) (deoxyribonucleic acid/ribonucleic acid [DNA/RNA]), proteins, chromosomes, enzymes, cancer chemotherapy sensitivity, and/or other metabolite(s). MDTs may include multiple components, may analyze or identify a single mutation or multiple mutations, and may rely upon an algorithm or other form of data evaluation/derivation. MDTs are laboratory developed tests that may or may not have Food and Drug Administration (FDA) approval or clearance.

II. Reimbursement Guidelines

Providers are required to submit the appropriate DEX Z-Code® and associated CPT® code for a molecular pathology service and molecular diagnostic test submitted for reimbursement consideration. The DEX Z-Code® is a unique test identifier that, when reported in conjunction with the appropriate CPT®/HCPCS code, enables identification of the exact test that was performed and more efficient reimbursement determinations. Only Z-Code® and associated CPT® codes with a "Successful" technical assessment outcome and the appropriate intended use will be considered for reimbursement.

Providers must report molecular pathology and molecular diagnostic tests with the CPT® and/or HCPCS code(s) that was assigned through the Palmetto DEX Z-Code® registry.

For tests that may involve multiple genes, but produce a single result, only one Z-Code® should be submitted with a CPT® code. Claims with the same DEX Z-Code® associated with multiple CPT® codes for the same patient and date of service will be denied.

III. Claim Submission Requirements

To report an MDT service, please submit the following claim information:

- Select appropriate Molecular Pathology CPT® code
- Enter 1 unit of service (UOS)
- Enter the appropriate DEX Z-Code® identifier adjacent to the CPT® code in the comment/narrative field for the following professional claim field/types:
  - Loop 2400 or SV-101-7 for the 5010A1 837P
  - Box 19 for paper claim
- Enter the appropriate DEX Z-Code® identifier adjacent to the CPT® code in the comment/narrative field for the following Facility claim field/types:
  - Line SV-202-7 for 837I electronic claim
  - Block 80 for the UB04 claim form

For information pertaining to Medicare codes, coverage, and Palmetto LCD, visit:

LCD - MolDX: Molecular Diagnostic Tests (MDT) (L35025)

Article - Billing and Coding: MolDX: Molecular Diagnostic Tests (MDT) (A56853)*

*Note that the list of procedure codes within this link is for informational purposes only and is not inclusive of all procedure codes enforced within this reimbursement policy.

IV. Obtaining a Palmetto DEX Z-Code®

Before submitting claims for an MDT, laboratories must register and receive a DEX Z-Code® and appropriate CPT®/HCPCS code.

- To register with the DEX® Diagnostics Exchange Registry, visit https//app.dexzcodes.com
  - Select the appropriate organization type under the **Register My Organization** header and provide the requested information
- To add a test to the registry and receive a DEX Z-Code® and appropriate CPT®/HCPCS assignment:
  - After logging into the registry, select the **Add Test** button from either the Catalog Overview or My Diagnostics Exchange tab.
  - Complete all required fields and submit your test for review.

For more information, visit http://www.dexzcodes.com.

Pre-Implantation Genetic Testing

Policy Number: AHS – M2039 – Pre-Implantation Genetic Testing	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Preimplantation genetic testing (PGT) involves the biopsy of a single cell, or a few cells of embryos to facilitate genetic testing for various genetic conditions. These conditions range from aneuploidies to monogenic disorders to structural deformities of the chromosomes themselves (Schattman & Xu, 2024).

II. Related Policies

Policy Number	Policy Title
AHS-M2017	Genetic Testing for Cystic Fibrosis
AHS-M2145	General Genetic Testing, Germline Disorders
AHS-M2146	General Genetic Testing, Somatic Disorders
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Genetic counseling **IS REQUIRED** for individuals contemplating preimplantation genetic testing.

2) Preimplantation genetic testing for specific mutation(s) or chromosomal changes that have been associated with a specific disorder **MEETS COVERAGE CRITERIA** when one of the following conditions is met:

   a) Both biological parents are known carriers of an early-onset, autosomal recessive disorder.

b) One biological parent is a known carrier of an early-onset, autosomal recessive disorder and the other biological parent is unavailable for testing.

c) One biological parent is a known carrier of an early-onset, autosomal recessive disorder and together, the biological parents have produced previous offspring affected with the disorder.

d) One biological parent is a known carrier of an early-onset, autosomal dominant disorder.

e) One biological parent is a known carrier of an early-onset, X-linked disorder.

f) One biological parent carries a balanced or unbalanced chromosomal translocation.

3) In the absence of an early-onset, sex-linked disorder, preimplantation genetic testing for sex selection **DOES NOT MEET COVERAGE CRITERIA**.

4) Preimplantation genetic testing **DOES NOT MEET COVERAGE CRITERIA** for any of the following situations:

a) Preimplantation genetic testing for adult-onset disorders.

b) Preimplantation HLA genotyping for purposes of identifying potential tissue or organ donors.

c) Routine preimplantation screening for chromosomal abnormalities, including testing based on advanced maternal age.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) For all other situations not described above, preimplantation genetic testing **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
aCGH	Array-based comparative genomic hybridization
ACMG	American College of Medical Genetics and Genomics
AD	Autosomal dominant
AR	Autosomal recessive
ART	Assisted reproductive technology
ASRM	American Society of Reproductive Medicine

BFS	British Fertility Society
BMI	Body mass index
cLBR	Cumulative live birth rate
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid
DNA	Deoxyribose nucleic acid
ESHRE	European Society of Human Reproduction and Embryology
HLA	Human leukocyte antigen
ISAR	Indian Society for Assisted Reproduction
IVF	In vitro fertilization
LDTs	Laboratory-developed tests
NGS	Next-generation sequencing
PCR	Polymerase chain reaction
PGD	Preimplantation genetic diagnosis
PGD-A	Preimplantation genetic diagnosis for aneuploidy testing
PGDIS	Preimplantation Genetic Diagnosis International Society
PGS	Preimplantation genetic screening
PGT	Preimplantation genetic testing
PGT-A	Preimplantation genetic test for aneuploidy
PGT-M	Preimplantation genetic testing for monogenic defects
PGT-SR	Preimplantation genetic testing-structural rearrangements
qPCR	Quantitative real-time PCR
RPL	Recurrent pregnancy loss
SNP	Single nucleotide polymorphism
CCMG	Canadian College of Medical Geneticists
XL	X-linked

V. Scientific Background

Preimplantation genetic testing (PGT) in conjunction with assisted reproductive technology (ART) was developed to allow reproductive partners at risk of transmitting a genetic condition to their offspring to have an unaffected child without facing prenatal diagnosis and termination of pregnancy (PGDIS, 2008). Initially offered for diagnosis in couples at-risk for single gene genetic disorders, such as cystic fibrosis, spinal muscular atrophy and Huntington disease, preimplantation genetic diagnosis (PGD) has most frequently been employed in assisted reproduction as preimplantation

genetic screening (PGS) for detection of chromosome aneuploidy from advancing maternal age or structural chromosome rearrangements. The Preimplantation Genetic Diagnosis International Society (PGDIS) estimates that nearly 80% of PGT cycles have been performed for aneuploidy screening, 12% for single gene disorders, 6% for chromosome rearrangements and 2% for sibling human leukocyte antigen (HLA) matching (PGDIS, 2008). Both this and the European Society of Human Reproduction and Embryology (ESHRE) surveys confirm that aneuploidy testing is the major indication for PGT (Stern, 2014).

Embryonic genetic material used for PGT can be obtained from any of three sources: polar bodies from oocytes, blastomeres from day two or three, or trophectoderm cells from blastocysts (K. L. Scott et al., 2013). Polar bodies are typically analyzed if the embryo cannot be biopsied. However, polar body analysis is only useful for finding maternally inherited mutations or a cell division error during oocyte development. Furthermore, since genetic changes occur after the polar body develops, test results are of limited use. Additionally, as many as 30% of oocytes will not fertilize successfully, causing the test to fail (Schattman & Xu, 2024).

Blastomeres from day two or three (cleavage stage) were once the preferred practice in in-vitro-fertilization (IVF) as more embryos survived in culture by day three compared to days five or six (blastocyst stage). Despite the greater survival rate of day three embryos, these embryos were found to have a lower survival rate in a sustained implantation compared to day five embryos. Overall, trophectoderm biopsy on day five is preferable as it has no measurable impact on embryo development (Scott et al., 2013). Up to two or three dozen cells can be removed without disrupting development; although, common practice is to remove five to eight cells. Day five and later embryos also provide more DNA for testing compared to other stages of development (Schattman & Xu, 2024). Improved results have been seen with decreasing use of day three blastomere biopsy in favor of day five trophectoderm biopsy (K. L. Scott et al., 2013).

Pre-implantation genetic screening (PGS) is emerging as one of the most valuable tools to enhance pregnancy success with assisted reproductive technologies by assessing embryos for aneuploidy (Brezina et al., 2016).

As the genetic basis of more disorders are identified, increasing demand for and acceptance of the use of PGT for adult-onset disorders, such as Huntington disease, hereditary breast and ovarian cancer and Alzheimer disease, have occurred. Using PGD to screen embryos for diseases or mutations that confer an increased risk for developing a particular disease raises issues of how to weigh the benefits of PGD to the future child against the risks of PGD and ART (Stern, 2014). The Ethics committee

for the American Society of Reproductive Medicine (ASRM) found that PGD for adult-onset conditions is ethically justifiable when the conditions are serious and when there are no known interventions for the conditions or the available interventions are either inadequately effective or significantly burdensome (ASRM, 2013). The use of PGT for nonmedical sex selection or family balancing continues to be controversial, and the ethics committee has stated that it is acceptable for facilities to offer this service; however, employees wishing to decline participation in these procedures should be allowed to do so (ASRM, 2015).

Women recommended for pre-implantation genetic diagnosis for aneuploidy testing (PGD-A) or PGT for aneuploidy (PGT-A) are those of advanced reproductive age with a history of recurrent miscarriages and/or IVF failures; PGD-A is currently performed on trophectoderm biopsies by 24 different chromosome screening techniques (Vaiarelli et al., 2016). Trophectoderm biopsies are a safe and extensively validated approach with a low margin of error and miscarriage rate as well as a suspected high sustained pregnancy rate (Vaiarelli et al., 2016). However, Alteri et al. (2019) states that while PGT-A allows for an increased implantation rate, current data does not show an increase in successful pregnancy rates. Researchers agree that this technology is imperfect as Ledger (2019) reports that PGD-A can incorrectly designate an euploid embryo as an aneuploid embryo, leading to the unnecessary waste of embryos. These researchers also suggest that this type of screening may only be necessary in women between the ages of 35 and 44, as embryonic aneuploidy rates are low below 37 years of age and "costly screening for aneuploid seems pointless for women over 44 years of age, as almost all embryos are aneuploid" (Ledger, 2019).

The development of whole genome amplification and genomic tools, such as single nucleotide polymorphism (SNP) microarrays and comparative genomic hybridization microarrays, has led to faster, more accurate diagnoses that lead to improved pregnancy and live birth rates (Sullivan-Pyke & Dokras, 2018). Next-generation sequencing has also been used to distinguish between normal and abnormal embryos (García-Herrero et al., 2019). PGD-polymerase chain reaction (PCR) is often used to amplify the obtained DNA from the blastomere biopsy for further analysis (Feldman et al., 2017). Fluorescence In-situ Hybridization (FISH) has also been used for PGD and is an efficient method that may help to decrease IVF failure in infertile patients (Montazeri et al., 2018).

Other researchers are attempting to develop a non-invasive pre-implantation genetic testing technique. Farra et al. (2018) state that circulating cell-free embryonic DNA can be obtained from used culture media from blastocysts and in blastocoel fluid; this can then be used as a non-invasive method to evaluate genetic embryonic properties.

Proprietary Testing

Companies, such as Natera, have developed a preimplantation genetic test for monogenic/single gene conditions called Spectrum™ that includes PGT-A, PGT-M, and PGT-SR. This PGT-A uses SNP microarray technology. "Spectrum's SNP microarray platform typically yields >99% accuracy and allows for simultaneous PGT-M and/or PGT-SR with PGT-A" (Natera, 2022). Simon et al. (2018) studied IVF outcomes with this test when measuring PGT-A and euploid embryo transfer in day five or six embryos. An implantation rate and live birth rate of 69.9% and 64.5%, respectively, was identified (Simon et al., 2018). The authors concluded that "SNP-based PGT-A can mitigate the negative effects of maternal age on IVF outcomes in cycles with transfer, and that pregnancy outcomes from SET [single embryo transfer] cycles are not significantly different from those of double-embryo transfer cycles, and support the use of SET when transfers are combined with SNP-based PGT-A" (Simon et al., 2018).

iGLS Reproductive Genetics developed a PGT-A that uses next generation sequencing (NGS) to analyze thousands of DNA sequences that are unique to each chromosome allowing for the accurate identification of extra or missing chromosomes (iGLS, 2022).

PacGenomics has developed several PGT's for aneuploidies (PGT-A), structural chromosomal rearrangements (PGT-SR) with a subsequent PGT-SR Plus® which is used to differentiate between normal and balanced translocation carrier embryos in translocation cases, and for monogenic/single gene disorders (PGT-M). PGT-A for aneuploidies is performed on embryos created through IVF to screen for chromosomal abnormalities. PGT-SR is a genetic test performed on embryos created through IVF to screen for chromosomal structural rearrangements caused by balanced translocations and inversions. PGT-SR-Plus® can be added to PGT-SR which helps identify translocation carriers in patients who are not initially suspected to be at significant risk. PGT-M is performed on embryos created through IVF that is designed for individuals who know they are at an increased risk of having a child with a specific genetic disorder (PacGenomics, 2022).

Reproductive Genetic Innovations (RGI) developed several PGT tests including PGT-A, PGT-SR, and PGT-M which has similar functions to the other proprietary tests. RGI provides an additional test, PGT-HLA, which identifies embryos that are HLA compatible with a child who needs a bone marrow or cord blood transplant to help treat blood disorders (RGI, 2022).

Clinical Utility and Validity

Dreesen et al. (2014) performed a study assessing the accuracy of diagnoses made based on PGD. A total of 940 cases covering 53 genetic disorders were re-evaluated

using a PCR-based test. Of the 940 embryos, 881 (93.7%) of these embryos had two agreeing diagnoses. The first evaluation breakdown was 234 unaffected embryos, 590 affected, and 116 aberrant whereas the re-evaluation's breakdown was 283 unaffected embryos, 578 affected, and 79 aberrant. The sensitivity of this method was 99.2%, and its specificity was 80.2%. Allelic drop-out, mosaicism, and human error were the three most common causes of error (Dreesen et al., 2014).

Ghiossi et al. (2018) performed a study focusing on couples' decisions based on expanded carrier screening. Forty-five couples took a survey of their reproductive decision making after receiving their results, and of those 45, 28 said they would plan IVF with PGD or a prenatal diagnosis in future pregnancies. Of the 19 pregnant respondents, eight chose a prenatal diagnosis route, two planned amniocenteses but miscarried, and nine considered the condition insufficiently severe to warrant invasive testing. Three of the eight that chose the prenatal diagnosis route were affected by a condition, and two pregnancies were terminated. Disease severity was found to be a significant association with changes in decision making. Thirteen respondents did not plan to use the results from the carrier screening and four responses were unclear (Ghiossi et al., 2018).

Kamath et al. (2019) analyzed 207,697 data sets from women undergoing single-embryo transfer after PGT or IVF without PGT between the year 2000 and 2016. Results showed a significantly higher incidence of zygotic splitting following PGT (2.4%) compared to following non-PGT IVF (1.5%); this shows "a likely increased risk of monozygotic splitting following embryo biopsy" (Kamath et al., 2019) and highlights a potential risk with PGT embryonic biopsies.

A new study was published which compared the live birth rates of embryos fertilized without chromosome analysis compared to those analyzed via PGT-A and comprehensive chromosome screening of the first and second polar body (Verpoest et al., 2018). All mothers were of advanced maternal age between 36 and 40 years old. A total of 396 women enrolled in this multicenter, randomized clinical trial. Two hundred and five women had chromosomal screening, and 50 (24%) had a live birth within a year; in the group without intervention, which was comprised of 191 women, 45 (24%) had a live birth within a year (Verpoest et al., 2018). It is important to note that the groups had a slightly different number of participants. This study shows that PGT-A allows for similar birth rates when compared to embryos fertilized without chromosome analysis via intracytoplasmic sperm injection (ICSI). However, the authors warn that "Whether these benefits outweigh drawbacks such as the cost for the patient, the higher workload for the IVF lab and the potential effect on the children born after prolonged culture and/or cryopreservation remains to be shown" (Verpoest et al., 2018).

A meta-analysis focusing on evaluating the effectiveness and safety of PGT-A in women undergoing an IVF treatment was conducted in 2020. Thirteen randomized controlled trials—involving a total of 2794 women—reporting data on clinical outcomes were included. The meta-analysis concluded that there existed insufficient evidence for preimplantation genetic testing for abnormal chromosomes numbers to provide a difference in cumulative live birth rate, live birth rate after the first embryo transfer, or miscarriage rate between IVF with and IVF without PGT-A as currently performed, and therefore "the effect of PGT-A on clinical pregnancy rate is uncertain." The evidence evinced that though the observed cumulative live birth rate (cLBR) was 24% in the control group, the chance of live birth following the results of one IVF cycle with PGT-A is between 17% and 34%. Similarly, trials focusing on IVF with addition of PGT-A boasted an average cLBR of 29% in the control group, but the chance of live birth following the results of one IVF cycle with PGT-A was between 12% and 29%. When PGT-A is performed with FISH, the chance of live births after the first transfer in the control group (31%) fell to between 16% and 29% for those tested. Thus, the authors caution that "Women need to be aware that it is uncertain whether PGT-A with the use of genome-wide analyses is an effective addition to IVF, especially in view of the invasiveness and costs involved in PGT-A", going so far as to state that "PGT-A using FISH for the genetic analysis is probably harmful" (Cornelisse et al., 2020).

Next generation sequencing can be used for PGS to screen for aneuploidies in IVF scenarios. A study by Yap et al. (2019) analyzed results from a total of 391 IVF pregnancies whose embryos were cultured to the blastocyst stage; a total of 1361 blastocysts were analyzed (Yap et al., 2019). Of the 1361 blastocysts, 423 were identified as aneuploid, 723 as euploid and 216 as mosaic (contained varying cell lines) (Yap et al., 2019). These results show that next generation sequencing can be used to identify mosaic and aneuploid blastocysts and is an effective PGS tool.

Zeevi et al. (2021) studied the clinical validity of Haploseek, a method for preimplantation genetic testing and compared the results to polymerase chain reaction (PCR)-based PGT case results. A total of 151 embryo biopsies from 27 PGT cases were obtained and sequenced using Haploseek to predict the chromosome copy-number variants (CNVs) and relevant variant-flanking haplotypes in each embryo. For each of the 151 embryo biopsies, all Haploseek-derived haplotypes and CNVs were concordant with clinical PGT results. The authors conclude that "Haploseek is clinically accurate and fit for all standard clinical PGT applications" (Zeevi et al., 2021).

Kumar et al. (2022) noted the lack of comprehensive embryo genetic assessment in PGT. The authors used parental genome sequencing and embryo genotyping to create a whole-genome reconstruction. Using a combination of molecular and statistic techniques, the authors could infer inherited genome sequences and model

susceptibility to common conditions. The study included 110 embryos from ten couples and investigated 12 common conditions including cancer and autoimmune diseases. The method resulted in "genotype accuracy of 99.0–99.4% at sites relevant to polygenic risk scoring in cases from day-5 embryo biopsies and 97.2–99.1% in cases from day-3 embryo biopsies." The authors conclude that these results can "inform the discussion of utility and implementation of genome-based PGT in clinical practice" (Kumar et al., 2022).

VI. Guidelines and Recommendations

American College of Obstetricians and Gynecologists (ACOG)

In 2017, the ACOG noted that if a carrier couple (carriers for the same condition) is identified, genetic counselling is encouraged so that options such as preimplantation genetic diagnosis or prenatal diagnosis may be discussed. This guideline was reaffirmed in 2023 (ACOG, 2017).

In 2020, the ACOG published a series of recommendations in their "ACOG Committee Opinion" Number 799. The committee opinion was reaffirmed in 2023. These recommendations are shortened for brevity and reported below:

- "Preimplantation genetic testing-monogenic uses only a few cells from the early embryo, usually at the blastocyst stage, and misdiagnosis is possible but rare with modern techniques. Confirmation of preimplantation genetic testing-monogenic results with chorionic villus sampling (CVS) or amniocentesis should be offered."
- "To detect structural chromosomal abnormalities such as translocations, preimplantation genetic testing-structural rearrangements (known as PGT-SR) is used. Confirmation of preimplantation genetic testing-structural rearrangements results with CVS or amniocentesis should be offered."
- "The main purpose of preimplantation genetic testing-aneuploidy (known as PGT-A) is to screen embryos for whole chromosome abnormalities. Traditional diagnostic testing or screening for aneuploidy should be offered to all patients who have had preimplantation genetic testing-aneuploidy, in accordance with recommendations for all pregnant patients" (ACOG et al., 2020).

European Society for Human Reproduction and Embryology (ESHRE) PGD Consortium

In 2010, the ESHRE issued detailed guidelines related to technical aspects of PGD, specifically for the use of amplification techniques and for FISH. The ESHRE recommends that "misdiagnosis rates should be calculated for each type of assay and for all assays from a particular Centre." Additionally, they note that "Follow-up of

pregnancies (including multiple pregnancy rate and outcome), deliveries, and the health of children at birth and beyond should be attempted and maintained along with the cycle data" (Harton et al., 2010).

In 2020, the ESHRE expanded upon their practice recommendations for preimplantation genetic testing. For the organization of PGT, the ESHRE provided patient inclusion/exclusion criteria. In general, "It is recommended that PGT is only applied when genetic diagnosis is technically feasible, and the reliability of the diagnosis is high. Current procedures in most IVF/PGT centres allow for overall error rates (resulting in misdiagnosis) as low as 1 to 3%. Each centre should be aware of their error rates and include this information in their informed consents and reports in an open communication with the patient.

When considering PGT, safety issues, female age, impossibility to retrieve male or female gametes, body mass index (BMI) and other contraindications for IVF should be considered as possible exclusion criteria.

Furthermore, exclusion from PGT should be considered if the woman has serious signs and symptoms of an autosomal dominant or X-linked disorder (for which PGT is requested), which could introduce medical complications during ovarian stimulation, oocyte retrieval or pregnancy or medical risks at birth. PGT should be carefully considered if one of the partners has serious physical or psychological problems, either linked to the tested disease or due to other conditions."

Different preimplantation genetic testing for specific defects and disorders carried their own caveats and recommendations in terms of inclusion and exclusion of patients:

For *PGT-M, mitochondrial disorders and HLA*: "Cases of genetic variants of unknown significance that are not predictive of a phenotype should be excluded from PGT. PGT testing is inappropriate in case of uncertain genetic diagnosis (for example genetic/molecular heterogeneity), or in case of uncertain mode of inheritance.

For autosomal recessive disorders, where a single pathogenic variant has been diagnosed in the proband and only one parent, it is acceptable to offer PGT if the pathogenic genotype is attributed to a single gene and sufficient evidence from the family pedigree allows identification of the disease-associated haplotypes. Similarly, it is acceptable to offer PGT for known X-linked recessive single gene disorders with a clear unequivocal clinical diagnosis where no pathogenic variant was found in the proband but low- and high-risk haplotypes can be identified based on the family history.

Exclusion or non-disclosure testing can be indicated for late-onset disorders, such as Huntington's disease, to avoid pre-symptomatic testing of the partner with a family history of the disease. Exclusion testing is preferred over PGT with non-disclosure of the direct test results to the couple."

For *PGT for mitochondrial disorders*: "PGT is not indicated in case of homoplasmy. In cases where the causative pathogenic variant of the mitochondrial disease is encoded by nuclear DNA, testing is the same as for other monogenic disorders."

For *HLA Typing*: "When all other clinical options have been exhausted, selection of HLA-matched embryos via PGT is acceptable for couples who already have a child affected with a malignant, acquired disorder or a genetic disorder where the affected child is likely to be cured or life expectancy is substantially prolonged by transplantation with stem cells from an HLA-matched sibling. Testing can be performed for HLA typing alone, if the recurrence risk of the disease is low, or in combination with autosomal dominant/recessive or X-linked disorders."

For *PGT-SR*: "Depending on the technology used (FISH, quantitative real-time PCR (qPCR), comprehensive testing methods [array-based comparative genomic hybridisation (aCGH), single nucleotide polymorphism (SNP) array or next generation sequencing (NGS)]), different inclusion/exclusion criteria may apply. In general, PGT-SR is only recommended if the technique applied is able to detect all expected unbalanced forms of the chromosomal rearrangement. When comprehensive testing strategies are applied, it is acceptable to use information on copy number of nonindication chromosomes to refine embryo transfer strategies."

For *PGT-A*: "For all, but in particular for RIF, RM and SMF couples, a previous karyotype of both partners is recommended since there is a higher chance of structural rearrangements for these indications. If an abnormal karyotype is identified, the technology for the detection of unbalanced abnormalities can differ from the regular PGT-A" (ESHRE PGT Consortium Steering Committee et al., 2020).

Ethics Committee of the American Society for Reproductive Medicine (ASRM)

The ASRM ethics committee has published several opinion guidelines over the years.

In 2018, the ASRM published a committee opinion on the use of preimplantation genetic testing for monogenic defects (PGT-M) for adult-onset conditions. These guidelines stated the following:

- "Preimplantation genetic testing for monogenic disease (PGT-M) for adult-onset conditions is ethically justified when the condition is serious and no safe, effective interventions are available."

- "Reproductive liberty arguments ethically allow for PGT-M for adult-onset conditions of lesser severity or penetrance. In the latter cases, the application of the technology hinges on the evidence that PGT-M is a relatively low-risk procedure; this evidence may change."
- "The Committee to strongly recommend that an experienced genetic counselor with knowledge about PGT-M play a major role in counseling patients considering such procedures" (ASRM, 2018).

The ASRM also published an updated committee opinion in July 2023 detailing indications and management of preimplantation genetic testing for monogenic conditions, not limited to adult onset. These recommendations state the following:

- "Suggested categorization of PGT-M indications (derived from table):
  - Childhood-onset, lethal or severe condition
  - Serious adult-onset conditions
  - Mild conditions or indications of limited or questionable risk reduction:
    - Low penetrance or susceptibility genes
    - Mild genetic variants
    - Carrier status for autosomal recessive conditions with carrier manifestations
    - Mild, common, and/or treatable conditions
    - Variants appearing to be de novo in an affected child
    - Variants of uncertain significance
- Indications for which PGT-M is not recommended:
  - Autosomal recessive carrier status without manifestations of symptoms
  - Combination of variants not associated with disease
  - Pseudodeficiency alleles
  - Somatic-only variants"
- "Preimplantation genetic testing for monogenic conditions should be offered if a significant reproductive risk is identified. Acceptance of PGT-M should be optional"

However, with these categorizations, the committee reiterates some key considerations surrounding the application of PGT-M and the ethical arguments in certain situations: "The initial application of PGT-M was primarily to prevent the transmission of severe, untreatable, or life-threatening childhood-onset conditions. Today, however, the use of the technology extends to a much broader range of genetic conditions for which support of PGT-M is less clear or even controversial, including those with mild to moderate phenotypes and later age of onset and of much greater clinical variability and/or reduced penetrance. A survey of laboratory genetic counselors in 2021 found that all participants believed that PGT-M should be

allowed for conditions of lower penetrance, citing patient autonomy as a primary consideration. At this time, no guidelines exist to offer direction to those involved in determining when to offer or decline to perform PGT-M, although some ethical arguments exist. As such, physicians, genetic counselors, and PGT laboratories may develop internal policies regarding PGT-M availability within their institution. If certain types of conditions or clinical scenarios are deemed not appropriate for PGT-M, the patient should be informed of the policy as early in the process as possible." (Practice Committee and Genetic Counseling Professional Group of the American Society for Reproductive Medicine, 2023).

Similar guidelines were also published in 2013 by the ASRM regarding the use of PGD for serious adult-onset conditions:

- "Preimplantation genetic diagnosis (PGD) for adult-onset conditions is ethically justifiable when the conditions are serious and when there are no known interventions for the conditions or the available interventions are either inadequately effective or significantly burdensome.
- For conditions that are less serious or of lower penetrance, PGD for adult onset conditions is ethically acceptable as a matter of reproductive liberty. It should be discouraged, however, if the risks of PGD are found to be more than merely speculative.
- Physicians and patients should be aware that much remains unknown about the long-term effects of embryo biopsy on any developing fetus. Though thought to be without serious side effects, PGD for adult onset diseases of variable penetrance should only be considered after patients are carefully and thoroughly counseled to weigh the risks of what is unknown about the technology and the biopsy itself against the expected benefit of its use.
- It is important to involve the participation of a genetic counselor experienced in such conditions before patients undertake PGD. Counseling should also address the patient specific prognosis for achieving pregnancy and birth through in vitro fertilization (IVF) with PGD" (Ethics Committee of the American Society for Reproductive Medicine ASRM, 2013).

Additional guidelines were published in 2008, which stated the following:

- "Before PGD is performed, genetic counseling must be provided to ensure that patients fully understand the risk for having an affected child, the impact of the disease on an affected child, and the limitations of available options that may help to avoid the birth of an affected child.

- Prenatal diagnostic testing to confirm the results of PGD is encouraged strongly because the methods used for PGD have technical limitations that include the possibility for a false negative result.
- Available evidence does not support the use of PGS as currently performed to improve live-birth rates in patients with advanced maternal age.
- Available evidence does not support the use of PGS as currently performed to improve live-birth rates in patients with previous implantation failure.
- Available evidence does not support the use of PGS as currently performed to reduce miscarriage rates in patients with recurrent pregnancy loss related to aneuploidy" (ASRM, 2008).

Preimplantation Genetic Diagnosis International Society (PGDIS)

In the report from the 2021 PGDIS Expert Consultation on Mosaic Embryo Transfer, the PGDIS published a position statement on the transfer of mosaic embryos, including the following recommendations for clinicians:

- "Patients should continue to be advised that any genetic test based on sampling one or small number of cells biopsied from preimplantation embryos cannot be 100% accurate because of a combination of technical and biological factors, including cell mosaicism;
- Patient information and consent forms for aneuploidy testing should be modified to include the possibility of mosaic results; and
- In general, transfer of blastocysts with a normal euploid result should be prioritized over those with mosaic results unless other indications, such as patient preference, are raised" (Leigh et al., 2022).

American College of Medical Genetics and Genomics (ACMG)

The ACMG has released guidelines on prenatal/preconception carrier screening, primarily when to test:

- "Disorders should be of a nature that most at-risk patients and their partners identified in the screening program would consider having a prenatal diagnosis to facilitate making decisions surrounding reproduction.
- For each disorder, the causative gene(s), mutations, and mutation frequencies should be known in the population being tested, so that meaningful residual risk in individuals who test negative can be assessed."
- There must be validated clinical association between the mutation(s) detected and the severity of the disorder" (Grody et al., 2013).

In 2021 the ACMG published recommendations on screening for autosomal recessive and X-linked conditions during pregnancy and preconception. They reference an overlapping, tiered approach to testing defined as:

- Tier 1: Cystic fibrosis, spinal muscular atrophy, and risk based screening.
- Tier 2: "Conditions that have a severe or moderate phenotype and a carrier frequency of at least 1/100." (Includes Tier 1).
- Tier 3: "Conditions with a carrier frequency ≥ 1/200." (Includes Tier 2). Includes X-linked conditions.
- Tier 4: "Genes less common than those in Tier 3 and can identify additional at-risk couples." Conditions with a carrier frequency <1/200. (Includes Tier 3).

In terms of what screening approaches should be offered, the ACMG recommends that "all pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening. Tier 4 screening should be considered: when a pregnancy stems from a known or possible consanguineous relationship (second cousins or closer); [or] when a family or personal medical history warrants." The ACMG does NOT recommend "Offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups [or] routine offering of Tier 4 panels."

In terms of what autosomal recessive conditions are appropriate for carrier screening, the ACMG recommends that "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening for autosomal recessive and X-linked conditions. Reproductive partners of pregnant patients and those planning a pregnancy may be offered Tier 3 carrier screening for autosomal recessive conditions when carrier screening is performed simultaneously with their partner."

In terms of which X-linked conditions are appropriate for carrier screening, they note that "All XX patients should be offered screening for only those X-linked genes [listed here] as part of Tier 3 screening." The X-linked genes are: *ABCD1, AFF2, ARX, DMD, F8, F9, FMR1, GLA, L1CAM, MID1, NR0B1, OTC, PLP1, PRGR, RS1, SLC6A8*.

Lastly, the ACMG notes the "critical" importance of education and counseling in carrier screening and recommends that "carrier screening counseling should be provided by knowledgeable and appropriately trained health-care professionals and should be performed pre- and post-test" (Gregg et al., 2021).

British Fertility Society (BFS) Policy and Practice Guidelines

The BFS have published guidelines regarding PGS. These guidelines state that "It remains possible that PGS may be of benefit under certain circumstances. However at present patients should be informed that there is no robust evidence that PGS for

advanced maternal age improves live birth rate per cycle started, and PGS should preferably be offered within the context of robustly designed randomised trials performed in suitably experienced centres" (Anderson & Pickering, 2008).

Indian Society for Assisted Reproduction (ISAR)

The Indian Society for Assisted Reproduction released consensus guidelines about preimplantation genetic testing in *In vitro* fertilization clinics in India. The recommendations for PGT-A are: "PGT-A is recommended for: advanced maternal age (36–40 years), or repeated pregnancy loss – known etiologies. PGT-A is not recommended for: young, good prognosis patients (<35 years), or unexplained RPL, or low AMH – limited eggs; multiple IVF cycles may be necessary in order to obtain one euploid blastocyst."

The clinical recommendations for genetic testing for monogenic indications are:

- "Can be offered to all patients with single or multiple gene disorders with a positive mutation report
- Cannot be offered for diseases which as multifactorial and nongenetic based diseases
- In case PGT-A is desired, it should be performed on PGT-M screened embryos" (Malhotra et al., 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81228	Cytogenomic (genome-wide) analysis for constitution chromosomal abnormalities; interrogation of genomic regions for copy number variants, comparative genomic hybridization [CGH] microarray analysis
81229	Cytogenomic (genome-wide) analysis for consititutional chromosomal abnormalties; interrogation og genomic regions for copy number and single nucleotide polymorphism (SNP) variants, comparative genomic hybridization (CGH) microarray analysis
81349	Cytogenomic (genome-wide) analysis for constitutional chromosomal abnormalities; interrogation of genomic regions for copy number and loss-of-heterozygosity variants, low-pass sequencing analysis
81479	Unlisted molecular pathology procedure
0254U	Reproductive medicine (preimplantation genetic assessment), analysis of 24 chromosomes using embryonic DNA genomic sequence analysis for aneuploidy, and a mitochondrial DNA score in euploid embryos, results reported as normal (euploidy), monosomy, trisomy, or partial deletion/duplications, mosaicism, and segmental aneuploidy, per embryo tested Proprietary test: SMART PGT-A (Pre-implantation Genetic Testing - Aneuploidy) Lab/Manufacturer: Igenomix®
0396U	Obstetrics (pre-implantation genetic testing), evaluation of 300000 DNA single-nucleotide polymorphisms (SNPs) by microarray, embryonic tissue, algorithm reported as a probability for single-gene germline conditions Proprietary test: Spectrum PGT-M Lab/Manufacturer: Strata Oncology, Inc

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Prenatal Screening (Genetic)

Policy Number: AHS – M2179– Prenatal Screening (Genetic)	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Prenatal screening encompasses any testing done to determine the health status of the pregnant individual and/or fetus. Genetic prenatal screening encompasses screening to determine risk of fetal abnormalities, including genetic and developmental abnormalities. Any individual undergoing screening tests, especially genetic carrier screenings, must realize the limitations of screening tests and the difference between screening and diagnostic testing. Screening refers to testing of asymptomatic or healthy individuals to search for a condition that may affect the pregnancy or individual, whereas diagnostic testing is used to either confirm or refute true abnormalities in an individual (Grant & Mohide, 1982; Lockwood & Magriples, 2023).

This policy addresses broad prenatal genetic screening, as well as screening for conditions not addressed in condition-specific policies. For situations in which prenatal and preconception screening may be discussed in further detail, please see the "Related Policies" section of this policy document.

Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS-G2035	Prenatal Screening (Nongenetic)
AHS-G2055	Prenatal Screening for Fetal Aneuploidy
AHS-G2148	Genetic Testing for Hereditary Hearing Loss
AHS-M2017	Genetic Testing for Cystic Fibrosis
AHS-M2024	Genetic Testing for Polyposis Syndromes
AHS-M2028	Genetic Testing for *FMR1* Mutations

AHS-M2033	Chromosomal Microarray and Low-pass Whole Genome
AHS-M2039	Pre-Implantation Genetic Testing
AHS-M2077	Genetic Testing for Fanconi Anemia
AHS-M2167	Genetic Testing for Neurodegenerative Disorders
AHS-M2170	Red Blood Cell Molecular Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who are pregnant **or** who are capable of becoming pregnant and seeking pre-conception care, single gene or multi-gene panel screening of the individual for conditions classified through ACMG as a Tier 1, Tier 2, or Tier 3 condition (see Note 1) **MEETS COVERAGE CRITERIA**.

2) For pregnant individuals and those capable of becoming pregnant who come from a family with a genetic disorder for which a properly validated test is available, the following testing **MEETS COVERAGE CRITERIA**:

   a) Testing restricted to the known mutation.

   b) Comprehensive genetic testing, including multi-gene panel testing specific to the familial genetic disorder, when the specific familial mutation is unknown.

3) For individuals planning a pregnancy with a reproductive partner who is known or found to be a carrier of a recessively inherited disorder, genetic testing specific to the genes for which the reproductive partner is a carrier **MEETS COVERAGE CRITERIA**.

4) For RHD negative pregnant individuals, fetal RHD genotyping using maternal plasma **MEETS COVERAGE CRITERIA**.

5) For fetuses with a high risk for a genetic disorder, prenatal genetic testing using cells obtained for diagnostic cytogenetic testing (i.e., amniocentesis or chorionic villus sampling [CVS]) **MEETS COVERAGE CRITERIA**.

6) Carrier screening for the same gene more than once per lifetime **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

7) To screen for single-gene mutations (i.e., autosomal recessive, autosomal dominant, X-linked) in the fetus, the use of non-invasive prenatal screening (NIPS) **DOES NOT MEET COVERAGE CRITERIA.**

8) For all other inherited medical disorders not meeting the above criteria, pre-conceptional or prenatal genetic testing **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Please see the "Guidelines and Recommendations" section of this policy for ACMG's tiered system based on carrier frequency (Tables 1-6).

Note 2: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics and Genomics
ACOG	American College of Obstetricians and Gynecologists
ADA	American Diabetes Association
CAP	College of American Pathologists
CAVD	Congenital absence of the vas deferens
cfDNA	Cell-free deoxyribonucleic acid
CFTR	*CF transmembrane conductance regulator*
CMA	Chromosomal microarray
CNVs	Copy number variants
CVS	Chorionic villus sampling
DMD	Dystrophin
DNA	Deoxyribonucleic acid
FRAXE	Fragile site, folic acid type, rare, Fra(X)(Q28) E
GJB6	Gap junction protein
HBB	Human beta-globin gene
HDFN	Hemolytic disease of the fetus and newborn
ISPD	International Society for Prenatal Diagnosis
MMS	Microdeletion/microduplication syndromes
NGS	Next generation sequencing
NIPS-	Expanded non-invasive prenatal screening
NIPT	Non-invasive prenatal testing
NT	Nuchal translucency
PPVs	Positive predictive values
PQF	Perinatal Quality Foundation
RBC	Red blood cells

RHD	Rh blood group D antigen
sgNIPS	Single-gene noninvasive prenatal screening
SMA	Spinal muscular atrophy
SMFM	Society for Maternal Fetal Medicine
SMN1	*Survival of motor neuron 1*
SNP	Single nucleotide polymorphism
TMRC	Transfusion Medicine Resource Committee

V. Scientific Background

Prenatal screening is a part of overall prenatal care to promote optimal care of both mother and baby. Prenatal screening allows for assessment and monitoring of the fetus for the presence of congenital defects or disease. Various professional medical organizations provide guidelines for prenatal screening. "Screening is an offer on the initiative of the health system or society, rather than a medical intervention in answer to a patient's complaint or health problem. Screening aims at obtaining population health gains through early detection that enables prevention or treatment" (de Jong et al., 2015).

Genetic screening tests, including carrier screening for genetic mutations and fetal testing for chromosomal aneuploidy, can be a part of prenatal screening. Aneuploidy screening may be performed on cell-free DNA in maternal circulation or by examining maternal serum levels of specific biochemical markers for trisomy (Lockwood & Magriples, 2023). These non-invasive prenatal testing (NIPT) can possibly decrease the number of more invasive procedures and the risks of unwanted side effects. A chromosomal microarray (CMA) can screen all chromosomes in a single test and "can detect many very small variants that cannot be detected by traditional karyotyping" (de Jong et al., 2015). The American College of Obstetricians and Gynecologists (ACOG) recommends CMA for instances where the ultrasound of a fetus shows a major structural abnormality (ACOG, 2016a). CMA in this situation should be performed on DNA from amniotic fluid, chorionic villus cells, or cord blood, rather than on maternal serum cell-free DNA since the process does not include an amplification step and the maternal DNA signal would be many times higher than the fetal DNA (Miller, 2023).

Several companies, such as LabCorp, have developed panels to test for potential genetic mutations in pregnant individuals, or in individuals planning to become pregnant. This includes the Inheritest® Carrier Screening which encompasses six different panels to identify potential genetic mutations. These six panels include the Inheritest® 500 PLUS Panel (which screens 525 genes for several clinically relevant genetic disorders), the Inheritest® Comprehensive Panel (which screens for more than 110 disorders), the Inheritest® Ashkenazi Jewish Panel (which screens for more than 40 Ashkenazi Jewish related disorders), the Inheritest® Society-Guided Panel (which

screens for more than 13 disorders highlighted in the American College of Medical Genetics and Genomics and the American Congress of Obstetricians and Gynecologists guidelines), the Inheritest® Core Panel (which screens for cystic fibrosis, fragile X syndrome, and spinal muscular atrophy), and the Inheritest® CF/SMA (spinal muscular atrophy) Panel (which screens only for cystic fibrosis and spinal muscular atrophy) (LabCorp, 2023).

Additionally, the company BillionToOne has created a noninvasive prenatal screening test. UNITY Complete® uses cell-free DNA from a maternal blood draw and assesses for seven aneuploidies (trisomy 21, trisomy 18, trisomy 13, monosomy X, XXX, XXY, and XYY), and five recessive conditions (cystic fibrosis, spinal muscular atrophy, sickle cell disease, alpha thalassemia, and beta thalassemia). This screen functions in a sequential manner. First, the screen uses NGS of genomic DNA to assesses maternal carrier status for genes associated with the most common single-gene recessive disorders. If the pregnant individual is identified as a carrier for a pathogenic variant in one or more of these genes, the sample is then reflexed to single-gene noninvasive prenatal screening (sgNIPS). In sgNIPS, NGS is performed on cfDNA extracted from the original blood sample, from which fetal risk is calculated. Fetal risk assessment is summarized as low risk (fetal risk 1/500), high risk (fetal risk >1/4), increased risk or decreased risk (fetal risk between 1/500 and 1/4), or no result (BillionToOne, 2023; Hoskovec et al., 2023).

Red blood cell antigen discrepancy between a mother and fetus may also occur during pregnancy. This is known as hemolytic disease of the fetus and newborn (HDFN), and causes maternal antibodies to destroy the red blood cells of the neonate or fetus (Calhoun, 2023). Alloimmunization is the immune response which occurs in the mother due to foreign antigens after exposure to genetically foreign cells, occurring almost exclusively in mothers with type O blood. However, while ABO blood type incompatibility is identified in almost 15% of pregnancies, HDFN is only identified in approximately 4% of pregnancies (Calhoun, 2023). Another important inherited antigen sometimes found on the surface of red blood cells is known as the Rhesus (Rh)D antigen. During pregnancy and delivery, individuals who are RhD negative may be exposed to RhD positive fetal cells, which can lead to the development of anti-RhD antibodies. This exposure typically happens during delivery and affects subsequent pregnancies; infants with RhD incompatibility tend to experience a more severe form of HDFN than those with ABO incompatibility. The clinical presentation of HDFN may be mild (such as hyperbilirubinemia with mild to moderate anemia) to severe and life-threatening anemia (such as hydrops fetalis). Less severely affected infants may develop hyperbilirubinemia within the first day of life; infants with RhD HDFN may also present with symptomatic anemia requiring a blood transfusion. In more severe cases, infants with severe life-threatening anemia, such as hydrops fetalis, may exhibit shock at delivery requiring an emergent blood transfusion (Calhoun, 2023).

The administration of anti-D immune globulin has been able to dramatically reduce, but not eliminate, the number of RhD alloimmunization cases. "Anti-D immune globulin is manufactured from pooled plasma selected for high titers of IgG antibodies to D-positive erythrocytes" (Moise, 2024). Before the development of this anti-D immune globulin, it has been reported that 16% of pregnant RhD-negative individuals with two deliveries of RhD-positive ABO-compatible infants became alloimmunized. However, this rate falls to 1-2% with routine postpartum administration of a single dose of anti-D immune globulin. An additional administration in the third trimester of pregnancy further reduces the incidents of alloimmunization to 0.1-0.3% (Moise, 2024).

Fetal RhD genotyping using cell-free fetal DNA from maternal plasma can be performed to identify fetal blood type most accurately after 11 weeks of gestation. While the United States has not implemented fetal RhD genotyping for routine prophylaxis and fetal monitoring protocols, several European countries, such as Denmark, the Netherlands, England, Sweden, France and Finland, do utilize fetal RhD determination so that the administration of anti-D immune globulin can be avoided when an RhD-negative fetus is identified (Moise, 2024). Daniels et al. (2007) report that approximately 40% of RhD-negative pregnant individuals are carrying a RhD-negative fetus; genotypic screening would, therefore, be very valuable in preventing these individuals from receiving unnecessary anti-D immune globulin. Kent et al. (2014) suggest that the administration of anti-D immune globulin to the one third of pregnant individuals who do not require this administration is unethical, and that the availability of RhD genotyping to all RhD-negative pregnant individuals would assist in more informed choices being made regarding anti-D immune globulin administration. Finning et al. (2008) agree with the previous statements, declaring that "high throughput RHD genotyping of fetuses in all RhD negative [individuals] is feasible and would substantially reduce unnecessary administration of anti-RhD immunoglobulin to RhD negative pregnant [individuals] with an RhD negative fetus."

Analytical Validity

A prospective cohort study by de Haas et al. (2016) completed a nationwide program in the Netherlands to determine the sensitivity of fetal RhD screening for the safe guidance of targeted anti-immune globulin prophylaxis. A total of 25,789 RhD-negative pregnant individuals participated in this study. Fetal testing for the *RHD* gene was assessed in the 27th week of pregnancy. Fetal *RHD* test results were compared to serological cord blood results after birth. "Sensitivity for detection of fetal *RHD* was 99.94% (95% confidence interval 99.89% to 99.97%) and specificity was 97.74% (97.43% to 98.02%). Nine false-negative results for fetal RHD testing were registered (0.03%, 95% confidence interval 0.01% to 0.06%)" (de Haas et al., 2016). They conclude that fetal RhD testing is a highly reliable testing method.

Manfroi et al. (2018) completed fetal *RhD* genotyping with real-time polymerase chain reaction (qPCR) using cell-free fetal DNA extracted from maternal plasma. A commercial multiple-exon assay was used to determine fetal *RHD* genotypic accuracy. A total of 367 plasma samples obtained between the 24th and 28th weeks of pregnancy were used for this study. Neonatal results were available for 284 of the pregnancies. The sensitivity was reported at 100% and specificity at 97.5%. The diagnostic accuracy was 96.1% with the inclusion of 9/284 inconclusive results (Manfroi et al., 2018). The authors conclude that this is therefore an accurate and reliable tool for targeted prenatal immunoprophylaxis.

Clinical Utility and Validity

Education and counseling are a key factor in prenatal screening and diagnostic tests. Yesilcinar and Guvenc (2021) found that a proactive intervention approach decreased anxiety and decisional conflict in the pregnant individual and increased attitudes towards the tests, having a positive effect on the pregnant individual's knowledge level and decision satisfaction. This allowed the individual to make more informed decisions, such as opting to have screening and diagnostic testing performed. Decreasing anxiety during pregnancy is beneficial to the fetus and individuals receiving educational intervention showed decreased anxiety when receiving genetic screening results as compared to individuals not receiving the same intervention (Yesilcinar & Guvenc, 2021). Migliorini et al. (2020) have also reported that the use of cell free DNA (cfDNA) screening, combined with a detailed ultrasound examination, as a first-trimester risk assessment is associated with improved maternal reassurance and satisfaction and decreased anxiety, as compared to individuals who received standard first-trimester combined screening with nuchal translucency (NT) and biochemistry (Migliorini et al., 2020).

Biro et al. (2020) report on a noninvasive prenatal testing method for congenital heart disease, utilizing the measurement of cell-free nucleic acid and protein biomarkers in maternal blood. Congenital heart disease is considered the most common fetal malformation.. While prenatal ultrasonography is currently used to diagnose congenital heart disease, it is not the most accurate method. After a large review completed with PubMed and Web of Sciences databases, the authors conclude that most fetal congenital heart disease related disorders can be diagnosed by noninvasive prenatal testing (NIPT) techniques. Further, cell-free RNAs and circulating proteins are potential biomarkers for fetal congenital heart disease and may be able to improve the detection rate in early pregnancies (Biro et al., 2020).

A study by Persico et al. (2016) investigated the clinical implication of cfDNA testing in high-risk pregnancies. In their cohort of 259 singleton pregnancies, cfDNA testing

provided results in 249 (96.1%). Further, cfDNA testing identified 97.2% (35/36) of trisomy 21, 100% (13/13) of trisomy 18, 100% of trisomy 13 (5/5), and 75% of sex chromosome aneuploidies (3/4). The authors conclude that "a policy of performing an invasive test in [individuals] with a combined risk of ≥1 in 10 or NT ≥4 mm and offering cfDNA testing to the remaining cases would detect all cases of trisomy 21, 18 or 13, 80% of sex aneuploidies and 62.5% of other defects and would avoid an invasive procedure in 82.4% of euploid fetuses" (Persico et al., 2016). These data support the earlier meta-analysis that reported NIPT sensitivity of trisomy 21, trisomy 18, and trisomy 13 of 99%, 96.8%, and 92.1%, respectively and specificities of 99.92%, 99.85%, and 99.80%, respectively, for trisomies 21, 18, and 13 (Dondorp et al., 2015; Gil et al., 2014).

A multi-year study of more than 5000 patients in public hospitals in Spain examined the effect of NIPT on the number of invasive procedures performed, showing that the introduction of NIPT drastically reduced the incidences of invasive procedures. The data shows that despite a 60.5% reduction occurred in invasive procedures, the chromosomopathy detection rate was unaffected; moreover, the ratio of positive invasive procedures was improved to 50%, indicating that unwarranted invasive procedures had been avoided (Martinez-Payo et al., 2018). The authors of the study concluded, "NIPT introduction has caused a significant reduction of 60.5% of IP [invasive procedures] in high chromosomopathy risk patients after combined screening without modifying detection rate" (Martinez-Payo et al., 2018).

A meta-analysis was completed by Mackie et al. (2017), researching the accuracy of cell-free fetal DNA NIPT testing in singleton pregnancies. A total of 117 studies were included, analyzing 18 different conditions. For RHD testing, a sensitivity of 0.993 and specificity of 0.984 was identified and for fetal sex identification, a sensitivity of 0.989 and a specificity of 0.996 was calculated (Mackie et al., 2017). With such high sensitivity and specificity calculations, NIPT testing for fetal sex and RHD status may be considered accurate diagnostic tools.

Clausen et al. (2014) completed a two-year evaluation of nationwide prenatal RhD screening in Denmark. A total of 12,668 pregnancies were analyzed, with blood samples drawn in week 25 of pregnancy. DNA was extracted from these blood samples and was analyzed for the *RHD* gene. Results were later compared to the serological typing of the newborns after birth. "The sensitivity for the detection of fetal *RHD* was 99.9% (95% CI: 99.7-99.9%). Unnecessary recommendation of prenatal RhD prophylaxis was avoided in 97.3% of the [individuals] carrying an RhD-negative fetus. Fetuses that were seropositive for RhD were not detected in 11 pregnancies (0.087%)" (Clausen et al., 2014). This study shows high sensitivity of fetal *RHD* genotyping, results which were recently supported by another large-scale meta-analysis completed by Yang et al.

(2019), focusing on NIPT testing for fetal RhD status. A total of 3921 results confirmed that "High-throughput NIPT is sufficiently accurate to detect fetal RhD status in RhD-negative [individuals] and would considerably reduce unnecessary treatment with routine anti-D immunoglobulin" (Yang et al., 2019).

Darlington et al. (2018) completed an analysis of 11 French Obstetric Departments with a total of 949 patients to determine the effectiveness of RhD genotyping. The patients were separated into two groups (genotyping group: n=515, and control group: n=335). The authors concluded that "Early knowledge of the RHD status of the fetus using non-invasive fetal *RHD* genotyping significantly improved the management of *RHD* negative pregnancies with a small increase in cost" (Darlington et al., 2018).

Runkel et al. (2020) completed a systematic review to determine the benefit of NIPT for fetal RhD status in RhD-negative pregnant individuals because "All non-sensitized Rhesus D (RhD)-negative pregnant [individuals] in Germany receive antenatal anti-D prophylaxis without knowledge of fetal RhD status." The meta-analysis included data from 60,000 participants, with the focus of the research on the impact of fetal and maternal morbidity. The researchers concluded that "NIPT for fetal RhD status is equivalent to conventional serologic testing using the newborn's blood. Studies investigating patient-relevant outcomes are still lacking" (Runkel et al., 2020).

Hoskovec et al. (2023) evaluated the "clinical performance of carrier screening for cystic fibrosis, hemoglobinopathies, and spinal muscular atrophy with reflex single-gene noninvasive prenatal screening (sgNIPS)." In the study, 9151 pregnant individuals were screened for carrier status. As a result, 1669 (18.2%) of the sampled individuals were found to carry one or more harmful genetic variations and were subsequently tested using sgNIPS. The results of sgNIPS were then compared to the outcomes of 201 pregnancies, which were obtained from surveys completed by parents or reports from healthcare providers. In conclusion, carrier screening using sgNIPS during pregnancy presents an alternative approach that circumvents the need for a paternal sample. It offers accurate assessment of fetal risk promptly, facilitating prenatal counseling and pregnancy management.

Westin et al. (2022) conducted a retrospective study which aimed to "validate the sgNIPT in clinical samples and identify high-risk SCD fetuses in a cohort of at-risk pregnancies." This retrospective clinical investigation gathered 77 maternal blood samples from pregnant patients at either Baylor College of Medicine or the University of Alabama at Birmingham. These patients were identified as having at least one harmful HBB allele. The results of this study highlighted that sgNIPT screening promotes "efficient and accurate fetal risk assessment for SCD in pregnant patients" (Westin et al., 2022).

It is notable that the field continues to evolve, with potential shifts from one testing method to another in pursuit of optimality and comprehensiveness. A multicenter retrospective study of singleton high-risk pregnancies for chromosomal abnormalities was conducted by Zhu et al. (2020) to evaluate the utility of expanded noninvasive prenatal screening as compared with chromosomal microarray analysis (CMA). The analysis enrolled subjects who underwent expanded NIPS and CMA sequentially during pregnancy from 2015 through 2019. The study demonstrated that of the 943 high-risk pregnancies, 550 (58.3%) cases had positive NIPS results, while positive CMA results were detected in 308 (32.7%) cases, and the agreement rates between NIPS and CMA were 82.3%, 59.6% and 25.0% for trisomy 21, 18 and 13, respectively. Regarding rare aneuploidies and segmental imbalances, NIPS and CMA results were concordant in 7.5% and 33.3% of cases. However, copy number variants were better detected with CMA than with NIPS and additional genetic aberrations were detected by CMA in one of 17 high-risk pregnancies that were otherwise passed over when processed with NIPS. The researchers contend that CMA should be offered for high-risk pregnancies to provide comprehensive detection of chromosomal abnormalities in these pregnancies (Zhu et al., 2020).

This policy focuses on genetic testing performed during pre-conception and/or prenatal periods as part of a comprehensive prenatal care program.

VI. Guidelines and Recommendations

American College of Medical Genetics and Genomics (ACMG)

In 2021, ACMG released an updated guideline for screening for autosomal recessive and X-linked conditions during pregnancy and preconception. Their practice resource reviews aim to recommend "a consistent and equitable approach for offering carrier screening to all individuals during pregnancy and preconception" and replaces any earlier ACMG position statements on prenatal/preconception expanded carrier screening and provide the following recommendations:

- "Analytical validity of carrier screening is to be established by a laboratory in compliance with CLIA/CAP regulations and adhering to ACMG Laboratory Standards and Guidelines."
- "As evidence evolves, ClinVar and ClinGen continually update pathogenicity of variants and the association between genes and conditions, respectively."
- "Carrier screening enables those screened to consider their reproductive risks, reproductive options, and to make informed decisions."
- "Published evidence supports clinical utility for carrier screening of multiple conditions simultaneously."
- "The phrase "expanded carrier screening" be replaced by "carrier screening."

- "Adopting a more precise tiered system based on carrier frequency:
  - Tier 4: <1/200 carrier frequency (includes Tier 3) genes/condition will vary by lab
  - Tier 3: ≥ 1/200 carrier frequency (includes Tier 2) includes X-linked conditions
  - Tier 2: ≥1/100 carrier frequency (includes Tier 1)
  - Tier 1: *CF* [Cystic Fibrosis] + *SMA* [spinal muscular atrophy] + Risk Based Screening
    - "Tier 1 screening conveys the recommendations previously adopted by ACMG and ACOG" and "adopts an ethnic and population neutral approach when screening for cystic fibrosis and spinal muscular atrophy. Beyond these two conditions, additional carrier screening is determined after risk assessment, which incorporates personal medical and family history as well as laboratory and imaging information where appropriate."
    - "Tier 2 carrier screening stems from an ACOG recommendation for conditions that have a severe or moderate phenotype and a carrier frequency of at least 1/100." However, "data demonstrate that carrier screening for two common conditions using a carrier frequency threshold of 1/100 may not be equitable across diverse populations. Others have shown that limiting the carrier frequency to ≥1/100 creates missed opportunities to identify couples at risk for serious conditions."
    - "We define Tier 3 screening as carrier screening for conditions with a carrier frequency ≥1/200 . . . Tier 2 and Tier 3 screening prioritize carrier frequency as a way to think about conditions most appropriate for screening in the general population. However, when ACOG proposed this level, they did not specify whether it was thinking about carrier frequency in terms of the global population or subpopulations. We use "carrier frequency" to mean in any ethnic group with reasonable representation in the United States."
    - "Tier 4 includes genes less common than those in Tier 3 and can identify additional at-risk couples. Tier 4 has no lower limit carrier screening frequency and can greatly extend the number of conditions screened . . . the clinical validity at this level of carrier screening may be less compelling, therefore we suggest reserving this level of screening for consanguineous pregnancies (second cousins or closer) and in couples where family or medical history suggests Tier 4 screening might be beneficial . . . Importantly, patients should understand that their chance of being a carrier for one or more conditions increases as the number of conditions screened is increased."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening.

- Tier 4 screening should be considered:
  - When a pregnancy stems from a known or possible consanguineous relationship (second cousins or closer);
  - When a family or personal medical history warrants.
- ACMG does NOT recommend:
  - Offering Tier 1 and/or Tier 2 screening, because these do not provide equitable evaluation of all racial/ethnic groups.
  - Routine offering of Tier 4 panels.
- "Carrier screening paradigms should be ethnic and population neutral and more inclusive of diverse populations to promote equity and inclusion."
- "All pregnant patients and those planning a pregnancy should be offered Tier 3 carrier screening for autosomal recessive (Tables 1–5) and X-linked (Table 6) conditions."
- "Reproductive partners of pregnant patients and those planning a pregnancy may be offered Tier 3 carrier screening for autosomal recessive conditions (Tables 1–5) when carrier screening is performed simultaneously with their partner."
- "All XX patients should be offered screening for only those X-linked genes listed in Table 6 as part of Tier 3 screening."
- "When Tier 1 or Tier 2 carrier screening was performed in a prior pregnancy, Tier 3 screening should be offered" (Gregg et al., 2021).

CFTR Variant Testing

In 2020, the ACMG provided a technical standard for *CFTR* variant testing. These standards state the following as it pertains to pregnancy:

"During pregnancy, simultaneous testing may be desired depending on gestational age, family and personal history, ethnicity, or patient preferences. Carrier testing may be offered to individuals with a positive family history of CF, in partners of individuals with a positive family history, in partners of CAVD males, to reproductive age women, and to gamete donors. *CFTR* variant testing can also be performed for prenatal diagnosis using cells obtained for diagnostic cytogenetic testing (i.e., amniocentesis or chorionic villus sampling [CVS])" (Deignan et al., 2020).

"As a way to ensure that *CFTR* variant testing for carrier screening and diagnostic testing purposes remains inclusive, the ACMG recommends either a classification-based reporting approach or a classification-based (targeted) testing approach (which has historically been used for CFTR carrier screening). For those laboratories who wish to continue using a targeted testing approach, the ACMG-23 variant panel remains as the minimum list of CFTR variants that should be included. Laboratories may want to consider adding additional variants to their panel depending on the ethnic composition of their expected test population. However, the minimum list of CFTR variants recommended for pan-ethnic carrier screening has not been increased at this time" (Deignan et al., 2020).

In 2023, the ACMG provided updated recommendations for *CFTR* carrier screening which includes a new minimum *CFTR* variant set (increased from 23 to 100 variants). The updated ACMG position statement states the following:

"This new set now supersedes the previous set of 23 *CFTR* variants recommended by the ACMG. These revised recommendations apply only to carrier screening. They do not apply to *CFTR* variant testing for diagnosis or newborn screening. All other aspects of the updated 2020 ACMG *CFTR* technical standards still apply" (Deignan et al., 2020; Deignan et al., 2023).

American College of Obstetricians and Gynecologists (ACOG)

ACOG has several practice guidelines related to prenatal care as well as both pre-conception and prenatal testing. ACOG recommendations and guidelines include the following:

Genetic Testing and Genetic Counseling: Concerning genetic testing and genetic counseling, ACOG recommends:

- "The routine use of whole-genome or whole-exome sequencing for prenatal diagnosis is **not** recommended outside of the context of clinical trials until sufficient peer-reviewed data and validation studies are published" (ACOG, 2016a). This was reaffirmed in 2023.
- Chromosomal microarray analysis (CMA) is recommended for patients with a fetus with at least one major structure abnormality identified via ultrasound. CMA can be considered for all pregnant individuals who undergo prenatal diagnostic testing; however, "In a patient with a structurally normal fetus who is undergoing invasive prenatal diagnostic testing, either fetal karyotyping or a chromosomal microarray analysis can be performed. Chromosomal microarray analysis of fetal tissue (ie, amniotic fluid, placenta, or products of conception) is recommended in the evaluation of intrauterine fetal death or stillbirth when further cytogenetic analysis is desired because of the test's increased likelihood of obtaining results and improved detection of causative abnormalities" (ACOG, 2016a). This was reaffirmed in 2023.
- "All patients who are considering pregnancy or are already pregnant, regardless of screening strategy and ethnicity, should be offered carrier screening for cystic fibrosis and spinal muscular atrophy, as well as a complete blood count and screening for thalassemias and hemoglobinopathies. Fragile X premutation carrier screening is recommended for [individuals] with a family history of fragile X-related disorders or intellectual disability suggestive of fragile X syndrome, or [individuals] with a personal history of ovarian insufficiency. Additional screening also may be indicated based on family history or specific ethnicity" (ACOG, 2017a). This was reaffirmed in 2023.
- "The American College of Obstetricians and Gynecologists discourages direct-to-consumer genetic testing without appropriate counseling. . . Patients may present after direct-to-consumer testing already has been performed, and clinicians should be prepared to review these results or refer to a health care professional with the appropriate knowledge, training, and experience in interpreting test results. . . Given the insufficient data to support the use of single nucleotide polymorphisms (SNP) testing for medical purposes, SNP testing to provide individual risk assessment for a variety of diseases or to tailor drug therapy outside of an institutional review board-approved research protocol is not recommended. The American College of Obstetricians and Gynecologists recommends that the use of these technologies be viewed as investigational at this time" (ACOG, 2021).
- ACOG notes that "Cascade testing has been shown to be cost effective in part because testing for specific mutations (e.g., those identified in the affected relative) is less expensive than whole-gene sequencing" (ACOG, 2018). This was reaffirmed in 2022.

Prenatal Diagnostic Testing for Genetic Disorders: Concerning prenatal diagnostic testing for genetic disorders, ACOG has published the following recommendations:

- "An abnormal FISH result should not be considered diagnostic. Therefore, clinical decision making based on information from FISH should include at least one of the following additional results: confirmatory traditional metaphase chromosome analysis or chromosomal microarray, or consistent clinical information (such as abnormal ultrasonographic findings or a positive screening test result for Down syndrome or trisomy 18)."
- "All pregnant women should be offered prenatal assessment for aneuploidy by screening or diagnostic testing regardless of maternal age or other risk factors."
- "Prenatal genetic testing cannot identify all abnormalities or problems in a fetus, and any testing should be focused on the individual patient's risks, reproductive goals and preferences."
- "Genetic testing should be discussed as early as possible in pregnancy, ideally at the first obstetric visit, so that first-trimester options are available" (ACOG, 2016b).

Prevention of Rh D Alloimmunization: Concerning the prevention of Rh D alloimmunization, ACOG has published the guidelines supporting the administration of anti-D immune globulin to individuals in various scenarios. However, these guidelines do not mention the use of cell-free fetal DNA for fetal RHD testing to determine if anti-D immune globulin is needed (ACOG, 2017c).

Genetic Carrier Screening: Concerning genetic carrier screening, including testing for specific conditions, ACOG recommends [(ACOG, 2017a, 2017b) reaffirmed 2023]:

- "Carrier screening and counseling ideally should be performed before pregnancy.
- "If an individual is found to be a carrier for a specific condition, the individual's reproductive partner should be offered testing in order to receive informed genetic counseling about potential reproductive outcomes. Concurrent screening of the patient and her partner is suggested if there are time constraints for decisions about prenatal diagnostic evaluation."
- "Carrier screening for a particular condition generally should be performed only once in a person's lifetime, and the results should be documented in the patient's health record. Because of the rapid evolution of genetic testing, additional mutations may be included in newer screening panels. The decision to rescreen a patient should be undertaken only with the guidance of a genetics professional who can best assess the incremental benefit of repeat testing for additional mutations."

- "Prenatal carrier screening does not replace newborn screening, nor does newborn screening replace the potential value of prenatal carrier screening."
- "The cost of carrier screening for an individual condition may be higher than the cost of testing through commercially available expanded carrier screening panels. When selecting a carrier screening approach, the cost of each option to the patient and the health care system should be considered."
- "Screening for spinal muscular atrophy should be offered to all [individuals] who are considering pregnancy or are currently pregnant. In patients with a family history of spinal muscular atrophy, molecular testing reports of the affected individual and carrier testing of the related parent should be reviewed, if possible, before testing. If the reports are not available, *SMN1* deletion testing should be recommended for the low-risk partner."
- "Cystic fibrosis carrier screening should be offered to all [individuals] who are considering pregnancy or are currently pregnant. Complete analysis of the *CFTR* gene by DNA sequencing is not appropriate for routine carrier screening."
- "A complete blood count with red blood cell indices should be performed in all [individuals] who are currently pregnant to assess not only their risk of anemia but also to allow assessment for risk of a hemoglobinopathy. Ideally, this testing also should be offered to [individuals] before pregnancy. A hemoglobin electrophoresis should be performed in addition to a complete blood count if there is suspicion of hemoglobinopathy based on ethnicity (African, Mediterranean, Middle Eastern, Southeast Asian, or West Indian descent). If red blood cell indices indicate a low mean corpuscular hemoglobin or mean corpuscular volume, hemoglobin electrophoresis also should be performed."
- "Fragile X premutation carrier screening is recommended for [individuals] with a family history of fragile X-related disorders or intellectual disability suggestive of fragile X syndrome and who are considering pregnancy or are currently pregnant."
- "If a [individual] has unexplained ovarian insufficiency or failure or an elevated follicle-stimulating hormone level before age 40 years, fragile X carrier screening is recommended to determine whether she has an *FMR1* premutation."
- "All identified individuals with intermediate results and carriers of a fragile X premutation or full mutation should be provided follow-up genetic counseling to discuss the risk to their offspring of inheriting an expanded full-mutation fragile X allele and to discuss fragile X-associated disorders (premature ovarian insufficiency and fragile X tremor/ataxia syndrome)."
- "Prenatal diagnostic testing for fragile X syndrome should be offered to known carriers of the fragile X premutation or full mutation."

- "DNA-based molecular analysis (eg, Southern blot analysis and polymerase chain reaction) is the preferred method of diagnosis of fragile X syndrome and of determining *FMR1* triplet repeat number (e.g., premutations). In rare cases, the size of the triplet repeat and the methylation status do not correlate, which makes it difficult to predict the clinical phenotype. In cases of this discordance, the patient should be referred to a genetics professional."
- "When only one partner is of Ashkenazi Jewish descent, that individual should be offered screening first. If it is determined that this individual is a carrier, the other partner should be offered screening. However, the couple should be informed that the carrier frequency and the detection rate in non-Jewish individuals are unknown for most of these disorders, except for Tay–Sachs disease and cystic fibrosis. Therefore, it is difficult to accurately predict the couple's risk of having a child with the disorder."
- "Screening for Tay–Sachs disease should be offered when considering pregnancy or during pregnancy if either member of a couple is of Ashkenazi Jewish, French–Canadian, or Cajun descent. Those with a family history consistent with Tay–Sachs disease also should be offered screening. When one member of a couple is at high risk (i.e., of Ashkenazi Jewish, French–Canadian, or Cajun descent or has a family history consistent with Tay–Sachs disease) but the other partner is not, the high-risk partner should be offered screening. If the high-risk partner is found to be a carrier, the other partner also should be offered screening."
- "Enzyme testing in pregnant [individuals] and [individuals] taking oral contraceptives should be performed using leukocyte testing because serum testing is associated with an increased false-positive rate in these populations."
- "If Tay–Sachs disease screening is performed as part of pan-ethnic expanded carrier screening, it is important to recognize the limitations of the mutations screened in detecting carriers in the general population. In the presence of a family history of Tay–Sachs disease, expanded carrier screening panels are not the best approach to screening unless the familial mutation is included on the panel" (ACOG, 2017b).
- "Regarding expanded carrier screening panels, ACOG recommends that "the disorders selected for inclusion should meet several of the following consensus-determined criteria: have a carrier frequency of 1 in 100 or greater, have a well-defined phenotype, have a detrimental effect on quality of life, cause cognitive or physical impairment, require surgical or medical intervention, or have an onset early in life." ACOG further states that "screened conditions should be able to be diagnosed prenatally and may afford opportunities for antenatal intervention to improve perinatal outcomes, changes to delivery management to optimize newborn and infant outcomes, and education of the parents about special care needs after birth" (ACOG, 2017a).

Carrier Screening in the Age of Genomic Medicine: Concerning carrier screening in the age of genomic medicine, the ACOG has published the following guidelines (ACOG, 2017a):

- "Ethnic-specific, pan-ethnic and expanded carrier screening are acceptable strategies for prepregnancy and prenatal carrier screening.
- If a patient requests a screening strategy other than the one used by the obstetrician-gynecologist or other health care provider, the requested test should be made available to her after counseling on its limitations, benefits, and alternatives.
- All patients who are considering pregnancy or already pregnant, regardless of screening strategy and ethnicity, should be offered carrier screening for cystic fibrosis and spinal muscular atrophy, as well as a complete blood count and screening for thalassemias and hemoglobinopathies. Fragile X premutation carrier screening is also recommended for [individuals] with a family history of fragile x-related disorders or intellectual disability suggestive of fragile X syndrome, or [individuals] with a personal history of ovarian insufficiency. Additional screening also may be indicated based on family history or specific ethnicity.
- If a [individual] is found to be a carrier for a specific condition, her reproductive partner should be offered screening to provide accurate genetic counseling for the couple with regard to the risk of having an affected child. Additional genetic counseling should be provided to discuss the specific condition, residual risk, and options for prenatal testing.
- Individuals with a family history of a genetic disorder may benefit from the identification of the specific familial mutation or mutations rather than carrier screening. Knowledge of the specific familial mutation may allow for more specific and rapid prenatal diagnosis.
- Given the multitude of conditions that can be included in expanded carrier screening panels, the disorders selected for inclusion should meet several of the following consensus-determined criteria: have a carrier frequency of 1 in 100 or greater, have a well-defined phenotype, have a detrimental effect on quality of life, cause cognitive or physical impairment, require surgical or medical intervention, or have an onset early in life. Additionally, screened conditions should be able to be diagnosed prenatally and may afford opportunities for antenatal intervention to improve perinatal outcomes, changes to delivery management to optimize newborn and infant outcomes, and education of the parents about special care needs after birth.
- Carrier screening panels should not include conditions primarily associated with a disease of adult onset" (ACOG, 2017a). This guideline was reaffirmed in 2023.

International Society for Prenatal Diagnosis (ISPD), the Society for Maternal Fetal Medicine (SMFM), and the Perinatal Quality Foundation (PQF)

The ISPD, SMFM and PQF published the following guidelines on the use of genome-wide sequencing for fetal diagnosis:

- The use of diagnostic sequencing is currently being introduced for evaluation of fetuses for whom standard diagnostic genetic testing, such as chromosomal microarray analysis (CMA), has already been performed and is uninformative, is offered concurrently according to accepted practice guidelines, or for whom expert genetic opinion determines that standard genetic testing is less optimal than sequencing for the presenting fetal phenotype.
- The routine use of prenatal sequencing as a diagnostic test cannot currently be supported due to insufficient validation data and knowledge about its benefits and pitfalls (ISPD, 2018).

In addition to the joint position statement released in 2018, the IPSD released a guideline in 2020 on the use of cfDNA screening for trisomies in multiple pregnancies:

- "The use of first trimester cfDNA screening for the common autosomal trisomies is appropriate for twin pregnancies due to sufficient evidence showing high detection and low false positive rates with high predictive values. **Moderate."**
- "It is preferable for laboratories performing cfDNA testing in multi-fetal pregnancies to take evidence of zygosity into consideration (eg, chorionicity, sex of the fetuses, embryo transfer history) for the interpretation of both test results and fetal fractions. **Moderate."**
- "Screening options for triplet pregnancies are lacking and cfDNA may be a potential option. However, diagnostic testing should always be offered and the limitations of screening tests stressed. **Low"** (Palomaki et al., 2021).

College of American Pathologists (CAP) Transfusion Medicine Resource Committee (TMRC) Work Group

The following recommendations were given by the CAP TMRC Work Group:

- The Work Group recommends that *RHD* genotyping be performed whenever a discordant RhD typing result and/or a serological weak D phenotype is detected in patients, including pregnant individuals, newborns, and potential transfusion recipients. It is anticipated that the immediate benefit will be fewer unnecessary injections of RhIG and increased availability of RhD-negative RBCs for transfusion.
- Other than RHD genotypes weak D type 1, 2, or 3, the Work Group recommends that individuals with a serological weak D phenotype receive conventional

prophylaxis with RhIG, including postpartum RhIG if the newborn is RhD-positive or has a serological weak D phenotype (Sandler et al., 2015).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website https://www.cms.gov/Medicare-Coverage-Database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

The FDA has approved many tests for conditions that can be included in a prenatal screening, such as HSV, chlamydia, gonorrhea, syphilis, and diabetes. Additionally, many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	CPT Description
81171	AFF2 (ALF transcription elongation factor 2 [FMR2]) (eg, fragile X intellectual disability 2 [FRAXE]) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81172	AFF2 (ALF transcription elongation factor 2 [FMR2]) (eg, fragile X intellectual disability 2 [FRAXE]) gene analysis; characterization of alleles (eg, expanded size and methylation status)
81200	ASPA (aspartoacylase) (eg, Canavan disease) gene analysis, common variants (eg, E285A, Y231X)
81209	BLM (Bloom syndrome, RecQ helicase-like) (eg, Bloom syndrome) gene analysis, 2281del6ins7 variant
81241	F5 (coagulation factor V) (eg, hereditary hypercoagulability) gene analysis, Leiden variant

CPT	CPT Description
81242	FANCC (Fanconi anemia, complementation group C) (eg, Fanconi anemia, type C) gene analysis, common variant (eg, IVS4+4A>T)
81243	FMR1 (fragile X messenger ribonucleoprotein 1) (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; evaluation to detect abnormal (eg, expanded) alleles
81244	FMR1 (fragile X messenger ribonucleoprotein 1) (eg, fragile X syndrome, X-linked intellectual disability [XLID]) gene analysis; characterization of alleles (eg, expanded size and promoter methylation status)
81251	GBA (glucosidase, beta, acid) (eg, Gaucher disease) gene analysis, common variants (eg, N370S, 84GG, L444P, IVS2+1G>A)
81255	HEXA (hexosaminidase A [alpha polypeptide]) (eg, Tay-Sachs disease) gene analysis, common variants (eg, 1278insTATC, 1421+1G>C, G269S)
81257	HBA1/HBA2 (alpha globin 1 and alpha globin 2) (eg, alpha thalassemia, Hb Bart hydrops fetalis syndrome, HbH disease), gene analysis; common deletions or variant (eg, Southeast Asian, Thai, Filipino, Mediterranean, alpha3.7, alpha4.2, alpha20.5, Constant Spring)
81260	IKBKAP (inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase complex-associated protein) (eg, familial dysautonomia) gene analysis, common variants (eg, 2507+6T>C, R696P)
81290	MCOLN1 (mucolipin 1) (eg, Mucolipidosis, type IV) gene analysis, common variants (eg, IVS3-2A>G, del6.4kb)
81329	SMN1 (survival of motor neuron 1, telomeric) (eg, spinal muscular atrophy) gene analysis; dosage/deletion analysis (eg, carrier testing), includes SMN2 (survival of motor neuron 2, centromeric) analysis, if performed
81330	SMPD1(sphingomyelin phosphodiesterase 1, acid lysosomal) (eg, Niemann-Pick disease, Type A) gene analysis, common variants (eg, R496L, L302P, fsP330)
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP] by techniques such as restriction enzyme digestion or melt curve analysis)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-

CPT	CPT Description
	10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons))
81412	Ashkenazi Jewish associated disorders (eg, Bloom syndrome, Canavan disease, cystic fibrosis, familial dysautonomia, Fanconi anemia group C, Gaucher disease, Tay-Sachs disease), genomic sequence analysis panel, must include sequencing of at least 9 genes, including ASPA, BLM, CFTR, FANCC, GBA, HEXA, IKBKAP, MCOLN1, and SMPD1
81443	Genetic testing for severe inherited conditions (eg, cystic fibrosis, Ashkenazi Jewish-associated disorders [eg, Bloom syndrome, Canavan disease, Fanconi anemia type C, mucolipidosis type VI, Gaucher disease, Tay-Sachs disease], beta hemoglobinopathies, phenylketonuria, galactosemia), genomic sequence analysis panel, must include sequencing of at least 15 genes (eg, ACADM, ARSA, ASPA, ATP7B, BCKDHA, BCKDHB, BLM, CFTR, DHCR7, FANCC, G6PC, GAA, GALT, GBA, GBE1, HBB, HEXA, IKBKAP, MCOLN1, PAH)
81479	Unlisted molecular pathology procedure
81599	Unlisted multianalyte assay with algorithmic analysis
S3845	Genetic testing for alpha-thalassemia
S3846	Genetic testing for hemoglobin E beta-thalassemia
S3849	Genetic testing for niemann-pick disease
0400U	Obstetrics (expanded carrier screening), 145 genes by next-generation sequencing, fragment analysis and multiplex ligation-dependent probe amplification, DNA, reported as carrier positive or negative Proprietary test: Genesys Carrier Panel Lab/Manufacturer: Genesys Diagnostics, Inc
0449U	Carrier screening for severe inherited conditions (eg, cystic fibrosis, spinal muscular atrophy, beta hemoglobinopathies [including sickle cell disease], alpha thalassemia), regardless of race or self-identified ancestry, genomic sequence analysis panel, must include analysis of 5 genes (CFTR, SMN1, HBB, HBA1, HBA2 Proprietary test: UNITY Carrier Screen™ Lab/Manufacturer: BillionToOne Laboratory, BillionToOne, Inc

Prenatal Testing for Fetal Aneuploidy

Policy Number: AHS – G2055 – Prenatal Testing for Fetal Aneuploidy	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Aneuploidy is defined as an abnormal number of chromosomes present in the cell. Fetal aneuploidy is a condition where the fetus has one or more extra or missing chromosomes leading to either a nonviable pregnancy, offspring that may not survive after birth, or surviving newborn with congenital birth defects and functional abnormalities. The most common fetal aneuploidies associated with an additional chromosome are Down syndrome (trisomy 21), Edwards syndrome (trisomy 18), and Patau syndrome (trisomy 13). Prenatal screening for fetal aneuploidy is an assessment of the pregnant individual's risk of carrying a fetus with fetal aneuploidy using markers found in maternal serum (ACOG, 2016). Noninvasive-invasive prenatal screening is a method for screening for chromosomal abnormalities using a maternal blood sample where cell-free fetal DNA (cffDNA) is extracted and screened for aneuploidies (McKanna et al., 2018).

For guidance on the use of chromosomal microarray in the confirmation of fetal aneuploidy, please see AHS-M2033-Chromosomal Microarray and Low-pass Whole Genome Sequencing.

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For pregnant individuals who desire information on the risk of having a child with fetal aneuploidy, the following screening tests to detect fetal aneuploidy of chromosomes 13, 18, and 21 **MEET COVERAGE CRITERIA**:
    a) First-trimester (defined as 11-14 weeks) screening incorporating maternal serum markers (hCG, PAPP-A with NT).
    b) Second-trimester (15-22 weeks) screening incorporating triple maternal serum markers (hCG, AFP, uE3 with NT) and quad maternal serum markers (hCG, AFP, uE3, DIA with NT).
    c) First (11-14 weeks) and second (15-22 weeks) trimester integrated screening incorporating maternal serum markers (PAPP-A with NT) and quad maternal serum markers (hCG, AFP, uE3, DIA with NT).
    d) First (11-14 weeks) and second (15-22 weeks) trimester sequential screening incorporating maternal serum markers (PAPP-A, hCG with NT) and quad maternal serum markers (hCG, AFP, uE3, DIA with NT).
    e) First (11-14 weeks) and second (15-22 weeks) trimester contingent screening incorporating maternal serum markers (PAPP-A, hCG with NT); if positive, quad maternal serum markers (hCG, AFP, uE3, DIA with NT).
2) For pregnant individuals who desire information on the risk of having a child with fetal aneuploidy, non-invasive prenatal screening (NIPS) to detect fetal aneuploidy of chromosomes 13, 18, 21, X, and Y (singleton or twin pregnancies of at least 10 weeks gestation) **MEETS COVERAGE CRITERIA**.
3) For pregnant individuals who desire information on the risk of having a child with fetal aneuploidy or to pursue additional confirmatory testing of equivocal or positive results from the above testing, karyotyping to confirm fetal aneuploidy **MEETS COVERAGE CRITERIA**.
4) To detect fetal aneuploidy, the use of the "penta" screen (hCG, AFP, uE3, DIA with NT, and hyperglycosylated hCG) **DOES NOT MEET COVERAGE CRITERIA**.
5) Screening for the detection of fetal aneuploidies **DOES NOT MEET COVERAGE CRITERIA** in any of the following situations:
    a) Parallel or simultaneous testing with multiple screening methodologies for fetal aneuploidy.
    b) For the screening of pregnant individuals with higher order multiple gestation pregnancies.
    c) Repeat screening for pregnant individuals with negative screening results.

d) For the detection of other chromosomal abnormalities (e.g., microdeletion syndromes, unbalanced translocations, deletions, duplications) not addressed above.

e) For the determination of fetal sex.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

6) For the diagnosis of fetal aneuploidy, the use of single cell genotyping in trophoblasts isolated from maternal serum (e.g., Luna Prenatal Test) **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ACOG	The American College of Obstetrics and Gynecologists
ACMG	The American College of Medical Genetics and Genomics
AFP	Alpha-fetoprotein
ASRM	American Society for Reproductive Medicine
BMI	Body mass index
cfDNA	Cell-free deoxyribose nucleic acid
CffDNA	Cell-free fetal deoxyribose nucleic acid
CGH	Comparative genomic hybridization
CLIA '88	The Clinical Laboratory Improvement Amendments of 1988
CMA	Chromosomal microarray
CMS	Centers for Medicare and Medicaid
CPM	Confined placental mosaicism
CVS	Chorionic villa sampling
DIA	Dimeric inhibin A
DNA	Deoxyribose nucleic acid
dPCR-NIPT	Droplet digital polymerase chain reaction-non-invasive prenatal testing
E3	Estriol
FASTER	First and second trimester evaluation of risk
FDA	Food and Drug Administration
FPR	False-positive rate
GCPG	Practice Committee and Genetic Counseling Professional Group
β-hCG	β-human chorionic gonadotropin

hCG	Human chorionic gonadotropin
h-hCG	Hyperglycosylated human chorionic gonadotropin
Ifs	Incidental findings
ISPD	The International Society for Prenatal Diagnosis
ITA	Invasive trophoblast antigen
LDT	Laboratory-developed test
MPS	Massively parallel sequencing
MSS	Maternal serum screening
NEXT	Noninvasive examination of trisomy
NGS	Next generation sequencing
NIPD	Noninvasive prenatal diagnosis
NIPS	Noninvasive prenatal screening
NIPT	Noninvasive prenatal testing
NSGC	The National Society of Genetic Counselors
NT	Nuchal translucency
PAPP-A	Pregnancy-associated plasma protein-A
PPV	Positive predictive value
RATs	Rare autosomal trisomies
SCAs	Sex chromosome aneuploidies
SMFM	Society for Maternal-Fetal Medicine
SNPs	Single nucleotide polymorphisms
SURUSS	Serum, Urine and Ultrasound Screening Study
uE3	Unconjugated estriol

V. Scientific Background

Pregnant individuals are routinely offered blood-based screening or invasive diagnostic testing for identification of the most common fetal aneuploidies: trisomy 13 (Patau syndrome), trisomy 18 (Edwards syndrome) and trisomy 21 (Down syndrome). Approximately 90% of chromosomal abnormalities are due to an incorrect number of chromosomes, especially in these three triploid conditions as well as monosomy X (Turner syndrome). Approximately 15-20% of clinically recognized pregnancies result in first trimester spontaneous abortions, with 50% of these spontaneous abortions due to chromosomal abnormalities (Witters et al., 2011).

Historically, noninvasive blood-based aneuploidy screening has taken the form of first- and/or second-trimester analysis of biomarkers in maternal circulation, sometimes along with ultrasound measurement of fetal nuchal translucency (NT). Although both the sensitivity (detection rate) and specificity (true positive rate) of maternal serum screening tests for aneuploidy have improved significantly over time, the false positive

rate (two to five percent) remains higher than desirable. The detection rate of Down syndrome in the first trimester using a combination of NT and biochemical markers is typically 79% - 90% (Dey et al., 2013). Positive maternal serum screen results are usually followed by an invasive diagnostic test, such as karyotyping of a chorionic villus sample (in first trimester) or karyotyping of an amniotic fluid sample (second trimester).

Additionally, detection rates of maternal serum screens are typically below 99%, resulting in the inability of a normal result to confer complete confidence that the fetus is unaffected with aneuploidy (Dey et al., 2013). Thus, many pregnant individuals who are in a high-risk category due to age or other factors may opt for the more definitive, diagnostic, invasive testing, which has its own risks and relatively high costs. The availability of noninvasive testing may improve both the sensitivity and specificity of aneuploidy detection while resulting in fewer invasive procedures, less risk, and less overall cost.

Screening Tests

Chromosomal anomalies are a leading cause of perinatal mortality and developmental abnormality. The goal of prenatal testing is to screen for chromosomal anomalies and to provide genetic counseling for parents. The American College of Obstetrics and Gynecology (ACOG) recommends that prenatal testing is offered to all pregnant individuals (ACOG, 2016, 2020). Invasive testing, including chorionic villi sampling or amniocentesis, should be limited to high-risk patients owing to the potential risks for procedure-related pregnancy loss.

Genome-wide sequencing tests for fetal diagnostics have also been employed and are expected to increase in popularity as the cost decreases and as new tools are developed. These tests include DNA sequencing methods, such as whole exome-sequencing and targeted clinical panels, which can further evaluate fetal structural anomalies first detected in an ultrasound (ISPD, 2018). This diagnostic sequencing method has been used for various fetal diagnostic measures including standard genetic testing and chromosomal microarray analysis. While cfDNA could theoretically be analyzed to screen for other genetic disorders beyond common aneuploidies, no professional guideline currently recommend expanded screening for additional genetic disorders (Glenn E Palomaki, 2024). Screening for these additional genetic conditions (other aneuploidies, microdeletions/microduplications, and single gene disorders) while increasingly commercially available, has not been recommended for routine use by leading medical societies and is considered “investigational” (Glenn E Palomaki, 2024).

Chromosomal microarray (CMA) testing refers to the use of comparative genomic hybridization (CGH) arrays to compare the DNA of a patient with a normal control (Aradhya et al., 2007). CMA is significantly more sensitive (10 to 100 kb) than traditional karyotyping (5 to 10 Mb) and has a turnaround time of five days quicker than karyotyping (Robson et al., 2017), while providing an alternative to karyotyping when dividing cells are not available for analysis. This technique may be used for several different purposes, such as identifying a cause of pregnancy loss or identifying other aneuploid conditions, such as Down syndrome (Reddy et al., 2012). This method of diagnostic prenatal sequencing is currently investigational because of limited data and is utilized most prominently in research settings or clinically on a case-by-case basis (ISPD, 2018).

Biochemical Markers in Maternal Serum

Many studies revealed that maternal age, fetal NT, maternal serum free β-human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein-A (PAPP-A) have been associated with aneuploidy. The "Quad screen", comprising alpha-fetoprotein (AFP), hCG, unconjugated estriol (E3), and inhibin A, is the most efficient multiple-marker screening test in the second trimester. In addition, there are more options such as integrated, sequential testing, and cell-free DNA screening. Many studies are ongoing to reveal the most sensitive, specific and effective screening tools for use during the first trimester (Park et al., 2016).

To improve the accuracy of serum markers, ultrasound markers are used. NT refers to the fluid filled space measured on the dorsal aspect of the fetal neck. An enlarged NT (>3.0 mm/99th percentile of the crown-rump length) is independently associated with fetal aneuploidy and structural malformations (ACOG, 2016, 2020).

Screening studies of pregnant individuals reported an association between increased NT in the first trimester of pregnancy (10-13 weeks of gestation) and chromosomal defects, most commonly Down syndrome (trisomy 21) but also trisomy 18 and 13. NT could be done alone as a first-trimester screen or in combination with maternal serum markers, free beta subunit of human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein-A (PAPP-A). All three trisomies (chromosomes 13, 18, and 21) "are associated with increased maternal age, increased fetal NT and decreased PAPP-A, but in trisomy 21 serum free β-hCG is increased whereas in trisomies 18 and 13 free β-hCG is decreased" (Shiefa et al., 2013). Low β-hCG in the first trimester has also been associated with an increased risk of significant copy number variants on chromosomal microarray analyses (Bornstein et al., 2018).

Analytical Validity of Biochemical Markers

Screening for chromosomal abnormalities using biochemical markers include the first trimester combined test, triple test, quadruple test, sequential test, and integrated test. Except for the first trimester combined test, all others can provide screening results in the second trimester. In the first trimester combined test, the risk is calculated based on the ultrasonographic findings of NT and maternal serum levels of free β-hCG and PAPP-A. First-trimester screening not only allows early reassurance or early diagnosis of aneuploidy, but it also provides an option of earlier and safer termination of pregnancy in affected cases. Consequently, the first trimester combined test has become one of the most popular and useful screening strategies. Lee et al. (2013) conducted a 13-year study of 25,104 pregnant individuals using the first trimester Down syndrome screening. "The detection rates for trisomy 21, trisomy 18, Turner syndrome, and other chromosome anomalies were 87.5% (21/24), 69.2% (9/13), 81.8% (9/11), and 60% (18/30), respectively, with a false positive rate (FPR) of 5.4% (1353/25,026). Further evaluation of the detection rates for trisomy 21, by gestational age at 11, 12, and 13 weeks, were 92.3%, 87.5%, and 66.7%, respectively" (Lee et al., 2013).

For second-trimester screening for Down syndrome, the sensitivity and specificity of the triple test—co-testing AFP, unconjugated E3, and free β-hCG—are higher than screening with AFP alone. However, when the false-positive rate is fixed at five percent, to compare the screening performance between the screening tools, the detection rate was found to be 66.8% to 77% with the triple test and 75.9% to 92% with the first trimester combined test. The sensitivity of the triple test was lower than the combined test (Baer et al., 2015).

The quadruple test, which uses the fourth marker, inhibin A, in addition to the other three markers, has seven percent higher sensitivity when applying a fixed five percent false-positive rate. A study conducted by Wald et al. (2003) revealed that when inhibin A was added to the traditional triple marker test, a detection rate of 83% was achieved, which was six percent higher than the 77% detection rate found with the triple test. This result was similar to that produced with the first trimester combined test (Park et al., 2016).

Many studies, including the Serum, Urine and Ultrasound Screening Study (SURUSS) (Wald et al., 2003) and the First and Second-Trimester Evaluation of Risk (FASTER) study (Malone et al., 2005), have offered evidence suggesting that first-trimester screening for Down syndrome with measurement of fetal NT and maternal serum markers is at least as accurate as alternative tests and may allow for earlier confirmation or exclusion of Down syndrome. These studies evaluated several tests in parallel, including first trimester testing with NT and maternal markers, the triple test, second-semester quadruple test and a combined first- and second-trimester test (both

with and without NT), stepwise sequential testing (results given after first-trimester testing, move on to second-trimester testing), and integrated screening (results given only after first and second-trimester testing). In a direct comparison of the first-trimester test to the triple test, the SURUSS study has shown that setting the false-positive rate at 5% resulted in an 83% detection rate, which was superior to what was historically expected of the triple test (Wald et al., 2003). SURUSS results were based on data from 47,053 pregnancies (101 with Down syndrome). The FASTER trial was conducted in the United States and was sponsored by the National Institutes of Health. The study enrolled 38,167 pregnant individuals and provided further evidence that first-trimester combined screening was effective, but it did not provide NT measurement alone; results showed that integrated first- and second-trimester screening provided higher detection rates. The SURUSS and FASTER studies also found that overall, first-trimester screening with NT alone is inferior to either first- or second-trimester combined screening. Additional testing may not be necessary in those few cases when NT is at least 4.0 mm due to the high likelihood of Down syndrome in these cases (Malone et al., 2005; Wald et al., 2009; Wald et al., 2003).

Studies have found a high rate of successful imaging of the fetal nasal bone and an association between absent nasal bone and the presence of Down syndrome in high-risk populations. However, there is insufficient evidence on the performance of fetal nasal bone assessment in average-risk populations. Of concern is the low performance of fetal nasal bone assessment in a subsample of the FASTER study conducted in a general population sample. Two studies conducted outside of the United States have found that, when added to a first-trimester screening program evaluating maternal serum markers and NT, fetal nasal bone assessment can result in a modest decrease in the false-positive rate. Several experts in the field are proposing that fetal nasal bone assessment be used as a second stage of screening to screen pregnant individuals found to be of borderline risk using maternal serum markers and NT. Considering the uncertainty of test performance in average-risk populations and the lack of standardization in the approach to incorporating this test into a first-trimester screening program, detection of fetal nasal bone is considered investigational (Wald et al., 2009).

Palomaki et al. (2004) demonstrate that hyperglycosylated hCG (h-hCG), also known as invasive trophoblast antigen (ITA), may be a promising screening marker for Down syndrome detection in the second trimester. In the study, serum samples of 45 Down syndrome cases and 238 unaffected control pregnancies between 14 to 20 weeks of gestation were collected and measured for h-hCG, along with other screening markers (Palomaki et al., 2004). As seen in the figure below, h-hCG, in combination with four other screening markers, increased the detection rate to 83% at a five percent false-positive rate from the 72% detection rate by the tripe test (Palomaki et al., 2004;

QuestDiagnostics, 2022). In addition, "The median [h-hCG] in Down syndrome pregnancies was >3.00 multiples of the median, higher than that found for human chorionic gonadotropin (hCG)." The author recommends that "the highest screening performance for Down syndrome can be obtained by integrating first- and second-trimester serum and ultrasound markers into a single interpretation in the second trimester. This integrated test approach can detect 90% of Down syndrome pregnancies at a 3% false-positive rate" (Palomaki et al., 2004).

Cell-Free Fetal DNA from Maternal Serum

In 1997, researchers reported the identification of cell-free fetal DNA (cffDNA) in the circulation of pregnant individuals (Lo et al., 1997). The fetal fraction of cffdna increases throughout gestation. cffDNA is usually detectable within six to seven weeks of gestation, with the earliest detection reported at 4.5 weeks. Therefore, it allows for noninvasive procedures to be performed much earlier in the pregnancy and eschews the need for standard biochemical and invasive screens. Moreover, given that cffDNA is cleared from maternal circulation within hours following birth and removal of the placenta, cffDNA is specific to the ongoing pregnancy at the time of sampling (Shaw et al., 2020). At 10 weeks of gestation, the fetal fraction comprises at least three to four percent whereas it can account for up to 50% of the total cell-free DNA at term (Palomaki et al., 2024). Since then, laboratories have validated several different techniques for the use of cell-free DNA as a screening test for fetal aneuploidy, and these methods have been termed noninvasive prenatal screening (NIPS) or noninvasive prenatal testing (NIPT).

Noninvasive prenatal screening is a testing method which utilizes cell-free DNA from the plasma of pregnant individuals to screen for fetal aneuploidy. It is important to note that cell-free DNA screening does not assess risk of fetal anomalies, including neural tube defects or ventral wall defects (ACOG, 2015). NIPS methods only provide an estimate of whether the risk of aneuploidy is increased or decreased; NIPS does not provide a definitive diagnosis of aneuploidy. As with other aneuploidy screening tests, it is recommended that positive results of NIPS be followed by diagnostic testing such as traditional karyotyping of fetal cells obtained via chorionic villus sampling or amniocentesis (Gregg et al., 2016).

One cell-free fetal DNA detection method for NIPS, known as massively parallel sequencing (MPS), is a technique in which millions of pieces of maternal and fetal chromosomal material are sequenced and quantified. The MPS method is able to detect many types of aneuploidies, including those which are less commonly seen (Devers et al., 2013). MPS can detect common aneuploidies with both high sensitivity and high specificity for trisomies 13, 18, and 21. Bianchi et al. (2012) found the

detection rate sensitivity for trisomy 21 to be 100%, the detection rate sensitivity for trisomy 18 to be 97.2%, and the detection rate sensitivity for trisomy 13 to be 78.6%; specificity was 100% for all three of the aforementioned trisomies.

Detection of aneuploidy using circulating cell-free fetal DNA can also be performed using selective analysis of specific loci only from the chromosomes of interest, as opposed to sequencing of all chromosomes performed in MPS. This directed analysis of cell-free fetal DNA has also been shown to have high sensitivity and high specificity for the common trisomies. Lee et al. (2019) utilized plasma from 1,055 pregnant individuals and found that NIPT with cell-free fetal DNA "showed 100% sensitivity and 99.9% specificity for trisomy 21, and 92.9% sensitivity and 100% specificity for trisomy 18, and 100% sensitivity and 99.9% specificity for trisomy 13" (Lee et al., 2019).

The third approach to detect aneuploidy from cffdna is based on the amplification of single nucleotide polymorphisms (SNPs) on the chromosome of interest. In a study by Eiben et al. (2015), 2,942 patients underwent SNP-based noninvasive prenatal screening (NIPS) in which the source for cffdna was derived from placental cells. Sixty-five patients (2.2%) had positive noninvasive prenatal screening results for aneuploidy and further invasive testing confirmed aneuploidy in fifty-nine of those patients (90.8%). The remaining six patients were false positives due to a discrepancy between the genetic status of the fetus and placenta, a condition known as confined placental mosaicism (CPM). The fetal fraction was abnormally low (less than eight percent) and indicative of fetal-placental discrepancies. Although a reliable screening method, the author suggests that SNP-based NIPS "cannot be used as a standalone test without ultrasound examination or invasive confirmation" (Eiben et al., 2015).

Despite the apparent advantages of NIPS over standard maternal serum screening in screening for common aneuploidies, there are limitations. "Reported Ifs [incidental findings] range from fetal or maternal deletions and duplications or mosaic sex chromosome aneuploidy in the mother or fetus, presenting as aneuploidy risk on NIPS, to mosaicism and uniparental disomy to abnormal results because of the presence of cell-free DNA originating from an undiagnosed maternal tumor" (Westerfield et al., 2014). When ultrasound evaluation reveals fetal anomalies that may be consistent with one of those scenarios, invasive diagnostic testing with karyotyping or microarray may be more appropriate. NIPS also cannot distinguish the cause of aneuploidy, nor can it differentiate among the presence of an extra chromosome, a Robertsonian translocation, or high-level mosaicism. The determination of the type of aneuploidy is important for accurate counseling and future risk assessment (Neufeld-Kaiser et al., 2015; Strom et al., 2017; Westerfield et al., 2014). Also, some samples contain insufficient amounts of cell-free DNA, which is unknown until the test procedure has commenced. Early gestational age (<10 weeks) and high body mass index have been

shown to be associated with reduced amounts of circulating cell-free fetal DNA. Additionally, NIPS for aneuploidy does not detect the presence of neural tube defects, which is included in traditional second trimester maternal serum screening. It has been suggested that the testing of maternal serum AFP in the second trimester should be offered to pregnant individuals who underwent first-trimester aneuploidy screenings (Palomaki et al., 2024).

And so, while promising on the screening front, research has yet to support NIPT's diagnostic prowess. NIPT platforms typically screen for common trisomies with or without sex chromosome anomalies, and therefore overlook most other chromosomal rearrangements (Al Toukhi et al., 2019; Shaw et al., 2020). Furthermore, the power of NIPT is limited by discordant—e.g., false-positive and false-negative—results, due to issues including vanishing twin syndrome, where a spontaneous early miscarriage may still release cffDNA and interfere with early NIPT results. Abnormal maternal cells mixing with normal fetal cells, producing mosaicism as aforementioned, has been reportedly repeatedly and therefore is an incidental cause of discordant results, suggesting that pregnant individuals with known malignancies should be dissuaded from NIPT (Bianchi et al., 2015; Shaw et al., 2020).

Extension of NIPT to sex chromosome aneuploidies and rare autosomal trisomies has also been explored, though its utility remains controversial. The increased variability in its use here is due in part to the sensitivity of NIPT to detect sex chromosome aneuploidies—e.g., Turner syndrome (45, X) and Klinefelter syndrome (45, XXY)—being lower than that of common trisomies. Moreover, as NIPT screens were originally limited in scope to identify trisomies 13, 18, and 21, the utility of NGS-based NIPT to also detect rare autosomal trisomies (RATs) has yet to be informed by the clinical community, and offers inspiration for future directions (Shaw et al., 2020).

Analytical Validity of Cell-free Fetal DNA Testing

A study by Palomaki et al. (2012) of 4664 pregnancies at high-risk for Down syndrome using the MPS method had a detection rate of 98.6% with a false-positive rate of only 0.20% (3/1471) (Palomaki et al., 2011). Results also identified MPS as a successful detection method for both trisomy 18 and trisomy 13. The authors state, "Among the 99.1% of samples interpreted (1,971/1,988), observed trisomy 18 and 13 detection rates were 100% (59/59) and 91.7% (11/12) at false-positive rates of 0.28% and 0.97%, respectively… Among high-risk pregnancies, sequencing circulating cell-free DNA detects nearly all cases of Down syndrome, trisomy 18, and trisomy 13, at a low false-positive rate. This can potentially reduce invasive diagnostic procedures and related fetal losses by 95%. Evidence supports clinical testing for these aneuploidies" (Palomaki et al., 2012).

Norton et al. (2015) reported near-perfect accuracy of detection for trisomy 21 (Down syndrome) with the use of cell-free DNA (cfDNA) (sensitivity, 100% [38 of 38 cases of trisomy 21]; false-positive rate, 0.06% [9 false positives among 15,841 pregnant individuals]) in the Noninvasive Examination of Trisomy (NEXT) study. Norton and colleagues found that cfDNA testing for trisomy 21, as compared with standard screening, had a better global performance during the first trimester of pregnancy. However, they did not provide information about the 14 fetal chromosomal abnormalities in the 15,841 screened pregnancies, other than for trisomies 13, 18, and 21 (Norton et al., 2015).

In 2017, the Dutch Ministry of Health introduced a nationwide implementation study on NIPT as a first-tier strategy offered to all pregnant individuals in the TRIDENT-2 study. TRIDENT-2 was specific in its scope, as it excluded pregnancies with a vanishing or dischorionic twin, fetal ultrasound including a nuchal translucency greater than or equal to 3.5mm, or gestational age less than 11 weeks. Moreover, pregnant individuals with a history of being high-risk for the common trisomies and who have had an organ transplant were excluded as well, as were pregnant individuals with malignant neoplasia. Of all pregnancies that year, 73,239 (42%) opted for NIPT, it was found that though the number of common trisomies 13, 18, and 21 detected by NIPT was comparable to those of earlier studies, PPVs were higher than expected (53% PPV, 98%, 96%, respectively) with high sensitivities (100%, 91%, 98%, respectively), as confirmed by invasive prenatal testing or by postnatal bloodwork (van der Meij et al., 2019). However, the researchers do acknowledge potential limitations, namely not having presented data on sex chromosome aneuploidies and using different sequencing methods (e.g., NextSeq vs. HiSeq) and fetal fraction benchmarks for rejection across their three testing centers. However, despite issues to external validity, the authors conclude that "this study has confirmed that genome-wide NIPT is a reliable and robust screening test for the detection of fetal trisomies 21, 18, and 13" as they urge further research on screening for fetal pathology and adverse pregnancy outcomes (van der Meij et al., 2019).

As a secondary finding of the TRIDENT-2 study, NIPT may play a future role in raising suspicion of rare maternal malignancies. The TRIDENT-2 study enrolled 231,896 pregnant patients with NIPT results and showed incidental findings of malignancy-suspicious-NIPT in a small proportion of patients (Heesterbeek et al., 2022). The most common malignancies in individuals capable of becoming pregnant who are also of reproductive age include breast, cervical, ovarian, and colorectal cancers; leukemia; Hodgkin and non-Hodgkin lymphoma; thyroid cancer; and melanoma. When tumor cfDNA is incidentally found in maternal blood, there are no current professional guidelines that address the clinical management of cfDNA results. While only (0.02%) of NIPT results in the Heesterbeek et al. (2022)study showed indications of a maternal

malignancy, researchers pointed out this information has clinical significance and can prompt a diagnostic workup through magnetic resonance imaging and computed tomography to enable counseling and confirmative diagnosis in these rare instances (Heesterbeek et al., 2022).

Luo et al. (2021) aimed to explore the efficacy of using NIPT to predict sex chromosome aneuploidies (SCAs) in a 34,717-patient sample study in China. Of the clinical pregnancies examined, 229 (0.66%) were associated with sex chromosome aneuploidies, with 78 of the cases reporting positive for 45,X and 151 sex chromosome trisomies (47,XXX, 47,XXY, 47XYY). In total, 193 of the 229 NIPT positive results acquiesced to confirmatory invasive prenatal diagnosis via karyotyping analysis of amniotic fluid and fluorescent *in situ* hybridization, and it was found that only 67 (34.7%) were true positives. The authors reported similarly low PPVs, with 23.07% for 45,X and 36%, 50%, and 27.27% for 47,XXX, 47,XXY, 47XYY, respectively. Given this performance of the NIPT, the authors concluded that "Confirmatory testing of abnormal results is recommended prenatally or after birth," insinuating the current impotency of NIPT (Luo et al., 2021).

A two-year longitudinal study which utilized 11,414 material blood samples for NIPT. Among the 11,213 cases with confirmatory results, "94 T21, 39 T18, 8 T13, 15 XO, 6 XXX, 3 XYY, 5 XXY and 11,042 euploid cases were detected." Overall, the sensitivity of NIPT was 98.90% (T21), 100.00% (T18), 100.00% (T13), 90.91% (XO), 100.00% (XXX), 100.00% (XYY), and 100.00% (XXY), while the specificity was 99.96% (T21), 99.97% (T18), 99.99% (T13), 99.96% (XO), 99.98% (XXX), 100.00% (XYY), and 99.99% (XXY). The authors concluded that "NIPT showed excellent performance as screening test for the detection of fetal T21, T18, T13 and SCA [sex chromosome aneuploidies] in mixed-risk pregnancies in Iran" (Garshasbi et al., 2019).

A study out of the Illumina laboratory (formerly Verinata) compared NIPS to standard maternal serum screening in pregnant individuals at average-risk for fetal aneuploidy. Their report included data of 5974 samples tested for trisomies 13, 18, and 21 as well as monosomy X. Aneuploidy was detected in 4.8% of samples with only 0.2% putative false-positives and 0.08% false-negatives; however, 2.8% of cases had indefinite results for a single chromosome (Futch et al., 2013). Illumina more recently reported a more extensive study consisting of 85,298 clinical cases. "Aneuploidy was detected or suspected in 2142 (2.5%) samples. For aneuploidy detected cases with known clinical outcomes, the overall positive predictive value (PPV) was 83.5% (608/728); observed PPVs for trisomies 21, 18, and 13 ranged from 50.0 to 92.8%" (Taneja et al., 2016).

Liang et al. (2019) used cell-free plasma DNA to assess the clinical utility of using an expanded noninvasive prenatal screening ("NIPS-Plus") to detect aneuploidy and

genome-wide microdeletion/microduplication syndromes (MMS). Of the 94,085 individuals with singleton pregnancies enrolled in the study, 1128 were suspected of having clinically significant fetal chromosomal abnormalities. Follow-up testing in the study reported the positive predictive values (PPVs) of 95%, 82%, 46%, 29%, and 47% for T21, T18, T13, rare trisomies, and sex chromosome aneuploidies, respectively. For known MMS (n=32), PPVs were 93% (DiGeorge), 68% (22q11.22 microduplication), 75% (Prader-Willi/Angelman), and 50% (Cri-du-Chat). Thus, the researchers conclude that "the data have potential significance in demonstrating the usefulness of cfDNA profiling" and that "NIPS-Plus can be used as a first-tier pregnancy screening method to improve detection rates of clinically significant fetal chromosome abnormalities" (Liang et al., 2019).

A retrospective study by Wu et al. (2020) compared positive noninvasive prenatal screening (NIPS) results for aneuploidy to standard diagnostic tests such as traditional karyotyping and chromosomal microarray analysis (CMA). The study enrolled 551 pregnant individuals who screened positive for trisomy 13, trisomy 18, trisomy 21, and other sex chromosomal aneuploidies. Samples were obtained from either amniotic fluid or fetal cord blood and subsequent karyotyping or CMA confirmed a total of 256 out of 551 cases (46.4%) to possess chromosomal abnormalities concordant or partially concordant with NIPT results. Placental biopsies were obtained to assess the etiology of NIPS false positives and confined placental mosaicism (CPM) was found in 60% of the biopsies. The authors also reported that pregnant individuals with advanced maternal age (>35 years) had the highest positive predictive value (PPV) for trisomy 21 (87.8%), trisomy 18 (59.3%), and trisomy 13 (37.5%), while the PPV was significantly lower for pregnant individuals with young maternal age (<34 years) for trisomy 21 (71.9%), trisomy 18 (0%), and trisomy 13 (16.7%). This suggests that NIPS performs better in predicting aneuploidies for pregnancies with advanced maternal age than for pregnancies with young maternal age. However, the author notes that the PPVs showed "no significant upward trend when compared based on specific age categories (an interval of 5 years), which suggested that NIPT-positive result deserves equal attention from both providers and patients regardless of maternal age" (Wu et al., 2020).

Table 1. Down Syndrome Detection Rates (DRs) Obtained from Various Screening Tests[12]

Test Name	Alias	Markers Included	DR, %[a]
Triple Screen	Maternal Serum Screen 3	Age, AFP, hCG, uE3	72
Quad Screen	Maternal Serum Screen 4	Age, AFP, hCG, uE3, DIA	79
Penta Screen	Maternal Serum Screen 5	Age, AFP, hCG, uE3, DIA, h-hCG	83

[a] Detection rate at a 5% false-positive rate.

Muzzey et al. (2020) studied and compared the sensitivities of both traditional aneuploidy screening and customized whole genome sequencing NIPS for pregnant individuals with high body mass index (BMI). Generally, pregnant individuals with high BMI have reduced fetal fraction during cf-DNA based NIPS, causing up to 24.3% of tests to fail. The study included 58105 patients, and the authors analyzed fetal fraction, aneuploidy, and BMI. Overall, across all obesity classes, and assuming no fetal fraction related rest failures, "analytical sensitivity for the investigated NIPS exceeded that of traditional aneuploidy screening for trisomies 13, 18, and 21." The authors conclude that customized NIPS with "high accuracy at low FF and a low test-failure rate" is preferable over traditional aneuploidy screening for individuals with high BMI (Muzzey et al., 2020).

Dar et al. (2022) investigated the performance of cell-free DNA screening against a genetic confirmation of results with the goal of analyzing test performance and test failure (no-call rates). A total of 20,194 pregnant individuals were enrolled with a median gestational pregnancy of 12.6 weeks. The results of the genetic test were confirmed for 17,851 cases (88.4%). Among these were 13,043 low-risk and 4808 high-risk cases for aneuploidy. A total of 133 trisomies were diagnosed. These were composed of 100 (trisomy 21), 18 (trisomy 18) and 15 (trisomy 13). The positive rate of cfDNA screens was lower in the low-risk group as compared to the high-risk cohort (0.27% versus 2.2% P<.0001). Sensitivity and specificity were comparable between the two risk groups. The PPV for the low- and high-risk groups was 85.7% versus 97.5%, respectively. There were also 602 individuals who had a "no-call" outcome post-draw and 287 (1.61%) after a second draw. The authors concluded that in pregnant individuals "at a low risk for aneuploidy, single-nucleotide polymorphism-based cell-free DNA has high sensitivity and specificity, positive predictive value of 85.7% for trisomy 21 and 74.3% for the three common trisomies." They also noted that "patients who receive a no-call result are at an increased risk of aneuploidy and require additional investigation" (Dar et al., 2022).

Dai et al. (2022) studied the sensitivity and specificity of a multiplex droplet digital PCR NIPT (dPCR-NIPT) assay. The authors propose that this test has a higher sensitivity than traditional serum biochemical tests and has a lower cost than NGS-NIPTs. The clinical performance of the dPCR-NIPT assay was tested with 238 maternal plasma samples, 36 of which were trisomy positive. "The dPCR-NIPT assay demonstrated a detection sensitivity of 100% and a specificity of 95.12%." The authors noted that this is the first study done on the dPCR-NIPT assay but concluded that it is "superior" to traditional serum biochemical tests and NGS-NIPTs (Dai et al., 2022).

Proprietary Testing

Several methods for detection of fetal aneuploidy by analysis of circulating cell-free fetal DNA are commercially available. All have been validated in pregnancies deemed to be at high-risk for aneuploidy. Evaluation of this technology for use in low- or average-risk pregnancies is ongoing.

Current commercially available laboratory-developed noninvasive prenatal tests for aneuploidy include: the MaterniT21™ Plus Test(Integrated Genetics/LabCorp) (LabCorp, 2023a), the verifi™ Prenatal Test and verifi™ Plus Prenatal Test (Illumina) (Illumina, 2023), the Harmony Prenatal Test™ (Roche) (Roche, 2023), the Panorama test (Natera, available from several reference laboratories) (Natera, 2023), QNatal® Advanced test (QuestDiagnostics, 2023), Prequel test (Myriad, 2023), CentoNIPT® test (Centogene, 2023), ClariTest™ Core (GenPath, 2023), IONA® test and Sage™ prenatal screen (YourgeneHealth, 2023), Invitae NIPS test (Invitae, 2023), and Clarigo test (AgilentTechnologies, 2022). Other examples include, but are not limited to, the VERACITY® test out of NIPD Genetics (NIPD, 2023), the Vanadis® NIPT system (PerkinElmer, 2023), the NIFTY® Test and NIFTY® Test Pro (BGI, 2023), and the informaSeq® Prenatal Test (Genetics, 2016).

Regarding serum screening options for common birth defects, Integrated Genetics, a LabCorp Specialty Testing Group, names the Afp4®, which screens for Down syndrome, trisomy 18, and open neural tube defects in the second trimester, and SerumIntegratedScreen®, which screens for the same, but combines results from both the first and second trimesters. Other tests mentioned include the FirstScreen®, IntegratedScreen®, and SequentialScreen®, the latter of which boasts that "Part 1 [between 10th and 14th weeks of pregnancy] leads to the detection of approximately 70% of Down syndrome cases and 80% of trisomy 18 cases, and Part two [between 15th and 22nd weeks of pregnancy] leads to detection of approximately 90% of Down syndrome cases, 90% of trisomy 18 cases and 80% of open neural tube defects" (LabCorp, 2023b).

The Luna Prenatal Test is a prenatal genetic test that uses a cell-based approach to extract fetal DNA from fetal trophoblast cells present in maternal blood (Luna, 2022a). A key advantage of this test, highlighted in a white paper, is its ability to accurately analyze a single fetal cell, ensuring access to pure fetal DNA.

In an analytical validation overview of the Luna Prenatal Test, two groups of pregnant individuals (one group composed of 59 high-risk individuals who received CVS or amniocentesis) and a second group (158 low-risk individuals who had no known diagnostic testing) were recruited. A third set of test samples was analyzed for comparison composed of "seven Coriell cell lines harboring known chromosome abnormalities" (Luna, 2022b). Single cells (enriched from maternal whole blood) were

processed individually to access pure fetal or cell line DNA. Subsequently, the DNA from each individual cell was "sequenced by low-pass massively parallel sequencing technology to generate a genome-wide copy number profile, which was evaluated for genome-wide copy number changes larger than 1.5 Mb"(Luna, 2022b). The first group of 59 samples had 11 samples excluded. Of the remaining 48 pregnancies (49 fetuses), results indicated an accuracy of 100% (92.75-100% confidence interval), specificity 100% (54.07-100% confidence interval), sensitivity of 100% (91.78-100% confidence interval), PPV of 100%, and NPV of 100% in detecting chromosomal abnormalities (complete agreement between CVS/amniocentesis and Luna); they also noted a plan to increase the sample size to 200 for a larger data set as this was a limited study.

For the second test group, a report was issued for 91.1% of cases, with 8.9% receiving a result of "no scorable cells." In the second group validation study, they found "complete intra-case concordance for 404 cells from 118 cases" (Luna, 2022b). The third set used human cultured cells (lymphoblast or fibroblast) with known aneuploidy or deletion. From the results: "out of a total of 148 scorable cells, the known abnormality was detected and called by the NxC software in every cell except one. Thus, the analytic sensitivity and specificity were 100% with the expected finding being reported in every cell" (Luna, 2022b).

The test makers also note: "We do not claim that the Luna Prenatal Test is diagnostic for aneuploidy, because there are recommendations from professional organizations that a final diagnosis should not rest on testing of trophoblasts alone" (Luna, 2022b).

Bellair et al. (2024) evaluated the noninvasive prenatal genetic "Luna test" using sequence-based copy number analysis of single trophoblasts from maternal blood. Blood samples were collected from 401 pregnant individuals (8-22 weeks), processed to isolate and sequence trophoblast cells. Of the 243 pregnancies undergoing chorionic villus sampling (CVS) or amniocentesis, 160 showed normal results, while 15 had abnormalities, including 14 aneuploidy cases and one Williams syndrome deletion. Placental mosaicism occurred in 7 of 236 Luna test cases and 3 of 188 CVS cases, with no usable trophoblasts recovered in 32 samples. In 158 low-risk pregnancies, 133 were normal, seven showed aneuploidy, and three had likely pathogenic deletions/duplications. Although the sample size was small, the Luna test identified aneuploidies and genetic deletions/duplications, showing consistency with CVS/amniocentesis results, though further data is needed for precise test accuracy (Bellair et al., 2024).

VI. Guidelines and Recommendations

The American College of Obstetrics and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine (SMFM)

The American College of Obstetrics and Gynecologists and the Society for Maternal-Fetal Medicine offered Recommendations for Clinical Management Guidelines for Obstetricians and Gynecologists on Screening for Aneuploidy.

The following recommendations and conclusions are based on good and consistent scientific evidence (Level A):

- "Prenatal genetic screening (serum screening with or without nuchal translucency [NT] ultrasound or cell-free DNA screening) and diagnostic testing (chorionic villus sampling [CVS] or amniocentesis) options should be discussed and offered to all pregnant [individuals] regardless of maternal age or risk of chromosomal abnormality. After review and discussion, every patient has the right to pursue or decline prenatal genetic screening and diagnostic testing.
- If screening is accepted, patients should have one prenatal screening approach, and should not have multiple screening tests performed simultaneously.
- Cell-free DNA is the most sensitive and specific screening test for the common fetal aneuploidies. Nevertheless, it has the potential for false-positive and false-negative results. Furthermore, cell-free DNA testing is not equivalent to diagnostic testing.
- All patients should be offered a second-trimester ultrasound for fetal structural defects, since these may occur with or without fetal aneuploidy; ideally this is performed between 18 and 22 weeks of gestation (with or without second-trimester maternal serum alpha-fetoprotein).
- Patients with a positive screening test result for fetal aneuploidy should undergo genetic counseling and a comprehensive ultrasound evaluation with an opportunity for diagnostic testing to confirm results.
- Patients with a negative screening test result should be made aware that this substantially decreases their risk of the targeted aneuploidy but does not ensure that the fetus is unaffected. The potential for a fetus to be affected by genetic disorders that are not evaluated by the screening or diagnostic test should also be reviewed. Even if patients have a negative screening test result, they may choose diagnostic testing later in pregnancy, particularly if additional findings such as fetal anomalies identified on ultrasound examination become evident.
- Patients whose cell-free DNA screening test results are not reported by the laboratory or are uninterpretable (a no-call test result) should be informed that test failure is associated with an increased risk of aneuploidy, receive further genetic counseling and be offered comprehensive ultrasound evaluation and diagnostic testing.
- If an enlarged nuchal translucency or an anomaly is identified on ultrasound examination, the patient should be offered genetic counseling and diagnostic testing for genetic conditions as well as a comprehensive ultrasound evaluation

including detailed ultrasonography at 18–22 weeks of gestation to assess for structural abnormalities.
- [Individuals] with a positive screening test result for fetal aneuploidy should be offered further detailed counseling and testing" (ACOG, 2020).

The following recommendations and conclusions are based on limited or inconsistent scientific evidence (Level B):

- "The use of cell-free DNA screening as follow-up for patients with a screen positive serum analyte screening test result is an option for patients who want to avoid a diagnostic test. However, patients should be informed that this approach may delay definitive diagnosis and will fail to identify some fetuses with chromosomal abnormalities.
- In clinical situations of an isolated soft ultrasonographic marker (such as echogenic cardiac focus, choroid plexus cyst, pyelectasis, short humerus or femur length) where aneuploidy screening has not been performed, the patient should be counseled regarding the risk of aneuploidy associated with the finding and cell-free DNA, quad screen testing, or amniocentesis should be offered. If aneuploidy testing is performed and is low-risk, then no further risk assessment is needed. If more than one marker is identified, then genetic counseling, maternal–fetal medicine consultation, or both are recommended.
- No method of aneuploidy screening that includes a serum sample is as accurate in twin gestations as it is in singleton pregnancies; this information should be incorporated into pretest counseling for patients with multiple gestations.
- Cell-free DNA screening can be performed in twin pregnancies. Overall, performance of screening for trisomy 21 by cell-free DNA in twin pregnancies is encouraging, but the total number of reported affected cases is small. Given the small number of affected cases it is difficult to determine an accurate detection rate for trisomy 18 and 13" (ACOG, 2020).

The following recommendations and conclusions are based primarily on consensus and expert opinion (Level C):

- "The use of multiple serum screening approaches performed independently (eg, a first-trimester screening test followed by a quad screen as an unlinked test) is not recommended because it will result in an unacceptably high positive screening rate and could deliver contradictory risk estimates.
- In multifetal gestations, if a fetal demise, vanishing twin, or anomaly is identified in one fetus, there is a significant risk of an inaccurate test result if serum-based

aneuploidy screening or cell-free DNA is used. This information should be reviewed with the patient and diagnostic testing should be offered.

- Patients with unusual or multiple aneuploidies detected by cell-free DNA should be referred for genetic counseling and maternal–fetal medicine consultation" (ACOG, 2020).

The American College of Obstetrics and Gynecologists also comments on the specific types of screening, which include triple, quadruple (quad) and "penta" screens. These screens may be performed in the first trimester (10-14 weeks gestation) or second trimester (15-22 weeks). Triple screens measure serum hCG [human chorionic gonadotropin], AFP [alphafetoprotein], and uE3 [unconjugated estriol], while the quad screen includes DIA [dimeric inhibin A] with the three previously mentioned markers. Some laboratories have been noted to offer a "penta" screen, which includes hyperglycosylated hCG along with the four analytes of the quad screen, but ACOG states that "its performance has not been evaluated rigorously in prospective studies". ACOG discusses several testing algorithms in the include, which are summarized in the table below:

Screening Approach	Approximate Gestational Age Range for Screening (Weeks)	Detection Rate (DR) for Trisomy 21 (%)	Screen Positive Rate* (%)	Advantages	Disadvantages	Method
Cell-free DNA†	9–10 to term	99	2–4% Includes inability to obtain results, which is associated with increased risk†	1. Highest DR 2. Can be performed at any gestational age after 9–10 weeks 3. Lowest false-positive rate	Results may reflect underlying maternal aneuploidy or maternal disease	Several molecular methods
First trimester‡	10–13 6/7§	82–87‖	5	1. Early screening 2. Single time point test	Lower DR than tests with first and second trimester component NT required	NT+PAPP-A, free beta hCG, +/− AFP¶
Quad screen‡	15–22	81	5	1. Single time point test 2. No specialized US required	Lower DR than first trimester and first and second trimester combined tests	hCG, AFP, uE3, DIA
Integrated‡	10–13 6/7§, then 15–22	96	5	High DR	Two samples needed No first-trimester results NT required	NT+PAPP-A, then quad screen
Serum integrated‡	10–13 6/7§, then 15–22	88	5	1. DR compares favorably with first-trimester screening 2. No specialized US required	Two samples needed No first-trimester results	PAPP-A + quad screen
Sequential#: stepwise	10–13 6/7§, then 15–22	95	5	1. First-trimester results provided 2. Comparable performance to integrated, but FTS results provided	Two samples needed NT required	NT+ free beta hCG + PAPP-A, +/− AFP¶, then quad screen
Contingent screening**		88–94	5	First-trimester test result: Positive: diagnostic test or cell-free DNA offered Negative: no further testing Intermediate: second-trimester test offered Final: risk assessment incorporates first- and second-trimester results	Possibly two samples needed NT required	NT+hCG+ PAPP-A, +/− AFP¶, then quad screen

Finally, ACOG notes that other trisomies, such as trisomies 16 or 22, can be tested for. However, ACOG recommends against screening for these two aneuploidies due to lack of validated data (ACOG, 2020).

The National Society of Genetic Counselors (NSGC)

The NSGC issued a position statement that supports noninvasive prenatal screening as an option for pregnancies considered high-risk for trisomy 13, 18 or 21. "The National

Society of Genetic Counselors currently supports Noninvasive Prenatal Testing/Noninvasive Prenatal Diagnosis (NIPT/NIPD) as an option for patients whose pregnancies are considered to be at an increased risk for certain chromosome abnormalities. NSGC urges that NIPT/NIPD only be offered in the context of informed consent, education, and counseling by a qualified provider, such as a certified genetic counselor. Patients whose NIPT/NIPD results are abnormal, or who have other factors suggestive of a chromosome abnormality, should receive genetic counseling and be given the option of standard confirmatory diagnostic testing" (Devers et al., 2013).

The NSGC expounded upon their recommendations for prenatal screening and diagnostic testing for chromosomal aneuploidy in a set of practice guidelines. For all patients, it is recommended that "Providers should offer the options of maternal serum screening (MSS) and diagnostic testing for chromosome aneuploidy to every patient", provided that the providers themselves are made aware of factors that may impact their patients' options and that the patients are made aware of the costs and benefits of such options. However, "An ultrasound to assess the fetal anatomy is suggested at approximately 18w0d-20w0d gestation for all patients regardless of whether or not they choose to have screening or diagnostic testing" (Wilson et al., 2013).

The NSGC also presented the following recommendations for low-risk patients less than 14 weeks of gestation:

- "For patients who may consider CVS [chorionic villi screening] or amniocentesis, *stepwise sequential screening or combined first trimester screening* should be considered."
- "If CVS is not an option, *integrated screening* may be considered in order to maximize detection rates."
- "If a patient completes combined first trimester screening, a separate second trimester MSS for chromosome aneuploidy is *NOT* indicated. Screening for chromosome aneuploidy in the second trimester in patients who present prior to 14 weeks should *ONLY* be performed as a part of integrated, serum integrated, stepwise sequential, or contingency screening."
- "Patients who have an increased NT [nuchal translucency] (≥ 95th % or ≥ 3.0mm) should be offered diagnostic testing by either CVS or amniocentesis. A referral for a fetal echocardiogram should also be considered if the NT ≥3.5mm."
- "Early amniocentesis (prior to 15 weeks of gestation) is *not* recommended due to the increased risks for pregnancy loss, clubfoot, and fluid leakage. CVS should be offered as the diagnostic testing option for chromosome aneuploidy in the first trimester."

For low-risk patients after 14 weeks of gestation, they recommend the following:

- "Patients who desire MSS but did not have MSS in the first trimester should be offered a *quad* or *penta* screen rather than a triple screen due to the increased detection rates.
- Amniocentesis should be offered as the diagnostic testing option for chromosome aneuploidy for patients after 15 weeks of gestation."

The NSGC also recommend for those patients at increased risk for chromosome aneuploidy that if the patient presents prior to 14 weeks gestation, "CVS and amniocentesis should both be offered as diagnostic testing options for chromosome aneuploidy", whereas if the patient presents after 14 weeks gestation, "amniocentesis should be offered as the diagnostic testing option for chromosome aneuploidy." Lastly, the NSGC reiterated that patients may be offered NIPT (noninvasive prenatal testing) should they desire screening information (Wilson et al., 2013).

The International Society for Prenatal Diagnosis (ISPD)

The ISPD recognizes that massively parallel sequencing for detection of Down syndrome can be helpful for individuals with high-risk pregnancies, when "suitable genetic counseling" is provided (Benn et al., 2013).

The International Society for Prenatal Diagnosis released a statement regarding cell-free DNA screening for Down syndrome in multifetal pregnancies in 2020. The following recommendations were made:

- "The use of first trimester cfDNA screening for the common autosomal trisomies is appropriate for twin pregnancies due to sufficient evidence showing high detection and low false positive rates with high predictive values.
- The finding of an increased risk on a cfDNA screening test in multiple pregnancies should be followed by counseling and an offer of diagnostic testing to confirm results…CVS and amniocentesis procedures in multiple pregnancies are reliable and safe when performed by a provider experienced in these situations; subsequent diagnostic tests are highly reliable… Maternal age and nuchal translucency (with or without biochemistry) detects up to 80% of Down syndrome at a 5% false positive rate in twin pregnancies.
- It is preferable for laboratories performing cfDNA testing in multifetal pregnancies to take evidence of zygosity (e.g., chorionicity, sex of the fetuses, embryo transfer history) for the interpretation of both test results and fetal fractions…Interpretation of the cfDNA test results could differ depending on test methodology, fetal fraction and chorionicity/zygosity…Fetal fractions are higher in

twin pregnancies, but lower for individual fetuses when compared to singletons. Fetal fractions are correlated between dizygous twins, but can still vary two-fold.
- cfDNA based screening for common trisomies in twins provides higher positive predictive values among twin pregnancies compared with traditional serum and nuchal translucency-based screening in twins, but are associated with test failures…When a cfDNA test failure occurs consider ultrasound and diagnostic testing. If there is sufficient time, a second sample draw may also be considered.
- Screening options for triplet pregnancies are lacking and cfDNA may be a potential option. However, diagnostic testing should always be offered and the limitations of screening tests stressed" (Palomaki et al., 2020).

The American College of Medical Genetics and Genomics (ACMG)

The ACMG notes that "Pretest information should be provided … to ensure patients make informed decisions. Aneuploidy screening is not a routine prenatal test; it is acceptable for patients to decline screening." The ACMG also cautions that "All reports should clearly state that NIPS is a screening test and not diagnostic," and that results be presented in a clear and easily understandable fashion. ACMG guidelines state that "in pregnancies with multiple gestations and/or donor oocytes, testing laboratories should be contacted regarding the validity of NIPS before it is offered to the patient as a screening option" (Gregg et al., 2016).

The American College of Medical Genetics and Genomics published an evidence-based clinical guideline in 2023 on noninvasive prenatal screening (NIPS) for fetal chromosome abnormalities in a general-risk population. Their recommendations are reported below.

- "Recommendation: ACMG Recommends NIPS Over Traditional Screening Methods for All Pregnant Patients With Singleton Gestation for Fetal Trisomies 21, 18, and 13 (Strong Recommendation Based on High Certainty of Evidence)"
- "Recommendation: ACMG Recommends NIPS Over Traditional Methods for Trisomy Screening in Twin Gestations (Strong Recommendation, Based on High Certainty of Evidence)"
- "Recommendation: ACMG Recommends That NIPS Be Offered to Patients with a singleton gestation to Screen for Fetal SCA [sex chromosome aneuploidies] (Strong Recommendation, Based on High Certainty of Evidence)"
- "Recommendation: ACMG Suggests That NIPS for 22q11.2 Deletion Syndrome Be Offered to All Patients (Conditional Recommendation, Based on Moderate Certainty of the Evidence)"
    - "A conditional recommendation should be interpreted as follows: most patients would request this and most clinicians would offer NIPS for this

purpose, after a discussion about the benefits and limitations of screening and in the context of shared decision-making."

- "Recommendation: At This Time, There Is Insufficient Evidence to Recommend Routine Screening for CNVs Other Than 22q11.2 Deletions (No Recommendation, Owing to Lack of Clinically Relevant Evidence and Validation)"

"Recommendation: At This Time, There Is Insufficient Evidence to Recommend or Not Recommend NIPS for the Identification of RATs [rare autosomal trisomies] (No Recommendation, Owing to Lack of Clinically Relevant Evidence)" (Dungan et al., 2023)

Practice Committee and Genetic Counseling Professional Group (GCPG) of the American Society for Reproductive Medicine)

The American Society of Reproductive Medicine notes that screening tests (maternal serum biochemical screening, nuchal translucency and fetal anatomy scan, and noninvasive prenatal screening with cell-free DNA) cannot diagnose chromosomal aneuploidy. "In some cases, ultrasound and biochemical analytes may help identify congenital anomalies that may be associated with an aneuploid pregnancy; however, many aneuploidies (and mosaic aneuploidies in particular) do not result in visible ultrasound anomalies or skewed biochemical analytes and may be easily missed." Cell-free DNA testing "may test for a select number of full and partial aneuploidies, or all aneuploidies within a specified chromosomal resolution, depending on the specific test used by the laboratory. If the chromosome or chromosomal segment of interest is in fact able to be assessed by the assay used, an aneuploidy may be detected. However, it is important to recognize that NIPT is not designed for the detection of mosaicism and may result in false-negative results. False-positive results may also occur because NIPT analyzes placental (and not fetal) DNA" (ASRM, 2020).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration

In April 2021, the FDA released a statement titled, "Genetic Non-Invasive Prenatal Screening Tests May Have False Results: FDA Safety Communication," that detailed safety concerns regarding the use of NIPS tests outside of standard screening purposes. Specifically, they reinforced that NIPS tests are laboratory-developed tests not regulated by the FDA and that the use of NIPS should be confined to screenings, rather than diagnoses. "The accuracy and performance of NIPS tests have not been evaluated by the FDA and these tests can give false results, such as reporting a genetic abnormality when the fetus does not actually have one. NIPS tests are screening tests, which means the NIPS test may only tell you the risk of the fetus having certain genetic abnormalities. They are not diagnostic tests, which are generally used to more definitively confirm or rule out a suspected genetic abnormality." Additionally, "The FDA recommends that patients discuss the benefits and risks of NIPS tests with a genetic counselor or other health care provider before deciding to get these tests. Patients should also discuss the results of NIPS tests with a genetic counselor or other health care provider before making any decisions about their pregnancy. Health care providers should be aware of the risks and limitations of using these screening tests and should not use the results from these tests alone to diagnose chromosomal (genetic) abnormalities or disorders" (FDA, 2022).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81420	Fetal chromosomal aneuploidy (eg, trisomy 21, monosomy X) genomic sequence analysis panel, circulating cell-free fetal DNA in maternal blood, must include analysis of chromosomes 13, 18, and 21
81422	Fetal chromosomal microdeletion(s) genomic sequence analysis (eg, DiGeorge syndrome, Cri-du-chat syndrome), circulating cell-free fetal DNA in maternal blood
81479	Unlisted molecular pathology procedure
81507	Fetal aneuploidy (trisomy 21, 18, and 13) DNA sequence analysis of selected regions using maternal plasma, algorithm reported as a risk score for each trisomy Proprietary test: Harmony™ Prenatal Test Lab/Manufacturer: Ariosa Diagnostics

81508	Fetal congenital abnormalities, biochemical assays of two proteins (PAPP-A, hCG [any form]), utilizing maternal serum, algorithm reported as a risk score
81509	Fetal congenital abnormalities, biochemical assays of three proteins (PAPP-A, hCG [any form], DIA), utilizing maternal serum, algorithm reported as a risk score
81510	Fetal congenital abnormalities, biochemical assays of three analytes (AFP, uE3, hCG [any form]), utilizing maternal serum, algorithm reported as a risk score
81511	Fetal congenital abnormalities, biochemical assays of four analytes (AFP, uE3, hCG [any form], DIA) utilizing maternal serum, algorithm reported as a risk score (may include additional results from previous biochemical testing)
81512	Fetal congenital abnormalities, biochemical assays of five analytes (AFP, uE3, total hCG, hyperglycosylated hCG, DIA) utilizing maternal serum, algorithm reported as a risk score
81599	Unlisted multianalyte assay with algorithmic analysis
82105	Alpha-fetoprotein (AFP); serum
82106	Alpha-fetoprotein (AFP); amniotic fluid
82677	Estriol
84163	Pregnancy-associated plasma protein-A (PAPP-A)
84702	Gonadotropin, chorionic (hCG); quantitative
84703	Gonadotropin, chorionic (hCG); qualitative
84704	Gonadotropin, chorionic (hCG); free beta chain
86336	Inhibin A
88235	Tissue culture for non-neoplastic disorders; amniotic fluid or chorionic villus cells
88267	Chromosome analysis, amniotic fluid or chorionic villus, count 15 cells, 1 karyotype, with banding
88269	Chromosome analysis, in situ for amniotic fluid cells, count cells from 6-12 colonies, 1 karyotype, with banding
88271	Molecular cytogenetics; DNA probe, each (eg, FISH)
88280	Chromosome analysis; additional karyotypes, each study
88285	Chromosome analysis; additional cells counted, each study
0327U	Fetal aneuploidy (trisomy 13, 18, and 21), DNA sequence analysis of selected regions using maternal plasma, algorithm reported as a risk score for each trisomy, includes sex reporting, if performed Proprietary test: Vasistera™ Lab/Manufacturer: Natera, Inc
0341U	Fetal aneuploidy DNA sequencing comparative analysis, fetal DNA from products of conception, reported as normal (euploidy), monosomy, trisomy,

	or partial deletion/duplication, mosaicism, and segmental aneuploid Proprietary test: Single Cell Prenatal Diagnosis (SCPD) Test Lab/Manufacturer: Luna Genetics, Inc

Proteogenomic Testing of Individuals with Cancer

Policy Number: AHS – M2168 – Proteogenomic Testing of Individuals with Cancer	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Proteogenomic testing (encompassing analysis of both the genome and the proteome) is emerging as a new discipline in clinical settings. Until recently, genomic and proteomic analyses have remained in relative isolation. However, as techniques continue to improve, integrated analysis of both large-scale items has become more and more feasible. With precise and personalized medicine continuing to be a point of emphasis in clinical evaluation, proteogenomic analysis has received significant attention in treating cancer (Ang et al., 2019).

II. Related Policies

Policy Number	Policy Title
AHS-G2054	Liquid Biopsy
AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with cancer, integrated comprehensive tumor profiling to calculate a tumor mutational burden score using genomic and/or transcriptomic data in conjunction with immunohistochemistry analysis (e.g., OncoExTra™, Caris MI Tumor Seek™, Caris MI Profile™ Comprehensive Testing) **MEETS COVERAGE CRITERIA** as

defined within AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

2) For individuals with cancer, integrated analysis of proteomic, genomic, **and/or** transcriptomic testing with or without algorithmic analysis (e.g., GPS Cancer®, DarwinOncoTarget™/DarwinOncoTreat™) **DOES NOT MEET COVERAGE CRITERIA**.

3) Tumor gene expression profiling with algorithmic analysis providing gene pathway activity scores **DOES NOT MEET COVERAGE CRITERIA**.

4) Optical genome mapping with or without whole genome sequencing and transcriptome analysis **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ACMG	American College of Medical Genetics
AKT1	Protein kinase B
ALK	Anaplastic lymphoma kinase
AML	Acute myeloid leukemia
AMP	Adenosine monophosphate
APC	*Adenomatous polyposis coli*
APOLLO	Applied Proteogenomics Organization Learning and Outcomes
ASCO	American Society of Clinical Oncology
AURKB	Aurora kinase b
BCCs	Basal cell carcinomas
BRCA1	Breast cancer gene 1
BRCA2	Breast cancer gene 2
BRDs	Bromodomain
CAP	College of American Pathologists
CAPN2	Calpain 2
CDK4/6	Cyclin-dependent kinases 4 and 6
CEBPA	*CCAAT Enhancer Binding Protein Alpha*
CLIA'88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid
CPTAC	Clinical Proteomic Tumor Analysis Consortium

CREBBP	cAMP response element-binding protein
CRISPR	*Clustered regularly interspaced short palindromic repeats*
CTDSP2	*Carboxy-terminal domain, RNA polymerase II, polypeptide A*
DBNL	Drebrin like
dMMR	Mismatch repair deficiency
DNA	Deoxyribose nucleic acid
DoD	Department of Defense
EGFR	Epidermal growth factor receptor
EP300	E1A binding protein P300
ER+	Estrogen receptor-positive
ERBB2	Erb-B2 receptor tyrosine kinase 2
FDA	Food and Drug Administration
FFPE	Formalin-fixed paraffin-embedded
FLT3	*Fms related receptor tyrosine kinase 3*
GBMs	Glioblastomas
GEM	Georgia Estoteric and Molecular Laboratory
GRP	Glucose related protein
GRP78	Glucose regulated protein 78
H2B	Histone H2b
HCC	Hepatocellular carcinoma
HER2	Human epidermal growth factor receptor 2
HSP90β	Heat shock protein HSP 90-beta
HSPB1	Heat shock protein beta member 1
ICIs	Immune checkpoint inhibitors
INTS7	*Integrator complex subunit 7*
ISR	Illumina short read
KMT2A-PTD	*Lysine (K)-specific methyltransferase 2A- partial tandem duplication*
KRAS	*Kirsten rat sarcoma viral oncogene homolog*
LDTs	Laboratory developed tests
LNCaP	Lymph node carcinoma of the prostate
METABRIC	Molecular Taxonomy of Breast Cancer International Consortium
mRNA	Messenger ribonucleic acid
MSI	Microsatellite instability
NCCN	National Comprehensive Cancer Network
NFKBIZ	*NF-kappa-B inhibitor zeta*
NGS	Next generation sequencing

NICE	The National Institute for Health and Care Excellence
NPM1	*Nucleophosmin 1*
NRAS	*Neuroblastoma RAS viral oncogene homolog*
OGM	Optical genome mapping
PC-3	Prostate cancer cell line 3
PC-3M	Prostate cancer cell 3M
PCOs	Provisional clinical opinions
PD-L1	Programmed death ligand 1
postM	Post-menopausal
preM	Pre-menopausal
pre-mRNA	Messenger ribonucleic acid precursors
Rb	Retinoblastoma
RB1	*Retinoblastoma transcriptional corepressor 1*
RNA	Ribonucleic acid
rRNAs	Ribosomal ribonucleic acids
RUNX1	*Runt related transcription factor 1*
SeC	Sebaceous carcinomas
SCCs	Squamous cell carcinomas
SH3BGRL	*SH3 domain binding glutamate rich protein like*
siRNAs	Short-interfering ribonucleic acids
SNPs	Single nucleotide polymorphisms
TCGA	The Cancer Genome Atlas
TGFβ	Transforming growth factor beta
TMB	Tumor mutational burden
TML	Tumor mutational load
TP53	*Tumor protein p53*
UV	Ultraviolet
VA	Department of Veterans Affairs
WGS	Whole genome sequencing

V. Scientific Background

As newer and faster technology makes evaluating enormous amounts of molecular information possible, proteogenomic testing is on the rise. Techniques such as whole genome sequencing, transcriptome sequencing, and proteomic analysis, previously not clinically viable, are now within the clinical laboratory landscape. Information yielded from these tests may be used for a variety of purposes, including prognosis, diagnosis, identifying targeted treatments, and more. Proteogenomic testing typically revolves around three different sets of analytes: DNA, RNA, and proteins (Fancello & Burger, 2022).

DNA is the first stage in the genetic flow of information, represented by genes, including both exons and introns. All the protein-coding genes are represented in the exome, where at least 85% of pathogenic mutations are found. The exome represents a mere 1.5%-2% of the genome, thereby typically making it more cost-effective to sequence than the whole genome (Hulick, 2022). The entire exome includes approximately 30 megabases compared to the 3.3 gigabases of the genome. However, a pathogenic mutation may be in a noncoding region of the genome, such as mutations that result in dysfunction of gene regulation, resulting in situations where sequencing of the entire genome may be useful (Hulick, 2022).

RNA is the second stage in the genetic flow of information, as DNA is transcribed into RNA. Transcriptome sequencing refers to "digital counts" of each RNA molecule, or direct sequencing and quantification of RNA. The RNA transcript being quantified is not a perfect complement of the original DNA sequence; certain regulatory processes and post-transcriptional modifications, such as splicing, polyadenylation, and capping, alter the pre-mRNA sequence. Furthermore, additional regulatory RNA classes are not translated into a protein product, including but not limited to, ribosomal RNAs (rRNAs facilitate the translation of mRNA to protein) or short-interfering RNAs (siRNAs, capable of downregulating the translation of mRNA to protein). Transcriptome sequencing identifies these regulatory RNA sequences that are not otherwise identified at the DNA or protein level (Steiling, 2023).

Proteins are the third stage in the genetic flow of information, as most RNA is translated into protein products. Proteomics is a qualitative and quantitative assessment of the protein constituents in each biological sample. Mass spectrometry is typically used to identify peptide sequences, and these sequences are used to infer protein identity and quantity. "Shotgun" proteomics is the most common method of identifying and labeling large amounts of proteins, analyzing both the "parent" ions eluting from the liquid chromatographer and the "daughter" ions, which are comprised of fragments of the parent ion. The apparatus then attempts to match the ions using several features, such as signal intensity and mass to charge ratio. From here, the peptide sequences (and therefore proteins) are inferred (Ang et al., 2019).

Integration of all three disciplines may be termed "proteogenomic" testing. The drive for "precision" and "personalized" medicine has encouraged more in-depth research on the genetic landscape, particularly for heterogenous conditions such as cancer. Proteogenomic testing has been proposed to fill clinical gaps that exist with disciplines in isolation, including finding the connections from genotype to phenotype. Identifying targeted therapies, drug resistance mechanisms, and other potentially crucial clinical factors are all questions that may be answered with proteogenomic testing. Although the individual methodologies used to perform proteogenomic testing are well-

validated in research settings (next generation sequencing [NGS], mass spectrometry), numerous challenges and limitations exist in translating them to the clinical realm. For example, there is currently no amplification technique available for proteins that would allow for smaller samples to be used. Additionally, reproducibility issues presented by the current techniques used in proteomic research can occur. Overall, validation of the enormous database of proteomics, as well as development of the bioinformatic infrastructure required to connect proteogenomics to the clinic, is still in progress (Ang et al., 2019).

In 2016, the Clinical Proteomic Tumor Analysis Consortium (CPTAC) created the Applied Proteogenomics Organizational Learning and Outcomes (APOLLO) network. The APOLLO network was launched to incorporate proteogenomics into patient care and is a collaborative effort between the Department of Defense (DoD) and the Department of Veterans Affairs (VA). APOLLO is currently analyzing proteogenomic data from 8,000 human tissue samples; this data will be publicly available once curated (NIH, 2016). As of 2022, the CPTAC has begun to release some individual genomic, proteomic, and imaging data sets from this ongoing research but combined proteogenomic analysis from this data is just beginning to emerge(Dong et al., 2022; Krug et al., 2020; Wang et al., 2021).

Proprietary Testing

Several proteogenomic testing platforms are commercially available.

GPS Cancer®

The GPS Cancer® test from NantOmics, a member of the NantWorks family, utilizes quantitative proteomics through mass spectrometry, whole genome sequencing (over 20,000 genes across three billion base pairs), and whole transcriptome sequencing technologies (over 200,000 RNA transcripts). These three factors combined provide oncologists with a comprehensive molecular profile of a patient's cancer. The test is intended to provide information about targeted therapies, such as which therapies a patient may benefit from or which therapies a patient may resist (NantOmics, 2023). Finally, the third component of GPS Cancer® is the tumor "normal" sequencing. This component provides a comparison of a patient's healthy, unaffected genome to the genome affected by the tumor. It is intended to provide "pharmacogenomic analysis for potential drug toxicity and/or interactions" and to separate mutations caused by cancer from those that were present prior to cancer (NantOmics, 2023).

DarwinOncoTarget™ and DarwinOncoTreat

DarwinOncoTarget™ and DarwinOncoTreat™ are synergistic proteogenomic tests offered by Columbia University. DarwinOncoTarget™ identifies 193 potentially targetable proteins while DarwinOncoTreat™ assesses the regulatory activity of 6293 proteins ("tumor-checkpoints"). DarwinOncoTreat™ then "prioritizes" drugs based on their ability to revert the activity of these checkpoints. DarwinOncoTarget™ is available for all malignancies whereas DarwinOncoTreat™ is only available for certain cancer subtypes (Columbia, 2023).

Caris Molecular Intelligence

Other proprietary proteogenomic platforms are offered by Caris Molecular Intelligence. The MI Cancer Seek utilizes an NGS technique to identify "Whole exome sequencing for DNA mutations, copy number alterations, insertions/deletions, genomic signatures MSI [microsatellite instability] and TMB [tumor mutational burden], and whole transcriptome sequencing for RNA fusions and variant transcripts" (Caris, 2023b). The Caris Molecular Intelligence Comprehensive Tumor Profiling test uses precision medicine to assess DNA, RNA, and proteins to aid individualized treatment regimens (Caris, 2023a).

Praxis Genomics Optical Genome Mapping, Whole Genome Sequencing, and Transcriptome Analysis

Praxis Genomics offers a proteogenomic approach via combined testing with their Optical Genome Mapping, Whole Genome Sequencing, and Transcriptome Analysis. Optimal Genome Mapping (OGM), developed by Bionano Genomics LLC, evaluates DNA samples for large-scale changes such as chromosomal transfer of DNA fragments, chromosomal inversion or complex rearrangement, measurement of repetitive regions that control adjacent gene expression, and measurement of tandem repeat expansions. Whole Genome Sequencing obtains sequence from the entire genome (roughly 3 billion units). Praxis uses the Dragen alignment and variant calling pipeline to identify genomic changes. Highly repetitive DNA content and genomic rearrangements cannot be detected with whole genome sequencing. Transcriptome analysis allows for the evaluation of the functional consequences of DNA mutations found in Optical Genome Mapping or Whole Genome Sequencing. "Only by building on the diverse strength of OGM and ISR [Illumina Short Read] WGS and transcriptome sequencing can we increase the sensitivity and specificity of genetic diagnosis until novel technologies even more precise and faster come along" (Praxis, 2022).

OncoSignal™

Philips' OncoSignal™ technology is used by Protean BioDiagnostics as an "innovative and unique test to expand the information that can be obtained from cancer tissue

analysis," as part of their proprietary Oncology MAPS™ solution. OncoSignal™ uses advanced molecular and bioinformatic systems to measure mRNA expression patterns, calculating the specific activity of seven key oncogenic drive signal pathways (Estrogen receptor, Androgen receptor, Phosphoinositide 3-kinase, Hedgehog pathway, Notch signal, transforming growth factor receptor beta, and Mitogen activated protean kinase). These pathways "measure key oncogenic drivers of numerous distinct cancer types including but not limited to breast cancer, prostate cancer, ovarian cancer, colon cancer, lymphoma and more." Each pathway is given a score based on molecular and bioinformatic findings and pathway activity is interpreted as low, normal, or high in comparison to the normal physiological range. The clinically-used Oncology MAPS™ report then provides targeted treatment recommendations (AccessWire, 2022; Protean, 2023).

MosaicNeedle™

Nanomosaic Inc. developed MosaicNeedle™ technology for proteomic and multi-omic investigation and application (PRNewswire, 2022). The commercial launch of their Tessie™ platform for proteomics and multi-omics is slated to occur in 2022. According to Nanomosaic, their proteomics technology "bridges the gaps of functional information lost due to post-transcriptional and post-translational modifications in a genomic approach." Because the traditional proteogenomic approach typically requires multiple diverse assays and workflows, this novel technology simplifies by using "densely integrated nanoneedle sensors on a planar substrate that integrates proteogenomic analysis in one platform." Each nanoneedle binds a single molecule and detects both nucleic acids and proteins in a single assay process. The result is a full proteogenomic quantification in one single reaction, on one platform, with high sensitivity and lower cost (Quan et al., 2022).

Clinical Utility and Validity

North et al. (2018) used NantHealth's profile to characterize 32 cases of sebaceous carcinomas (SeC). The authors identified ultraviolet (UV) damage in ten samples and microsatellite instability in nine samples. UV cases of SeC were shown to have more severe histopathologic features, including poorer differentiation and an "infiltrative" growth pattern. The authors also noted that the transcriptomes of the UV SeC cases were like cutaneous squamous cell carcinomas (SCCs) and basal cell carcinomas (BCCs). Overall, three distinct classes of sebaceous carcinoma were identified based on mutation pattern and cell of origin (North et al., 2018).

Liao et al. (2015) used two genetic datasets (TCGA and METABRIC) to characterize over 2500 cases of breast cancer in pre-menopausal (preM) and post-menopausal individuals (postM) (defined as ≤45 years and ≥55 years respectively, individuals of

ages 45-55 were not included). The following molecular features were examined: gene expression, somatic mutation, copy number, methylation, and protein expression. In preM tumors, the authors identified unique methylation patterns, copy numbers, and somatic mutations in estrogen receptor-positive (ER+) tumors. Further investigation of this subset revealed "elevated integrin/laminin and EGFR signaling, with enrichment for upstream TGFβ-regulation." The authors concluded that preM ER+ tumors have "distinct molecular characteristics" compared to postM ER+ tumors (Liao et al., 2015).

Rabizadeh et al. (2018) compared tumor-only DNA sequencing to tumor-normal DNA (containing controls for germline mutations) plus RNA sequencing. A total of 621 patients with 30 different cancer types were studied using a 35-gene sequencer and the precision of somatic variant calling was evaluated. Without the germline controls, 94% of the variants were single nucleotide polymorphisms (SNPs) and considered false positives. Removing these SNPs resulted in a 48% false-positive rate. Tumor-only sequencing ultimately led to a 29% false-positive rate in "at least one of twelve genes with directly targetable drugs" and RNA analysis revealed that 18% of variants were not expressed (Rabizadeh et al., 2018).

Sjostrom et al. (2020) evaluated the utility of transcriptomic profiling in breast cancer and whether these results could safely allow patients to decline systemic therapy. A 141-gene signature was derived from a node-negative cohort previously untreated with chemotherapy. This signature was used to evaluate 454 node-negative, ER+, and systemically untreated cancer patients. The authors noted that this was a low-risk subgroup but did find that of the patients in the lowest 25th percentile of signature scores, 95% of patients were metastasis-free after 15 years despite lack of endocrine therapy. The authors concluded that "transcriptomic profiling identifies patients with an excellent outcome without any systemic adjuvant therapy in clinically low-risk patients of…two separate cohorts" (Sjostrom et al., 2020).

Feng et al. (2019) evaluated the proteomic profile of sorafenib resistance in hepatocellular carcinoma patients. Tumor samples from 60 patients were examined. The authors identified three proteins that were overexpressed in sorafenib-resistant cells: 78 kDa glucose related protein (GRP78), 14-3-3ε, and heat shock protein 90β (HSP90β). Approximately 73% of cells had high GRP78 expression, 18% had high 14-3-3ε expression, and 85% had high HSP90β expression. The authors also noted that elevated GRP78 was associated with the shortest progression-free survival of patients treated with sorafenib. The authors concluded that "GRP78 can be a predictive biomarker in HCC patients treated with sorafenib" (Feng et al., 2019).

Shiba et al. (2019) evaluated the genetic landscape of pediatric acute myeloid leukemia. The authors performed a transcriptome analysis in 139 patients (of 369 in

the total cohort). Fifty-four in-frame gene mutations and one *RUNX1* out-of-frame fusion were found in 53 of the 139 patients. Moreover, 258 gene fusions were found in the 369 total patients. Five novel gene fusions were found, and several fewer common gene rearrangements were identified. Out of the 111 remaining patients, "*KMT2A-PTD*, biallelic *CEBPA*, and *NPM1* gene mutations were found in 11, 23, and 17 patients, respectively." The authors noted these mutations were mutually exclusive compared with other gene fusions. The authors remark that risk stratification should be reconsidered (Shiba et al., 2019).

Yang et al. (2019) evaluated the genomic landscape of rectal cancer patients who did not respond to chemotherapy. The authors performed whole exome sequencing on 28 paired tumors collected before and after chemotherapy. Several mutations were identified (*CTDSP2, APC, KRAS, TP53* and *NFKBIZ*) that appeared to confer selective advantages to cancer cells and the authors noted that chemotherapy altered the genomic landscape of these tumors and that high intratumoral heterogeneity in any stage of cancer contributed to poor survival in patients (Yang et al., 2019).

Tredan et al. (2019) evaluated the impact of broad molecular profiling on identifying targeted therapies. A "molecular tumor board," consisting of molecular biologists, medical oncologists, and pathologists, selected the genes to be included in the profile and a total of 69 genes were included on the final panel. A total of 1980 molecular profiles were constructed. Of these profiles, 948 had no actionable mutations (leaving 1032 with at least one actionable mutation) and a targeted therapy was recommended for 699 of these patients. A total of 182 targeted therapies were initiated, with only 23 patients experiencing an objective response (13% of patients receiving therapy, 0.9% of the total cohort of 2579 patients). The authors concluded that "molecular screening should not be used at present to guide decision-making in routine clinical practice outside of clinical trials" (Tredan et al., 2019).

Kwon et al. (2019) identified and analyzed mutant peptides in prostate cancer cell lines. The authors obtained four cell lines of varying aggression (LNCaP, LNCaP-LN3, PC-3, and PC-3M) and profiled the resulting mutant peptides. A total of 70 mutant peptides were identified. Expression of seven mutant peptides were found to be altered in tumors, with "CAPN2 D22E" as the most significantly up-regulated peptide. Increased levels of the *INTS7* gene and decreased levels of the *SH3BGRL* gene were found to be correlated with aggressiveness of prostate cancer (Kwon et al., 2019).

Wang et al. (2019) constructed a "quantitative proteome and transcriptome abundance atlas" of 29 paired healthy human tissues. A total of 18,072 transcripts and 13,640 proteins (including 37 without "prior protein-level evidence") were represented. However, the authors concluded that proteogenomics remains challenging. The

authors noted that out of 9848 amino acid variants found by exome sequencing, only 238 could be confidently detected at the protein level. The authors also remarked that many proteins could not be detected despite highly expressed mRNA, that very few proteins showed tissue-specific expression, and that strong differences existed between mRNA and protein quantities. Overall, the writers determined that proteogenomics "needs better computational methods and requires rigorous validation" (Wang et al., 2019).

Treue et al. (2019) performed analysis on a model of a drug-resistant *EGFR*-mutated non-small cell lung cancer case. The authors integrated several proteogenomic techniques, including whole exome sequencing and "global time-course discovery phosphoproteomics" to identify molecular alterations. The writers remarked that this allowed them to reduce the complexity of the model down to 44 "predicted" phosphoproteins and 35 "topologically close" genetic alterations. From here, the authors found that targeting of HSPB1, DBNL, and AKT1 showed "potent antiproliferative effects overcoming resistance against EGFR-inhibitory therapy" (Treue et al., 2019).

Salem et al. (2018) evaluated the correlation of tumor mutational load (TML; "high" defined as greater than or equal to 17 mutations/MB), PD-L1 expression, and mismatch repair deficiency (dMMR) status with response to immune checkpoint inhibitors (ICIs). A total of 4125 tumors from 14 different gastrointestinal sites were examined. A 592 gene panel was used to calculate the TML. Microsatellite instability (MSI), PD-L1 expression, and dMMR status were all evaluated. The authors found that high-TML was "strongly associated" with high MSI. Right-sided colon and small-bowel adenocarcinomas had the highest rates of high-TML tumors (14.6% and 10.2% respectively) whereas pancreatic neuroendocrine and gastrointestinal stromal tumors had the lowest (1.3%, 0%). The authors noted that high-TML rate varied "widely" among gastrointestinal cancers (Salem et al., 2018).

Gillette et al. (2020) utilized proteogenomics to reveal therapeutic vulnerabilities in lung adenocarcinoma. Comprehensive proteogenomic characterization was performed on 110 tumors. "Multi-omics clustering revealed four subgroups defined by key driver mutations, country, and gender" (Gillette et al., 2020). Therapeutic vulnerabilities were identified in the *KRAS, EGFR,* and *ALK* genes and the authors note that "this proteogenomics dataset represents a unique public resource for researchers and clinicians seeking to better understand and treat lung adenocarcinomas" (Gillette et al., 2020).

Krug et al. (2020) integrated mass spectrometry-based proteomics and next generation DNA and RNA sequencing to create a proteogenomic profile of 122 treatment-naïve

primary breast cancer tumors. They found that "proteogenomics challenged standard breast cancer diagnoses, provided detailed analysis of the ERBB2 amplicon, defined tumor subsets that could benefit from immune checkpoint therapy, and allowed more accurate assessment of Rb status for prediction of CDK4/6 inhibitor responsiveness." The authors note that their results "underscore the potential of proteogenomics for clinical investigation of breast cancer through more accurate annotation of targetable pathways and biological features of this remarkably heterogeneous malignancy" (Krug et al., 2020).

Wang et al. (2021) integrated genomic, proteomic, post-translational modification, and metabolomic data to examine 99 treatment-naïve glioblastomas (GBMs), where they identified key phosphorylation events as potential mediators of oncogenic pathway activation and potential targets for *EGFR*-, *TP53*-, and *RB1*-altered tumors. The identified "immune subtypes with distinct immune cell types are discovered using bulk omics methodologies" and note that "histone H2B acetylation in classical-like and immune-low GBM is driven largely by BRDs, CREBBP, and EP300." Their work highlights the important of an integrated proteogenomic approach in GBM and "highlights biological relationships that could contribute to stratification of GBM patients for more effective treatment" (Wang et al., 2021).

Joshi et al. (2021) examined the stepwise evolution of gilteritinib resistance in *FLT3*-mutated acute myeloid leukemia (AML). To mechanistically define both early and late resistance in AML, they integrated whole exome sequencing, CRISPR-CAS9, metabolomics, proteomics, and pharmacologic approaches. They found that "early resistant cells undergo metabolic reprogramming, grow more slowly, and are dependent upon Aurora kinase B (AURKB). Late resistant cells are characterized by expansion of pre-existing NRAS mutant subclones and continued metabolic reprogramming," creating a model that closely mirrors the timing, and mutations of AML patients treated with gilteritinib. They also note that "pharmacological inhibition of AURKB resensitizes both early resistant cell cultures and primary leukemia cells from gilteritinib-treated AML patients." Their findings support a "combinatorial strategy to target early resistant AML cells with AURKB inhibitors and gilteritinib before the expansion of pre-existing resistance mutations occurs" (Joshi et al., 2021).

Akcakanat et al. (2021) integrated DNA, RNA, and functional proteogenomics from tumor samples of 52 patients with metastatic breast cancer (inclusive of ten patients with both primary and metastatic tumors to chart the evolution of the tumor's profile). The aim was to determine potentially actionable alterations in metastatic breast cancer and analyze the molecular evolution of the tumors. Regarding proteomic profiling, needle biopsy samples were evaluated via reverse phase protein arrays. The panel was composed of 295 antibodies and the PI3K pathway activity score was "defined as the

sum of the normalized values of the 13phosphor-protein levels of Akt, 4E-BP1, S6K, and S6." Samples were considered PI3K activated if their PI3K scores were in the top quartile. In discussion, the authors noted: "Neither genomic alterations predicted gene or protein expression nor was there a strong correlation between proteomic and transcriptomic data. [However] we cannot exclude the possibility that the lack of concordance between DNA alterations and RNA and protein and protein phosphorylation are not merely the result of tumor heterogeneity and the tumor cellularity of the samples" (Akcakanat et al., 2021).

VI. Guidelines and Recommendations

Since this is an emerging field, there is limited guidance from applicable professional societies. As of publication date, no specific guidance was found from professional medical societies, including NCCN, ACMG, NICE, AMP, and CAP.

National Comprehensive Cancer Network

Currently, the NCCN does not list proteogenomic testing as a recommended technique for any type of cancer. Furthermore, proprietary comprehensive genomic profiles have been submitted for inclusion in guidelines for several types of cancer, but they have never been included as a recommended technique as of June 23, 2022 (NCCN, 2023).

American Society of Clinical Oncology

In 2020, the American Society of Clinical Oncology (ASCO) published a clinical oncology educational book which included an article on integrating genetic and genomic testing into oncology practice. Transcriptome and proteomic sequencing were not mentioned in the article. However, the authors note that "Examples of the integration of genomic information into the care of patients with cancer include germline testing for *BRCA1/2* in breast, ovarian, pancreatic, and prostate cancer; evaluation of mismatch repair in endometrial cancer; and somatic sequencing in lung cancer" (Domchek et al., 2020). In 2022, they published a guideline on "Neoadjuvant Chemotherapy, Endocrine Therapy, and Targeted Therapy for Breast Cancer," where it was noted that "although tumor histology, grade, stage, and estrogen, progesterone, and human epidermal growth factor receptor 2 (HER2) expression should routinely be used to guide clinical decisions, there is insufficient evidence to support the use of other markers or genomic profiles" (ASCO, 2022).

In 2022, ASCO published a provisional clinical opinion titled, "Somatic Genomic Testing in Patients with Metastatic or Advanced Cancer." They note an increasing number of

therapies have been approved to treat cancers harboring specific genomic biomarkers. The following represents their recommendations (Chakravarty et al., 2022):

- "Patients with metastatic or advanced cancer should undergo genomic sequencing in a certified laboratory if the presence of one or more specific genomic alterations has regulatory approval as biomarkers to guide the use of or exclusion from certain treatments for their disease."
- "Multigene panel–based assays should be used if more than one biomarker-linked therapy is approved for the patient's disease."
- "Site-agnostic approvals for any cancer with a high tumor mutation burden, mismatch repair deficiency, or neurotrophic tyrosine receptor kinase (NTRK) fusions provide a rationale for genomic testing for all solid tumors."
- "Multigene testing may also assist in treatment selection by identifying additional targets when there are few or no genotype-based therapy approvals for the patient's disease."
- "For treatment planning, the clinician should consider the functional impact of the targeted alteration and expected efficacy of genomic biomarker–linked options relative to other approved or investigational treatments."

Regarding proteogenomic or protein profiling, ASCO recommended:

- "Several hundred genes and their mutant protein products have been linked to increased cell signaling, proliferation, and survival in cell lines or mouse models and thus proposed to be cancer drivers. However, at this time, few genomic alterations have been clinically proven as therapeutic targets. Therefore, in addition to the functional effects of mutations on protein chemistry and signaling, evidence of clinical relevance should be considered."
- "Clinical decision making should incorporate (1) the known or predicted impact of a specific genomic alteration on protein expression or function and (2) clinical data on the efficacy of targeting that genomic alteration with a particular agent (strength of recommendation: strong)" (ASCO, 2021; Chakravarty et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-

database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration

Many labs have developed specific tests that they must validate and perform in house. These laboratory developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
81599	Unlisted multianalyte assay with algorithmic analysis
0019U	Oncology, RNA, gene expression by whole transcriptome sequencing, formalin-fixed paraffin-embedded tissue or fresh frozen tissue, predictive algorithm reported as potential targets for therapeutic agents Proprietary test: DarwinOncoTarget™/DarwinOncoTreat™ Lab/Manufacturer: Columbia University Department of Pathology and Cell Biology/Darwin Health
0260U	Rare diseases (constitutional/heritable disorders), identification of copy number variations, inversions, insertions, translocations, and other structural variants by optical genome mapping Proprietary test: Augusta Optical Genome Mapping Lab/Manufacturer: Georgia Esoteric and Molecular (GEM) Laboratory, LLC/Bionano Genomics Inc
0262U	Oncology (solid tumor), gene expression profiling by real-time RT-PCR of 7 gene pathways (ER, AR, PI3K, MAPK, HH, TGFB, Notch), formalin-fixed paraffin-embedded (FFPE), algorithm reported as gene pathway activity score Proprietary test: OncoSignal 7 Pathway Signal Lab/Manufacturer: Protean BioDiagnostics/Philips Electronics Nederland BV
0264U	Rare diseases (constitutional/heritable disorders), identification of copy number variations, inversions, insertions, translocations, and other structural variants by optical genome mapping Proprietary test: Praxis Optical Genome Mapping Lab/Manufacturer: Praxis Genomics LLC

CPT	Code Description
0266U	Unexplained constitutional or other heritable disorders or syndromes, tissue-specific gene expression by whole-transcriptome and next-generation sequencing, blood, formalin-fixed paraffin-embedded (FFPE) tissue or fresh frozen tissue, reported as presence or absence of splicing or expression changes Proprietary test: Praxis Transcriptome Lab/Manufacturer: Praxis Genomics LLC
0267U	Rare constitutional and other heritable disorders, identification of copy number variations, inversions, insertions, translocations, and other structural variants by optical genome mapping and whole genome sequencing Proprietary test: Praxis Combined Whole Genome Sequencing and Optical Genome Mapping Lab/Manufacturer: Praxis Genomics LLC
0298U	Oncology (pan tumor), whole transcriptome sequencing of paired malignant and normal RNA specimens, fresh or formalin-fixed paraffin-embedded (FFPE) tissue, blood or bone marrow, comparative sequence analyses and expression level and chimeric transcript identification Proprietary test: Praxis Somatic Transcriptome Lab/Manufacturer: Praxis Genomics LLC
0299U	Oncology (pan tumor), whole genome optical genome mapping of paired malignant and normal DNA specimens, fresh frozen tissue, blood, or bone marrow, comparative structural variant identification Proprietary test: Praxis Somatic Optical Genome Mapping Lab/Manufacturer: Praxis Genomics LLC
0300U	Oncology (pan tumor), whole genome sequencing and optical genome mapping of paired malignant and normal DNA specimens, fresh tissue, blood, or bone marrow, comparative sequence analyses and variant identification Proprietary test: Praxis Somatic Combined Whole Genome Sequencing and Optical Genome Mapping Lab/Manufacturer: Praxis Genomics LLC
0436U	Oncology (lung), plasma analysis of 388 proteins, using aptamer-based proteomics technology, predictive algorithm reported as clinical benefit from immune checkpoint inhibitor therapy. Proprietary test: PROphet® NSCLC Test Lab/Manufacturer: OncoHost, Inc
0454U	Rare diseases (constitutional/heritable disorders), identification of copy number variations, inversions, insertions, translocations, and other structural variants by optical genome mapping

CPT	Code Description
	Proprietary test: Chromosome Genome Mapping Lab/Manufacturer: UR Medicine Lab, Bionano Genomics, Inc
0485U	Oncology (solid tumor), cell-free DNA and RNA by next-generation sequencing, interpretative report for germline mutations, clonal hematopoiesis of indeterminate potential, and tumor-derived single-nucleotide variants, small insertions/deletions, copy number alterations, fusions, microsatellite instability, and tumor mutational burden Proprietary test: Caris Assure Lab/Manufacturer: Caris MPI, Inc d/b/a Caris Life Sciences

Red Blood Cell Molecular Testing

Policy Number: AHS – M2170 – Red Blood Cell Molecular Testing	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

The first successful blood transfusion can be dated back to the 1600s (Osterman & Arora, 2017), and molecular testing methods to analyze blood samples were introduced to the transfusion medicine community in the 1990s (Westhoff, 2006). Several ailments may warrant a blood transfusion and the phenotypic and genotypic determination of red blood cell antigens assist in limiting immune responses in transfusion patients. Agglutination tests via serology have been the gold standard for determining blood group antigens for more than 100 years (Boccoz et al., 2015), yet newer molecular techniques may grant added specificity (Elite, 2015).

For guidance regarding fetal RHD genotyping in RHD negative pregnant individuals, please refer to AHS- M2179-Prenatal Screening (Genetic).

II. Related Policies

Policy Number	Policy Title
AHS-M2131	Genetic Testing for Alpha- and Beta-Thalassemia
AHS-M2179	Prenatal Screening (Genetic)

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) Red cell genotyping (including C, c, D, E, e, K, k, Jka, Jkb, Fya, Fyb, S, s, U) **MEETS COVERAGE CRITERIA** in **any** of the following situations:

a) For individuals with sickle cell disease, thalassemia syndromes, hemoglobinopathies, and/or other medical conditions requiring recurring transfusions.

b) For individuals with post-transfusion hemolysis, when no antibodies are detectable and no other possible cause is known (e.g., sickle cell crisis, mechanical hemolysis due to heart valve failure).

c) For individuals with autoimmune hemolytic anemia.

d) For multiply transfused individuals and/or individuals who are direct antiglobulin test positive.

e) For pregnant individuals who, prior to their first transfusion, had non-transfusion-dependent thalassemia.

f) To help manage hemolytic disease of the fetus and newborn.

g) To resolve conflicting serological antibody results.

h) For individuals with suspected Duffy-null neutropenia.

2) Red cell genotyping (including C, c, D, E, e, K, k, Jka, Jkb, Fya, Fyb, S, s, U) **DOES NOT MEET COVERAGE CRITERIA** in **any** of the following situations:

a) For individuals who have had allogenic hematopoietic stem cell transplants.

b) For the diagnosis of sickle cell disease.

c) As a routine pre-transfusion test.

d) As a routine screen for individuals receiving a solid organ transplant.

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ABOi	ABO-Incompatible
ASH	American Society of Hematology
BCSH	British Committee for Standards in Hematology
CIBMTR	Center for International Blood and Marrow Transplant Research
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid Services

DAT	Direct antiglobulin test
DAT+	Direct antiglobulin test positive
EAU	European Association of Urology
EDQM	European Directorate for the Quality of Medicines & HealthCare
FDA	Food and Drug Administration
FUT2	*Fucosyltransferase 2*
HDFN	Hemolytic Disease of The Fetus and Newborn
HEA	Human erythrocyte antigen
HLA	Human leukocyte antigen
HSCT	Hematopoietic Stem Cell Transplantation
HTRs	Hemolytic transfusion reactions
ICTM	International Collaboration for Transfusion Medicine
ISBT	International Society of Blood Transfusion
KDIGO	Kidney disease improving global outcomes
LAMP	Loop-mediated isothermal amplification method
LDTs	Laboratory-developed tests
MHC	Major histocompatibility complex
MT SC	Molecular testing standards committee
NGS	Next generation sequencing
NHLBI	National Heart, Lung, And Blood Institute
NMDP	National marrow donor program
NTDT	Non-Transfusion-Dependent Thalassemia
PCR	Polymerase chain reaction
PCR-RFLP	PCR restriction fragment length polymorphism
RBC	Red blood cell
Rh	Rhesus
RT-q	Reverse Transcription-Quantitative
SCD	Sickle cell disease
SNPs	Single-nucleotide polymorphisms
SSP-PCR	Sequence-Specific PCR
TDT	Transfusion Dependent Thalassemia
TIF	Thalassemia International Federation

V. Scientific Background

Transfusion medicine requires extensive blood type knowledge to ensure a safe and efficient transfusion process. Blood type differs throughout the population based on an individual's genome, and genes can vary due to allelic variations. Alleles are alternative forms of the same gene that arise by mutation. Alleles cause genomic

changes that ultimately lead to a discrepancy in the proteins produced in the body. Single-nucleotide polymorphisms (SNPs) are also found in the genome and describe a location where the nucleotide that is present differs between individuals because a substitution has been made. Alleles are sometimes caused by SNPs but can also be caused by other genetic mutations as well, such as additions, deletions, and insertions. Further, SNPs do not always lead to new alleles, as they could occur in non-coding areas of the genome. These alleles and SNPs play an important role in blood type and, therefore, in blood transfusion outcomes. Genetic variations will always affect an organism's genotype, which is the set of genes carried by the individual's cells, but may or may not affect an organism's phenotype, which are the observable characteristics or physical expression of those genes.

Blood Groups

Blood is quite complex and can be categorized into several different groups. Historically, blood groups have been classified by the antigens found "on or in the surface of erythrocytes which are present in certain individuals of a species but are lacking in others" (Kabat, 1956). These antigens are proteins with the ability to promote an immune response in the body by inducing the formation of antibodies.

To date, dozens of blood groups have been identified. As of July 2023, the International Society of Blood Transfusion has recognized 45 blood group systems (ISBT, 2023). This number seems to be constantly changing as new discoveries are made. Only a few years earlier, McBean et al. (2014) reported that 35 blood group systems had been identified, as well as 44 blood group genes and 1568 alleles. Most of these blood group antigens result from SNPs (Boccoz et al., 2015).

Karl Landsteiner, an Austrian biologist in the twentieth century, received the Nobel Prize for the discovery of the first human blood grouping system, ABO, in the early 1900s (Harmening et al., 2012). The ABO group was later classified into four antigens (A, B, O and AB) and six genotypes (AA, AO, BB, BO, OO and AB) in 1924 (Zhang et al., 2015). Examples of these are shown below in Table 1. As likely inferred from the name, the ABO blood group has three main allelic forms at its chromosomal locus: A, B and O. An individual's ABO blood type is genetically inherited, and A and B alleles are inherited in a codominant manner over O (Harmening et al., 2012). The ABO locus has been identified on chromosome 9 at 9q34.1-q34.2; differences in the A and B alleles have been identified and include variations in seven nucleotides via substitution, with four translating into different amino acids (Bethesda, 2005).

Another inherited antigen found on the surface of red blood cells is the Rhesus (Shih et al.) antigen (+/-); after the ABO blood group, the Rh factor is the most clinically significant factor (Písačka, 2018). The Rh blood group system, also identified by Karl

Landsteiner alongside Alexander Weiner, was named for the rhesus monkey from which this blood group was originally discovered (Agre et al., 1990). The Rh+ genotype is completely dominant over Rh-. It was recently reported that the Rh blood group system is comprised of 54 antigens and is "the most complex and polymorphic system" (Raud et al., 2017). Several journal articles have identified genetic variants in the RH (*RHD* and *RHCE*) genes, including SNP substitutions, insertions, deletions, and rearrangements; however, the expression of these variants require further research to determine how overall blood type is affected (Raud et al., 2017). Westhoff (2006) states that more than 100 different *RHD* genes have been identified which encode "proteins with single amino acid changes, or rearranged genes encoding hybrid proteins, and over 50 different *RHCE* genes with single or multiple amino acid changes." Genetic variation in the *RHD* and *RHCE* genes, including partial D antigens, are common, especially in individuals with African descent; further, the weak D phenotype is commonly identified in Caucasians (Elite, 2015). Other minor blood group systems include Kell, Kidd, Duffy, MNS, P, Lewis, Junior, and Lutheran (Kahar & Patel, 2014; Raud et al., 2017).

Red blood cell genotyping is necessary to confirm the presence or absence of Duffy antigens (Fy(a) and Fy(b)) on red blood cells. The Duffy-null phenotype is more common in individuals of African descent and can be associated with resistance to malaria, particularly *Plasmodium vivax*. Genetic variation determines Duffy blood group status, which has impacts that may encompass: (1) malaria resistance, (2) hemolytic transfusion reactions, and (3) hemolytic disease of the fetus and newborn (HDFN). Duffy antigen expression also affects baseline neutrophil counts. However, the Duffy-null phenotype can also be linked to a benign form of neutropenia (i.e., low neutrophil count), which is prevalent in individuals of African ancestry. This condition (known as benign ethnic neutropenia) does not typically result in increased susceptibility to infections (Merz & Achebe, 2021; Merz et al., 2023). By confirming the Duffy-null phenotype through genotyping, it is possible to differentiate between benign ethnic neutropenia and other causes of neutropenia (that may be cause for heightened concern). Additionally, in transfusion settings, genotyping is essential to ensure compatibility and prevent alloimmunization (Quinn & Berliner, 2023).

Blood Transfusions

Certain antibodies are considered more clinically significant than others for blood transfusion purposes. Clinically significant antibodies (with antigens listed in the subsequent parentheses) include "ABO (A, B), Rh (D, C, c, E, e), Duffy (Fya, Fyb), Kidd (Jka, Jkb), Kell (K, k), and SsU (S, s, U)" and less clinically significant antibodies include "Lewis (Le^a, Le^b), MN, P1, Xg^a, Cartwright (Yt^a), Bg, Knops (Kn^a, McC^a, Yk^a),

Chido/Rodgers (Ch1/Rg1), Sda; as well as high titer low avidity (HTLA) antibodies" (Uhl, 2023).

The ABO blood group is widely accepted as the most important of all blood systems for blood transfusion and transplant purposes. This is because the ABO group is responsible for most immune responses due to blood type incompatibility (Hu et al., 2019). Further, ABO is "the only blood group system in which individuals predictably have antibodies in their serum to antigens" absent from their red blood cells (Harmening et al., 2012). It is known that individuals with type A blood (containing A antigens) have anti-B antibodies in their serum, individuals with type B blood (containing B antigens) have anti-A antibodies in their serum, individuals with type O blood (containing no antigens) have anti-A and anti-B antibodies in their serum, and individuals with type AB blood (containing A and B antigens) do not have any anti-A or anti-B antibodies in their serum (Bethesda, 2005). ABO antibodies form in the serum naturally and are stimulated when the immune system encounters the "missing" ABO blood group antigen from food or in micro-organisms; "This happens at an early age because sugars that are identical to, or very similar to, the ABO blood group antigens are found throughout nature" (Bethesda, 2005). Although every red blood cell reportedly expresses about two million ABO blood group antigens, ABO antigens are not only present on red blood cells; these antigens are also found on many types of human tissue and most endothelial and epithelial cells (Bethesda, 2005). In certain individuals, these antigens can also be found in saliva and most bodily fluids as well (Bethesda, 2005).

Table 1: Phenotypes, Genotypes and Antibodies of the ABO Blood Group

Blood Type	Phenotype (i.e. antigen)	Potential Genotype(s)	Antibodies found in serum
A	A	AA, AO	Anti-B
B	B	BB, BO	Anti-A
AB	A and B	AB	None
O	Neither A nor B	OO	Anti-A and Anti-B

Due to the presence of antigens and antibodies on red blood cells, safe blood transfusions rely heavily on blood type knowledge. Administration of the wrong blood type can immediately lead to red blood cell lysis and death, and it is a leading cause of transfusion-related death as reported to the Food and Drug Administration (FDA) (Harmening et al., 2012). If the incorrect blood type is given to a patient, antibodies begin complement causing "rapid intravascular hemolysis, triggering an acute hemolytic transfusion reaction that can cause disseminated intravascular coagulation, shock, acute renal failure, and death" (Bethesda, 2005).

Several medical procedures utilize blood antigen typing such as blood transfusions, bone marrow transplants, stem cell transplants, and organ transplants. Blood transfusions may be administered for a multitude of reasons, including severe blood loss, leukemia, sickle cell disease, thalassemia, anemia, and kidney disease. Bone marrow, which is found in several adult bones including those of the pelvis, can assist with the transplant of healthy blood stem cells to replace others that have been destroyed by disease or infection; bone marrow transplants are known to assist in the treatment of several cancers, including leukemia, myeloma and lymphoma (Miller et al., 2019; Shah et al., 2018). Several factors—including age, illness severity, co-morbidities, and hemorrhage amount and rate—should be taken into account before a blood transfusion occurs (Osterman & Arora, 2017; Yaddanapudi & Yaddanapudi, 2014). Still, it has been reported that the use of blood transfusions for medical practice has been notoriously overused since the 20th century for the treatment of anemia and hemorrhage (Yaddanapudi & Yaddanapudi, 2014). Based on data distributed by the Red Cross, more than 30 million blood components are transfused annually in the United States (Osterman & Arora, 2017). In addition to whole blood transfusions, several types of blood product transfusions are available, including platelet, plasma and cryoprecipitate (Yaddanapudi & Yaddanapudi, 2014).

Hematopoietic Stem Cell Transplantation (HSCT)

Hematopoietic stem cells are immature cells with the ability to develop into all types of blood cells including red blood cells, white blood cells, and platelets. The transplantation of these cells, known as a hematopoietic stem cell transplantation (HSCT), is a medical procedure which involves the intravenous transfusion of hematopoietic stem cells obtained from the same (autologous) or different (allogenic) individual. These stem cells can be obtained from the umbilical cord, bone marrow, or peripheral blood and may be used to improve hematopoietic function or fight diseases such as leukemias, lymphoid neoplasia, solid tumors, and non-malignant disorders (Passweg et al., 2016).

In contrast to the requirement of ABO match for other types of blood transfusions and solid organ transplants, ABO mismatch is acceptable in HSCTs (Shokrgozar & Tamaddon, 2018). HSCTs can be safely matched by the human leukocyte antigen (Mandelbrot et al.), which is inherited independently of the ABO antigens (Booth et al., 2013; Shokrgozar & Tamaddon, 2018). Approximately 40-50% of all HSCTs will involve recipient-donor ABO incompatibility (Booth et al., 2013; Worel, 2016). However, an ABO mismatch may cause the recipient to experience pure red blood cell aplasia, delayed hemolytic reactions, or delayed red blood cell engraftment (Booth et al., 2013). Researchers note that outcomes in ABO-incompatible HSCT have yielded inconsistent

results, and pre-transplant antigen evaluation may be important to determine the extent of the incompatibility (Booth et al., 2013; Parkhideh et al., 2019).

Solid Organ Transplants

Solid Organ transplants are common between blood group- compatible individuals, with this process currently considered the most effective treatment for end-stage organ failure (Hu et al., 2019). To date, most important tissues in the body have been successfully transplanted, with exception of the brain.

Solid organ transplant is generally completed with ABO identical donor organs; however, minor ABO-incompatible solid organ transplants may be performed (Uhl, 2023). While ABO compatibility is widely accepted as the primary immunologic barrier for solid organ transplants, human leukocyte antigen (Mandelbrot et al.) compatibility is also very salient (Fasano et al., 2017). The HLA complex is a key part of the immune system controlled by genes on chromosome six; the HLA loci are part of the major histocompatibility complex (MHC) which helps the immune system to recognize foreign molecules (Shankarkumar et al., 2002). Some HLA antigens are recognized on all tissues in the body (as opposed to mainly red blood cells), making these antigens an integral part of organ and tissue transplants. The importance of HLA antibodies have been studied extensively in renal transplants "where recipient antibodies directed against mismatched donor HLA antigens are associated with antibody mediated rejection and/or graft loss" (Fasano et al., 2017).

Hemoglobinopathies (Sickle Cell Disease and Thalassemia)

Hemoglobinopathies, such as sickle cell disease and thalassemia, are red blood cell disorders. Sickle cell disease is a collection of inherited blood disorders which cause the development of abnormal sickle-shaped red blood cells that disrupt blood flow and lead to a plethora of problems, including ischemia and inflammation (Ware et al., 2017). Approximately 300,000 new blood disorder cases are reported globally each year due to sickle cell disease (Strouse, 2016). Blood transfusions for those with sickle cell disease can assist with an increase in oxygenation to tissues in the body, restoration of blood volume, reduction of sickle erythropoiesis, and prevention of acute vaso-occlusion (Ware et al., 2017). Alloimmunization, which is when the immune system responds to foreign antigens after a blood transfusion, occurs in a percentage of transfusion cases. "Extended red blood cell (RBC) antigen matching is recommended to limit alloimmunization in patients with sickle cell disease" (Casas et al., 2015). Thalassemia is an inherited blood disorder in which an abnormal or inadequate amount of hemoglobin is produced. Thalassemia can be categorized as α-or β-thalassemia depending on which hemoglobin chain is affected (Brancaleoni et al.,

2016). Blood transfusions are a potential treatment option for individuals with this disease (Dhawan et al., 2014).

However, post-transfusion complications are frequent with hemoglobinopathies due to "subtle antigenic differences between donors and patients" (Belsito et al., 2017). For sickle cell disease, red blood cell alloimmunization is common, and red blood cell antigen discrepancies are particularly important to identify because delayed transfusion reactions may be life threatening (Ware et al., 2017). Regarding thalassemia, alloimmunization rates emphasize "the need for RBC antigen typing before first transfusion and issue of antigen matched blood (at least for Rh and Kell antigen)" (Dhawan et al., 2014). Patients with sickle cell disease and thalassemia develop alloantibodies at a much higher rate than typical transfusions; patients with diseases such as these, or other patients who receive blood transfusions often, will benefit from an extended phenotype determination either with serological methods or genotypic methods (Elite, 2015). Fasano and Chou (2016) have used red blood cell antigen genotyping for sickle cell disease, thalassemia and other complications that may arise from transfusions; "Genotyping can be used to determine RBC antigen phenotypes in patients recently transfused or with interfering allo- or autoantibodies, to resolve discrepant serologic typing, and/or when typing antisera are not readily available" (Fasano & Chou, 2016).

Blood Transfusion Molecular Testing

For more than 100 years, agglutination tests using serology have been considered the gold standard for determining blood group antigens (Boccoz et al., 2015). These agglutination tests are simple to perform and identify antibodies or antigens in a sample, allowing for blood type to be inferred. Antiglobulin (Coombs) testing is a common laboratory technique that utilizes a secondary antibody to detect antibodies in the patient's serum; direct antiglobulin testing detects antibodies on the surface of red blood cells, and indirect antiglobulin testing identifies alloantibodies in patient serum (Uhl, 2023). However, these methods have limitations, such as inadequate immunological reagent availability, rising reagent costs, and specificity discrepancies between minor and rare blood types (Boccoz et al., 2015; Westhoff, 2006). Further, a recent red blood cell transfusion may also affect serologic results.

Certain immunohematological tests, such as adsorption/elution techniques, enzyme tests and indirect antiglobulin tests, are important for the detection of specific weak D phenotypes, but other weak D phenotypes cannot be detected by serological techniques (Guzijan et al., 2019). Weak or partial blood type antigens such as Rh, Fy^b, Jk^a, and U have been known to cause blood typing discrepancies (Elite, 2015). Moreover, certain blood type antigens exist for which "there is no commercially

available antisera and poorly characterized patient-source antisera (e,g., hrB, hrS, Joa, Hy, U)" (Elite, 2015). These limitations are significant because researchers have noted that "In practice, serological matching for ABO blood group antigens, Rhesus antigens (RhD, RhC, and RhE), and Kell (K) antigens does not fully prevent alloimmunisation, because of RH alleles with reduced or altered antigen expression" (Ware et al., 2017).

To combat serologic discrepancies, several DNA-based molecular testing methods may now be used for blood transfusion purposes. These methods can resolve the red blood cell inconsistencies often caused by weak and partial antigens (Belsito et al., 2017). Nonetheless, molecular typing is expensive, and results may take a few days or weeks to be returned. Further, for the majority of transfusion recipients, matching beyond ABO and D blood type antigens is not necessary (Anstee, 2009). It is, therefore, unlikely that these methods will become a substitute for serological testing but may be used instead when more detailed results are required (Sapatnekar, 2015).

These molecular techniques include Sanger sequencing of both genomic DNA and complimentary DNA as well as SNP assay testing; an SNP assay may consist of polymerase chain reaction (PCR)-restriction fragment length polymorphism (PCR-RFLP) or sequence-specific PCR (SSP-PCR) (Elite, 2015). Additional DNA amplification techniques may also be used for red blood cell genotyping, including "PCR-single-strand conformation polymorphism, allele-specific-PCR, PCR-amplified product length polymorphism, reverse transcription-quantitative (RT-q)PCR and DNA chip" (Zhang et al., 2015). Further, next generation sequencing is considered very promising for HLA typing, but more research is required to determine if this method is useful in the identification of blood group antigens (Elite, 2015). Other methods include array-based techniques which allow for multi-parallel testing where numerous samples can be searched at once for SNPs or other analytes (Elite, 2015). Microarrays, which may be planar arrays or suspended bead arrays, help to overcome several serology limitations by "replacing the immunochemical reagents by synthetic and controlled probes" (Boccoz et al., 2015).

Genotyping assays from whole-blood samples, which use an on-chip test to identify up to 24 blood group antigens, are also available (Boccoz et al., 2015), and next generation sequencing (NGS) methods can detect *de novo* genetic polymorphisms, SNPs, and other genetic variants (Belsito et al., 2017). Liu et al. (2014) claim that NGS methods "assess genetic variations that cannot be achieved by traditional Sanger sequencing or other genotyping platforms." More recently, it has been reported that molecular diagnostics for red blood cell genotypes can now be determined in the clinical laboratory and that the majority of allelic variations can be contributed to SNPs (Wilkinson, 2016).

A few panel tests have been developed that identify several blood antigens simultaneously. The BLOODchip® ID CORE XT™ by Grifols Diagnostic Solutions Inc. is an FDA-approved test. The BLOODchip® ID CORE XT™ can simultaneously identify 37 blood antigens in the following ten blood group systems: Rh, Kell, Kidd, Duffy, MNS, Diego, Dombrock, Colton, Cartwright and Lutheran (Grifols, 2018). This kit will be particularly beneficial to patients who require ongoing blood transfusions, such as individuals with sickle cell disease and thalassemia, as well as for cancer patients who may require very thorough blood typing. This kit uses PCR to amplify DNA samples and can provide results in approximately four hours. A study of 1000 samples reported a sensitivity of 100% and, after bidirectional sequencing, a 100% specificity for the BLOODchip® ID CORE XT blood typing assay; one discrepancy was identified in the E-antigen and 33 discrepancies were identified in the Fy^b- antigen (Lopez et al., 2018).

The PreciseType® HEA Test by Immuncor, Inc. is an FDA-approved multiplexed molecular assay which provides information on 35 red blood cell antigens from eleven different blood groups (Rh, Kell, Duffy, Kidd, MNS, Lutheran, Dombrock, Landsteiner-Wiener, Diego, Colton and Scianna) (Immuncor, 2024). This test can also identify 24 gene mutations and one SNP commonly associated with hemoglobinopathies. This test uses PCR and requires no confirmation of results with antisera (Immuncor, 2024). Another test by One Lamda, LinkSēq™ Blood Genotyping, was released which is a real-time PCR for RBC, ABO and HPA Genotyping (Lambda, 2024).

There are many other assays not yet FDA-approved but are used for research and investigational purposes only. The chart below displays various blood group genotyping methodologies which detect polymorphisms and antigens (Sippert, 2019).

Name/Manufacturer	Principle	Number of polymorphisms and antigens identified
Immucor PreciseType Molecular BeadChip by BioArray Solutions (FDA approved)	Multiplex PCR followed by hybridization of amplified DNA to probes attached to spectrally distinguishable beads and elongation	24 polymorphisms associated with 38 antigens plus phenotypic variants and Hemoglobin S
BioArray RHCE and RHD BeadChip by BioArray Solutions	Multiplex PCR followed by hybridization of amplified DNA to probes attached to spectrally distinguishable beads and elongation	35+ *RHCE* variants; 80+ *RHD* variants

ID CORE XT by Progenika Biopharma (FDA-approved)	Multiplex biotinylating PCR followed by hybridization to probes on color-coded microspheres	29 polymorphisms associated with 37 antigens and phenotypic variants
ID RHD XT by Progenika Biopharma	Multiplex biotinylating PCR followed by hybridization to probes coupled to color-coded microspheres	6 *RHD* variants and HPA-1
Hemo ID DQS Panel by Agena Bioscience	Multiplex end-point PCR and single base primer extension	101 antigens associated with 16 systems, and 23 platelet and neutrophil antigens, in modules
HIFI Blood 96 by AXO Science	Automated multiplex PCR and microarray-based assay	15 polymorphisms associated with 24 antigens
RBC-FluoGene vERYfy eXtend by inno-train diagnostik GMBH	Automated TaqMan-based assay	70 antigens and phenotypic variants associated with 12 systems
RBC-ReadyGene by inno-train diagnostic GMBH	PCR-SSP-based assay	16 modules encompassing antigens and variant phenotypes within 13 systems
TaqMan genotyping on OpenArray by BioTrove	Nanofluidic TaqMan assays performed in OpenArray plates	16, 32 or 64 assays (custom designed)
Pre-designed TaqMan assays Thermo Fisher Scientific	Real-time allelic discrimination PCR	Polymorphisms associated with eight systems

Analytical Validity

A novel method for ABO genotyping was developed by Muro et al. (2012) which used allele-specific primers and real-time PCR; this method can be completed in less than two hours, detects SNPs at three different nucleotide positions in the ABO gene, and can determine six main ABO genotypes. The authors state that "this method could be applicable for rapid and simple screening of forensic samples" (Muro et al., 2012).

However, this method is limited for transfusion medicinal purposes as it only identifies ABO genotypes.

Zhang et al. (2015) developed a method of determining ABO blood group genotypes with a real-time loop-mediated isothermal amplification method (LAMP); this LAMP method used two SNPs at nucleotides 261 and 803 to differentiate six ABO genotypes in less than an hour. A total of 101 samples were tested in this study, and each sample resulted in an ABO genotype; "The results were compared with the phenotypes determined by serological assay and the genotypes determined by direct sequencing, and no discrepancies were observed" (Zhang et al., 2015). This shows that this LAMP method is an accurate and efficient method to assist in ABO blood type genotyping.

Krog et al. (2019) have developed 35 PCR assays for blood donor genotyping. This high-throughput PCR genotyping method analyzed samples from 1034 patients, identifying 62 discrepancies between initial results, 43 of which are due to serology techniques (Krog et al., 2019). The accuracy of the genotyping method was determined at 99.9% with only 17 errors; "Of 17 discrepancies caused by the genotype, three were incorrect antigen-negative predictions and could potentially, as the solitary analysis, have caused an adverse transfusion reaction" (Krog et al., 2019). This is an extremely sensitive and cost-efficient method with a high capacity for screening many donors.

Another set of researchers developed a method of amplifying DNA via PCR "directly from plasma or serum of blood donors followed by a melting curve analysis in a capillary rapid-cycle PCR assay" (Wagner et al., 2017). This method allows the DNA extraction step to be skipped, permitting this assay to be completed in only 40 minutes. A positive predictive value was identified at 100%, and a negative predictive value at 84%. The authors state that "With fast turnaround times, the rapid-cycle PCR assay may eventually be developed and applied to red cell genotyping in the hospital setting" (Wagner et al., 2017).

It has been reported that the genetic Rh complexity among sickle cell disease patients is so great that molecular assays are not detailed enough to identify all possible genetic variants; therefore, next generation sequencing has been employed to identify all Rh genetic variants in an effort to improve transfusion outcomes in sickle cell disease patients (Dezan et al., 2017). This study used samples from 35 sickle cell disease patients with "unexplained Rh antibodies"; a genotypic method which used *RHD* and *RHCE* gene-specific primers was compared to traditional serological data. It was reported that "Ten and 25 variant *RHD* and *RHCE* alleles were identified, respectively. Among all cases of unexplained Rh antibodies, 62% had been inaccurately classified by serological analysis and, of these, 73.1% were considered as relevant" (Dezan et al., 2017). This next generation sequencing assay is therefore an effective

measure to identify genetic variants and improve blood transfusion outcomes in the sickle cell disease population.

Molecular *RHD* typing was implemented at two institutions in Europe via PCR-SSP; this was completed to assist in blood transfusion cases (Guzijan et al., 2019). This molecular method confirmed the majority of serologically identified weak D variants with more detail, and it also identified a discrepancy in one sample (Guzijan et al., 2019). This study has verified the accuracy of this genotyping method to confirm *RHD* variants, which will assist in the implementation of safer blood transfusion practices.

Shah et al. (2019) compared serological and molecular detection methods for common red cell antigen groups in thalassemia major and sickle cell disease patients. Specifically, the authors compared the molecular genotyping of Rh (D, C, c, E, e), Kell (K, k), Duffy (Fy^a, Fy^b) and Kidd (Jk^a, Jk^b) blood group antigens using PCR and PCR-RFLP to red blood cell antigen phenotypes identified by serology; serological testing was completed by tube agglutination. The authors note that the serological testing for extended RHCcEe, Kell, Kidd and Duffy testing for multi-transfused patients may not generate the correct blood grouping of the recipient. The authors report that "In more than 80% of the cases recipient's molecular testing blood groups were at variance with serologically tested blood groups ($p < 0.0001$). Mixed field reactions in serological typing were common. In sickle cell anemia patients, no discrepancy was found" (Shah et al., 2019). This shows that molecular detection methods to determine the genotype was particularly useful in multi-transfused thalassemia patients.

Sheppard et al. (2020) investigated the diagnostic accuracy of two PCR-based group genotyping platforms for patients with sickle cell disease (SCD) including the human erythrocyte antigen (Shah et al.) BeadChip (Immucor, Norcross, GA) and ID CORE XT (Progenika-Grifols, Barcelona, Spain). DNA samples were extracted from 138 patients with SCD to compare predicted phenotype results and calculate a concordance rate. As a result, predicted phenotype results were comparable across platforms for 31 antigens and the concordance rate was 99.9%. The study also identified discrepancies between the two assays in the highly variable Rh blood group system. In some cases, the two assays interrogated different positions in the gene, and the software made different assumptions based on the population frequency of the alleles. The ID CORE XT was able to identify the phenotype in two of three samples which had discrepancies in the Rh blood group while the HEA BeadChip identified the phenotype in one of three samples due to lack of interrogation in the gene. The authors conclude that genotyping provides valuable information not available by serologic methods and both methods are beneficial due to the high concordance rate (Sheppard et al., 2020).

Jadhao et al. (2022) studied the use of RBCeq, an algorithm for accurate genetic blood typing which identifies 36 blood group systems. "The RBCeq algorithm demonstrated 99.07% concordance when validated on 402 samples which included 29 antigens with serology and nine antigens with SNP-array validation in 14 blood group systems and 59 antigens validation on manual predicted phenotype from variant call files." The authors conclude that the use of RBCeq can reduce pre-transfusion testing time and increase sample processing throughput (Jadhao et al., 2022).

Clinical Utility and Validity

It is imperative that patients with sickle cell anemia receive correct red blood cell transfusions. In an effort to compare the accuracy of new DNA-based testing methods to traditional agglutination methods, Casas et al. (2015) compared 494 red blood cell phenotypes of sickle cell disease patients determined by hemagglutination methods to genotypic predictions made by DNA-based testing methods. If any discrepancies were identified, repeat serologic testing was performed to confirm these results. It was found that "Seventy-one typing discrepancies were identified among 6360 antigen comparisons (1.1%). New specimens for repeat serologic testing were obtained for 66 discrepancies and retyping agreed with the genotype in 64 cases" (Casas et al., 2015). This shows that DNA-based red blood cell genotyping can provide more accurate results when compared to traditional serologic methods, leading to more safe and efficient treatments for sickle cell disease patients.

Flegel et al. (2015) completed a large-scale blood genotyping project; samples were analyzed from 43,066 blood donors from the Blood Center of Wisconsin. Red blood cell genotyping was completed with "a nanofluidic microarray system, using 32 single nucleotide polymorphisms to predict 42 blood group antigens" (Flegel et al., 2015). This microarray technique allowed researchers to fill 95% of antigen-negative red blood cell requests for hospitals served by the Blood Center of Wisconsin; the remining requests were filled via serology identification. This genotyping system is therefore efficient and should be used along with conventional serology methods.

The frequency of red blood cell autoimmunization and alloimmunization development in β-thalassemia major patients was studied by Dhawan et al. (2014); clinical and transfusion records from 319 patients were analyzed. A total of 18 patients were found to have alloantibodies, 90 patients developed autoantibodies, and nine patients had both alloantibodies and autoantibodies; "Alloimmunization was detected in 5.64% of multitransfused thalassemia patients. Rh and Kell blood group system antibodies accounted for more than 80% of alloantibodies. This study re-emphasizes the need for RBC antigen typing before first transfusion and issue of antigen matched blood (at least for Rh and Kell antigen)" (Dhawan et al., 2014).

Parkhideh et al. (2019) studied the effects of ABO incompatibility on the outcome of allogenic HSCTs. This retrospective study includes data from 186 different patients with 108 identical, 38 minor, 32 major and eight bidirectional ABO incompatible scenarios. The researchers did not identify any significant associations between ABO incompatibility and white blood cell or platelet engraftment, or graft-versus-host disease; however, white blood cell engraftment was significantly lower in patients with minor ABO incompatibilities (Parkhideh et al., 2019).

Shih et al. (2020) discussed using red cell antigen genotyping and serological phenotyping in SCD patients to risk-stratify patients for alloimmunization risk. In this study, 106 SCD patients underwent genotyping to assess whether partial antigen expression may lead to increased risk of alloimmunization and hemolytic transfusion reactions (HTRs). A total of 91% of the 106 patients showed additional clinically relevant genotyping information when compared to serological phenotyping alone. The FY*02N.01 was found in 90% of patients and RH variant alleles were found in 49% of patients, with most of them having putative partial antigen expression. Overall, genotyping helped discover more clinically relevant information and "genotyping SCD patients before transfusion may prevent alloimmunization and HTRs." Additionally, "knowledge of the FY*02N.01 variant allele increases feasibility of finding compatible blood" (Shih et al., 2020).

Vege et al. (2021) studied the impact of *RHD* genotyping on transfusion practice and identification of novel *RHD* alleles. A total of 57 samples from Denmark and 353 samples from the US were genotyped with *RHD* Beadchip in the US and CDE in Denmark. "Of Caucasian samples from Denmark, 90% (n = 51) had weak D types 1, 2, or 3; two had other weak D, two partial D, and two new alleles. In diverse ethnic U.S. samples, 44% (n = 155) had weak D types 1, 2, or 3 and 56% (n = 198) had other alleles. Most samples with weak or variable D typing from Denmark had alleles without risk for anti-D. In U.S. samples, 48% could safely be treated as D+, 18% may require consideration if pregnancy possible, and 34% could potentially benefit from being treated as D" (Vege et al., 2021).

VI. Guidelines and Recommendations

The AABB and The Molecular Testing Standards Committee (MT SC)

The second edition of the MT SC for red cell, platelet and neutrophil antigen guidelines states that "When a serological reagent is not available, molecular results shall be confirmed by another method (e.g., DNA sequencing) or an external laboratory" (MTSC, 2014). This committee is spearheaded by the AABB (formerly known as the American Association of Blood Banks).

American Society of Hematology (Jadhao et al.)

The ASH has published guidelines for sickle cell disease transfusion support. These guidelines give the following recommendations:

- "The ASH guideline panel suggests an extended red cell antigen profile by genotype or serology over only ABO/RhD typing for all patients with SCD (all genotypes) at the earliest opportunity (optimally before the first transfusion) (conditional recommendation based on very low certainty in the evidence about effects).
- The ASH guideline panel recommends prophylactic red cell antigen matching for Rh (C, E or C/c, E/e) and K antigens over only ABO/RhD matching for patients with SCD (all genotypes) receiving transfusions (strong recommendation based on moderate certainty in the evidence about effects" (Chou et al., 2020).

British Committee for Standards in Hematology (BCSH)

The BCSH has published guidelines on pre-transfusion compatibility procedures in blood transfusion laboratories. These guidelines state the following:

"If a patient shows signs of active haemolysis following transfusion but no antibodies are detectable and no other possible cause is known (e.g. sickle cell crisis or mechanical haemolysis due to heart valve failure), this can be due to very rare examples of antibodies which are not detectable by normal serological techniques. In this case:

i. Serological investigation should be undertaken using more sensitive techniques such as Polyethylene Glycol or enzyme IAT, which may require referral to a reference center.
ii. It may be appropriate to fully red cell genotype the patient and select donor blood matched as closely as possible.
iii. Advice should be sought from a clinical haematologist or from a reference laboratory at the local Blood Centre" (Milkins et al., 2013).

Regarding antibody screening, the BCSH states that "Antibody screening should always be performed as part of pre-transfusion testing as it provides the laboratory with a more reliable and sensitive method of detecting a red cell antibody than serological crossmatching" (Milkins et al., 2013).

For patients who have received a transfusion in the previous three months, the BCSH recommends:

i. "Phenotyping may be misleading due to the presence of transfused cells; In this case genotyping can be used as an alternative and is available from specialist laboratories.
ii. When an Rh antibody is suspected, the C, c, E, e types should be determined to aid in the selection of appropriately phenotyped red cells.
iii. Where antibody exclusion is problematic, more extensive phenotyping may be informative to identify antigens to which the patient may be alloimmunised" (Milkins et al., 2013).

For patients with autoimmune hemolytic anemia, BCSH guidelines state that the "Risk of transfusion reaction due to underlying alloantibodies can further be reduced by matching blood with the patient's own type. Determination of the phenotype in multiply transfused and/or DAT+ patients may be problematic and determination of genotype offers useful information in managing these complex cases; this particularly applies to regularly transfused cases and those with autoantibodies resistant to removal by adsorption" (Milkins et al., 2013).

Finally, for patients with sickle cell disease, the BCSH recommends the following:

"The patient's red cells should be phenotyped as fully as possible prior to transfusion. Where patients have already been transfused, the genotype can be determined.

i. An extended phenotype (or genotype) should include C, c, E, e, K, k, Jka, Jkb, Fya, Fyb, S, s.
ii. If S- s-, then U typing should be performed.
iii. As a minimum, red cells should be matched for Rh and K antigens" (Milkins et al., 2013).

The BCSH also published guidelines on red blood cell transfusion in sickle cell disease. The following recommendations are given for investigating a hemolytic transfusion reaction:

"Serological testing on pre-transfusion and post-transfusion blood samples.

- Repeat ABO/Rh D typing
- Check antibody screen on both samples
- Red cell units transfused within 12–24 h should be crossmatched against both the pre- and post-reaction samples
- Check the direct antiglobulin test (DAT). A positive DAT may be encountered as part of an investigation

Selection of red cell units for further transfusion

- Select ABO extended Rh and K matched units negative for the relevant antigen(s) to which there are current or historical antibodies
- Undertake serological crossmatch to check compatibility; electronic issue should not be used
- If the identity of the new alloantibody is in doubt despite further specialist testing, consider providing extended antigen matched blood (if serological phenotyping cannot be used because of the presence of transfused donor red blood cells, the sample should be sent to an appropriate reference laboratory for molecular red cell genotyping)" (Davis et al., 2017).

These guidelines later stated that "Fetal RHD typing using a high-throughput methodology in pregnant [individuals] who have not formed anti-D, as part of a screening program to target anti-D Ig prophylaxis, is sufficiently accurate for implementation from 11 weeks gestation. The cost effectiveness of such testing is dependent on provision at a point in the antenatal care pathway that does not necessitate an additional visit (Grade 1C)" (White et al., 2016).

Regarding serological methods, the guidelines state that samples from pregnant individuals "with immune anti-D or anti-c should be assessed serologically at 4 weekly intervals to 28 weeks gestation and at fortnightly intervals thereafter until delivery. Such cases should be referred to a fetal medicine specialist if the antibody reaches the critical level and/or the level is rising significantly, where assessment of the need for further monitoring will be made (Grade 1B)" and pregnant individuals "with anti-K or other Kell system antibodies (unless the father is confirmed to be negative for the corresponding antigen) should be assessed serologically at monthly intervals to 28 weeks gestation and at fortnightly intervals thereafter until delivery and referred to a fetal medicine specialist when the antibody is first identified (Grade 1B)" (White et al., 2016).

European Directorate for the Quality of Medicines & HealthCare (EDQM)

The EDQM has published a guide for the preparation, use and quality assurance of blood components. Regarding blood group testing for donor blood, it is stated that "Each donation should be tested for ABO and RhD blood groups and at least all first-time donors should be tested for clinically-significant irregular red-cell antibodies" and that "ABO and RhD blood groups should be verified on each subsequent donation" (EDQM, 2023). The guidelines also give laboratory testing steps for both serological and NAT testing.

The EDQM also recommends that serological testing is the standard procedure used in most laboratories and "molecular testing is becoming increasingly available and used as an alternate or supplemental technique to serological testing. In time, molecular

testing may replace the need for routine serological testing." Molecular testing should be performed when the results of serological testing of blood donors and patients are unclear, when there is a suspicion of weak antigens or variants, or when serological reagents directed to specific antigens do not exist or are not readily available. "It can also be useful in chronically transfused patients to predict their red cell phenotype and aid the selection of phenotyped or genotyped red cell components. Testing can be undertaken on samples from blood, amniocentesis, biopsy of chorionic villi, and plasma" (EDQM, 2023).

International Collaboration for Transfusion Medicine (ICTM)

The ICTM published red blood cell related guidelines for patients with hemoglobinopathies. These background of these guidelines state that "No international consensus exists for antigen matching in patients with SCD and b-thalassemia. Some transfusion medicine services provide preventive phenotype (or genotype) extensive matching for C, c, E, e, and K antigens in addition to routine ABO and D. Additional extended matching for Jka, Jkb, Fya, Fyb, and S, s is offered at some centers. In contrast, others provide ABO and D matched RBCs and switch to more extensive matching only if alloantibodies are detected" (Compernolle et al., 2018).

The following recommendations were given by the ICTM:

- "Patients with SCD who do not have alloantibodies and who are anticipated to have a transfusion (simple or exchange transfusion) should probably be transfused with CcEe and K-matched RBCs to reduce the risk of alloimmunization (low quality of evidence, weak recommendation). RBCs matched for CcEe and K can be provided by phenotyping or genotyping RBCs. The use of phenotyping or genotyping will depend on the costs of each method in each jurisdiction. Genotyping appears to be more accurate.
- Patients with thalassemia syndromes who do not have alloantibodies and who require RBC transfusion should probably be transfused with CcEe and K-matched RBCs to reduce the risk of alloimmunization (low quality of evidence, weak recommendation). RBCs matched for CcEe and K can be provided by phenotyping or genotyping RBCs. The use of phenotyping or genotyping will depend on the costs of each method in each jurisdiction. Genotyping appears to be more accurate" (Compernolle et al., 2018).

In 2020, the British Journal of Haematology released a position paper reviewing ICTMG guidelines and were in agreement with the above recommendations (Trompeter et al., 2020).

National Heart, Lung, and Blood Institute (NHLBI)

An expert panel from the NHLBI state that "RBC units that are to be transfused to individuals with SCD should include matching for C, E, and K antigens" (NHLBI, 2014). The laboratory method to perform the antigen matching is not mentioned in these guidelines.

Thalassemia International Federation (TIF)

The TIF published guidelines for the management of non-transfusion dependent thalassemia (NTDT) (Taher et al., 2018). These guidelines recommend that pregnant individuals "with NTDT who were previously never- or minimally-transfused, should be considered at high risk of alloimmunization if blood transfusions are to be administered during pregnancy. If blood transfusion is deemed necessary, extended genotype and antibody screening should be performed before giving any transfusion and fully-phenotyped matched blood should be given" (Taher et al., 2018).

The TIF also published guidelines for the management of transfusion dependent thalassemia (TDT) in 2014 which was updated in 2021 (Cappellini et al., 2014; TIF, 2021). These guidelines recommend the following for compatibility testing:

"Before embarking on transfusion therapy, patients should have extended red cell antigen typing that includes at least C, c, D, E, e, and Kell, (though preferably a full red cell phenotype/genotype panel) in order to help identify and characterize antibodies in case of later immunization.

If the patient is already transfused, antigen typing can be performed using molecular rather than serologic testing.

All patients with thalassaemia should be transfused with ABO and Rh(C, c, D, E, e) and Kell compatible blood in order to avoid alloimmunisation against these antigens.

There should be a valid group and antibody screen available prior to transfusion being administered.

At each transfusion, give ABO, Rh(D) compatible blood. Choosing units compatible units for ABO, C,c, E,e and Kell antigens is highly recommended.

Before each transfusion, perform a screen for new antibodies and an IAT cross-match, or in centres that meet regulatory requirements, perform an electronic cross-match where allowed" (TIF, 2021).

European Association of Urology (EAU)

The EAU updated their guidelines on renal transplantation in 2024. These guidelines include the following strong recommendations:

- "Determine the ABO blood group and the human leukocyte antigen A, B, C and DR phenotypes for all candidates awaiting kidney transplantation.
- Test both the donor and recipient for human leukocyte antigen DQ. Human leukocyte antigen DP testing may be performed for sensitised patients.
- Perform thorough testing for HLA antibodies before transplantation
- Perform adequate cross-match tests to avoid hyper-acute rejection, before each kidney and combined kidney/pancreas transplantation
- Prevent hyper-acute rejection by adequate ABO blood group and HLA matching of donor and recipients" (A. Breda, 2024).

The article also states that "compatibility for ABO blood group antigens and HLA antigens was of critical importance in kidney transplantation. This may change in the future, e.g. in the new U.S. allocation system A2 and A2B donors are transplanted into B recipients. To avoid an increasing imbalance between demand and supply in deceased-donor kidney transplantation in O recipients, ABO identity is demanded by several organ allocation organisations with a few exceptions, e.g. as in zero HLA-A+B+DR-mismatch kidneys. With the introduction of antibody elimination methods, potent immunosuppression and novel agents (e.g. anti B-cell drugs), successful ABO-incompatible living donor transplantations, with good long-term outcomes are possible" (A. Breda, 2024). ABO genotyping is not mentioned in these guidelines.

Kidney Disease Improving Global Outcomes (KDIGO)

The KDIGO published guidelines on the evaluation and care of living kidney donors. The following recommendations were given:

- "Donor ABO blood typing should be performed twice before donation to reduce the risk of unintended blood type incompatible transplantation.
- Human leukocyte antigen (Mandelbrot et al.) typing for major histocompatibility complex (MHC) Class I (A, B, C) and Class II (DP, DQ, DR) should be performed in donor candidates and their intended recipients, and donor-specific anti-HLA antibodies should be assessed in intended recipients
- Donor candidates who are ABO blood group or HLA incompatible with their intended recipient should be informed of availability, risks, and benefits of treatment options, including kidney paired donation and incompatibility management strategies" (Mandelbrot et al., 2020).

The guidelines also mention in a rationale section that "ABO blood typing should be performed in living donor candidates before donation, including routine duplicate testing, to reduce the risk of unintended blood type-incompatible transplantation. Unintended ABO-incompatible (ABOi) transplantation should be avoidable with ABO typing of the donor and the recipient; however, human errors have led to cases of

accidental ABOi organ transplantation in contemporary practice. ABO-subtype testing should be performed when donation is planned to recipients with anti-A antibodies" (Mandelbrot et al., 2020).

The authors later state that "While recipient care is out of the scope of this guideline, it is important to emphasize that recipient candidates should undergo antidonor antibody examinations, including complement-dependent cytotoxicity or flow cytometry crossmatching and Luminex (Bio-Rad Laboratories, Inc., Hercules, CA) assays to determine the history of sensitization, and this testing should be current before proceeding with donor nephrectomy and living donor transplantation" (Mandelbrot et al., 2020).

Eurotransplant Manual

Version 5.4 (Chapter 10) of the Eurotransplant Manual states that "In case of stem cell transplantation before organ transplantation, a new HLA typing and ABO blood group typing should be performed." The specific methodology is not mentioned (Eurotransplant, 2023).

National Marrow Donor Program (NMDP) and Center for International Blood and Marrow Transplant Research (CIBMTR)

The NMDP and CIBMTR have published guidelines on unreleated donors and cord blood units for HSCTs. These guidelines state that "Sufficient high-resolution donor-recipient HLA match is of primary importance in transplantation with adult unrelated donors"; further, "While HLA matching remains the primary criteria for donor selection, non-HLA factors are often considered when selecting donors, including cytomegalovirus serostatus, sex, age, ABO compatibility, prior pregnancies, and larger body weight" (Dehn et al., 2019).

American Red Cross

The American Red Cross published transfusion practice guidelines in 2021. They recommended RHD genotyping be used in individuals of childbearing potential to resolve serologic weak D phenotypes, or discrepant D types and that extended RBC phenotyping (i.e. C/c, E/e, K, Jka/Jkb, Fya/Fyb, M/N, and S/s) be performed routinely on all SCD patients by either serologic or molecular methods (Cross, 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state

coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

The Immucor PreciseType Human Erythrocyte Antigen Molecular BeadChip Test

This test was approved by the FDA in 2014 and is an in vitro diagnostic test that is able to molecularly determine allele variants which assist in the prediction of erythrocyte antigen phenotypes (FDA, 2020). This test is known as the first FDA approved device for molecular typing of red blood cells.

ID CORE XT by Progenika Biopharma

This molecular based assay tests for non-ABO red blood cell types. This is a PCR hybridization-based genotyping test and can identify alleles which encode for human erythrocyte antigens in DNA and was approved by the FDA in 2018 (FDA, 2018).

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81403	Molecular pathology procedure, Level 4 (eg, analysis of single exon by DNA sequence analysis, analysis of >10 amplicons using multiplex PCR in 2 or more independent reactions, mutation scanning or duplication/deletion variants of 2-5 exons)
81479	Unlisted molecular pathology procedure
0001U	Red blood cell antigen typing, DNA, human erythrocyte antigen gene analysis of 35 antigens from 11 blood groups, utilizing whole blood, common RBC alleles reported Proprietary test: PreciseType® HEA Test Lab/Manufacturer: Immucor, Inc

CPT	Code Description
0084U	Red blood cell antigen typing, DNA, genotyping of 10 blood groups with phenotype prediction of 37 red blood cell antigens Proprietary test: BLOODchip® ID CORE XT™ Lab/Manufacturer: Grifols Diagnostic Solutions Inc.
0180U	Red cell antigen (ABO blood group) genotyping (ABO), gene analysis Sanger/chain termination/conventional sequencing, ABO (ABO, alpha 1-3-N-acetylgalactosaminyltransferase and alpha 1-3-galactosyltransferase) gene, including subtyping, 7 exons Proprietary test: Navigator ABO Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0181U	Red cell antigen (Colton blood group) genotyping (CO), gene analysis, AQP1 (aquaporin 1 [Colton blood group]) exon 1 Proprietary test: Navigator CO Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0182U	Red cell antigen (Cromer blood group) genotyping (CROM), gene analysis, CD55 (CD55 molecule [Cromer blood group]) exons 1-10 Proprietary test: Navigator CROM Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0183U	Red cell antigen (Diego blood group) genotyping (DI), gene analysis, SLC4A1 (solute carrier family 4 member 1 [Diego blood group]) exon 19 Proprietary test: Navigator DI Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0184U	Red cell antigen (Dombrock blood group) genotyping (DO), gene analysis, ART4 (ADP-ribosyltransferase 4 [Dombrock blood group]) exon 2 Proprietary test: Navigator DO Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0185U	Red cell antigen (H blood group) genotyping (FUT1), gene analysis, FUT1 (fucosyltransferase 1 [H blood group]) exon 4 Proprietary test: Navigator FUT1 Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0186U	Red cell antigen (H blood group) genotyping (FUT2), gene analysis, FUT2 (fucosyltransferase 2) exon 2 Proprietary test: Navigator FUT2 Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0187U	Red cell antigen (Duffy blood group) genotyping (FY), gene analysis, ACKR1 (atypical chemokine receptor 1 [Duffy blood group]) exons 1-2 Proprietary test: Navigator FY Sequencing Lab/Manufacturer: Grifols Immunohematology Center

CPT	Code Description
0188U	Red cell antigen (Gerbich blood group) genotyping (GE), gene analysis, GYPC (glycophorin C [Gerbich blood group]) exons 1-4 Proprietary test: Navigator GE Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0189U	Red cell antigen (MNS blood group) genotyping (GYPA), gene analysis, GYPA (glycophorin A [MNS blood group]) introns 1, 5, exon 2 Proprietary test: Navigator GYPA Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0190U	Red cell antigen (MNS blood group) genotyping (GYPB), gene analysis, GYPB (glycophorin B [MNS blood group]) introns 1, 5, pseudoexon 3 Proprietary test: Navigator GYPB Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0191U	Red cell antigen (Indian blood group) genotyping (IN), gene analysis, CD44 (CD44 molecule [Indian blood group]) exons 2, 3, 6 Proprietary test: Navigator IN Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0192U	Red cell antigen (Kidd blood group) genotyping (JK), gene analysis, SLC14A1 (solute carrier family 14 member 1 [Kidd blood group]) gene promoter, exon 9 Proprietary test: Navigator JK Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0193U	Red cell antigen (JR blood group) genotyping (JR), gene analysis, ABCG2 (ATP binding cassette subfamily G member 2 [Junior blood group]) exons 2-26 Proprietary test: Navigator JR Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0194U	Red cell antigen (Kell blood group) genotyping (KEL), gene analysis, KEL (Kell metallo-endopeptidase [Kell blood group]) exon 8 Proprietary test: Navigator KEL Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0195U	KLF1 (Kruppel-like factor 1), targeted sequencing (ie, exon 13) Proprietary test: Navigator KLF1 Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0196U	Red cell antigen (Lutheran blood group) genotyping (Boccoz et al.), gene analysis, BCAM (basal cell adhesion molecule [Lutheran blood group]) exon 3 Proprietary test: Navigator LU Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0197U	Red cell antigen (Landsteiner-Wiener blood group) genotyping (LW), gene analysis, ICAM4 (intercellular adhesion molecule 4 [Landsteiner-Wiener

CPT	Code Description
	blood group]) exon 1 Proprietary test: Navigator LW Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0198U	Red cell antigen (RH blood group) genotyping (RHD and RHCE), gene analysis Sanger/chain termination/conventional sequencing, RHD (Rh blood group D antigen) exons 1-10 and RHCE (Rh blood group CcEe antigens) exon 5 Proprietary test: Navigator RHD/CE Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0199U	Red cell antigen (Scianna blood group) genotyping (SC), gene analysis, ERMAP (erythroblast membrane associated protein [Scianna blood group]) exons 4, 12 Proprietary test: Navigator SC Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0200U	Red cell antigen (Kx blood group) genotyping (XK), gene analysis, XK (X-linked Kx blood group) exons 1-3 Proprietary test: Navigator XK Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0201U	Red cell antigen (Yt blood group) genotyping (YT), gene analysis, ACHE (acetylcholinesterase [Cartwright blood group]) exon 2 Proprietary test: Navigator YT Sequencing Lab/Manufacturer: Grifols Immunohematology Center
0221U	Red cell antigen (ABO blood group) genotyping (ABO), gene analysis, next-generation sequencing, ABO (ABO, alpha 1-3-N-acetylgalactosaminyltransferase and alpha 1-3-galactosyltransferase) gene Proprietary test: Navigator ABO Blood Group NGS Lab/Manufacturer: Grifols Immunohematology Center
0222U	Red cell antigen (RH blood group) genotyping (RHD and RHCE), gene analysis, next-generation sequencing, RH proximal promoter, exons 1-10, portions of introns 2-3 Proprietary test: Navigator Rh Blood Group NGS Lab/Manufacturer: Grifols Immunohematology Center
0246U	Red blood cell antigen typing, DNA, genotyping of at least 16 blood groups with phenotype prediction of at least 51 red blood cell antigens Proprietary test: PrecisionBlood™ Lab/Manufacturer: San Diego Blood Bank
0282U	Red blood cell antigen typing, DNA, genotyping of 12 blood group system genes to predict 44 red blood cell antigen phenotypes

CPT	Code Description
	Proprietary test: Versiti™ Red Cell Genotyping Panel Lab/Manufacturer: Versiti™ Comprehensive Bleeding Disorder Panel

Testing for Alpha-1 Antitrypsin Deficiency

Policy Number: AHS – M2068 – Testing for Alpha-1 Antitrypsin Deficiency	Prior Policy Name and Number, as applicable: • M2068 Genetic Testing for Alpha-1 Antitrypsin Deficiency
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Alpha 1-antitrypsin deficiency (AATD) is a genetic disease that causes deficient or defective production of the alpha-1 antitrypsin (AAT) protease inhibitor that can affect the lungs, liver, and skin (Stoller, 2024). AAT deficiency results in unbalanced rapid breakdown of proteins, especially in the supporting elastic tissue of the lungs (NORD, 2024a).

II. Related Policies

Policy Number	Policy Title
	Not applicable

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals who are suspected of having alpha-1 antitrypsin (AAT) deficiency, serum quantification of alpha-1 antitrypsin (AAT) protein **and** AAT phenotyping **or** AAT proteotyping **or** genetic testing for AAT deficiency (see Note 1) **MEETS COVERAGE CRITERIA** once per lifetime in **any** of the following situations:
   a) For symptomatic individuals 18 years or older with emphysema, COPD, or asthma.

b) For individuals with unexplained liver disease (e.g., chronic hepatitis with or without cirrhosis, chronically elevated aminotransferase levels, portal hypertension, primary liver cancer).

c) For individuals with persistent obstruction on pulmonary function tests without identifiable risk factors (e.g., cigarette smoking, occupational exposure).

d) For individuals 18 years or older with necrotizing panniculitis.

e) For the siblings of an individual with known alpha-1 antitrypsin (AAT) deficiency.

f) For individuals with anti-proteinase three-positive vasculitis (C-ANCA [anti-neutrophil cytoplasmic antibody]-positive vasculitis).

g) For individuals with bronchiectasis without evident etiology.

h) For individuals with neonatal cholestasis.

2) For individuals who have negative genotype results for common variants or who have discordant results between AAT serum levels and proteotype, but for whom a clinical suspicion of AAT deficiency remains, isoelectric focusing/phenotyping **MEETS COVERAGE CRITERIA**.

3) For individuals with a first-degree relative (see Note 2) with AAT deficiency, comprehensive *SERPINA1* gene sequencing **MEETS COVERAGE CRITERIA**.

4) For individuals with negative genotype testing for common variants **or** discordant results between AAT serum levels and proteotype or phenotype, but for whom the clinical suspicion of AAT deficiency remains, comprehensive *SERPINA1* gene sequencing **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) For all other situations not described above, testing for AAT deficiency **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: AAT phenotyping should be performed using isoelectric focusing. AAT proteotyping (Pi-typing or protease inhibitor typing) for Z and S alleles should be performed using liquid chromatography-tandem mass spectrometry. Initial genetic testing should be restricted to genotyping of *SERPINA1* S and Z allele mutations.

Note 2: First-degree relatives include parents, full siblings, and children of the individual.

IV. Table of Terminology

Term	Definition
A1AT	Alpha-1 antitrypsin
AAT	Aspartate aminotransferase
AATD	Alpha 1-antitrypsin deficiency
ACG	American College of Gastroenterology
ALT	Alanine transaminase
AST	Aspartate aminotransferase
ATS/ERS	American Thoracic Society/European Respiratory Society
C-ANCA	C-Anti-neutrophil cytoplasmic antibody
CMS	Centers for Medicare and Medicaid Services
COPD	Chronic obstructive pulmonary disorder
CTS	Canadian Thoracic Society
ERS	European Respiratory Society
GC	Gas chromatography
GOLD	Global Initiative for Chronic Obstructive Lung Disease
HPLC	High-performance liquid chromatography
LBV	Likely benign variants
LDTs	Laboratory developed tests
MALDI	Matrix-assisted laser desorption ionisation
MMP-12	*Matrix metalloproteinase-12* gene
MS-TOF	Time of flight mass spectrometry
NAFLD	Non-alcoholic fatty liver disease
NICE	National Institute Health and Care Excellence
NORD	National Organization for Rare Disorders
ON-CD	Ontario Center
PCR	Polymerase chain reaction
Pi	Protease inhibitor
PiMZ	Protease inhibitor Z allele
PV	Pathogenic variant
QTOF	Quadrupole time of flight
RCTs	Randomized controlled trials
RFLP	Restriction fragment length polymorphism
SERPINA1	Serine protease inhibitor
UMV	Undefined molecular variants
WHO	World Health Organization

V. Scientific Background

Alpha-1 antitrypsin deficiency (AATD) is an underrecognized genetic condition that affects approximately 1 in 2,000 to 1 in 5,000 individuals and predisposes to liver disease and early-onset emphysema (Stoller & Aboussouan, 2012). It is estimated (Campos et al., 2005) that up to 80,000 to 100,000 people in the United States have the severe form of the disease (homozygous in null or abnormal alleles). There is much variation in the disease prevalence in other nations (de Serres et al., 2007), but most current estimates are that three million people worldwide have severe AATD (Stoller, 2023).

Alpha-1 antitrypsin deficiency is a result of abnormal alpha-1 antitrypsin (AAT) protein inherited in an autosomal recessive pattern with codominant expression in which both genes inherited can be active and contribute to the genetic trait they control. AAT is a member of the serine protease inhibitor (Pi) family, referred to as "serpins", and it inhibits the proteolytic enzymes elastase, trypsin, chymotrypsin, and thrombin. AAT is encoded by the gene *SERPINA1* (Stoller, 2023).

The AAT protein is produced in the liver and has a role in protecting lungs from injury by neutrophil elastase, which is secreted by white blood cells as a response to inflammation or infection. If the enzyme remains unchecked by AAT protein, damage to alveoli resulting in chronic obstructive pulmonary disease can occur. This includes emphysema, asthma, bronchiectasis, and spontaneous pneumothorax. Smoking and other environmental exposure can cause further damage (Stoller, 2023, 2024).

Abnormal molecules of AAT protein caused by this illness can also cause liver dysfunction. Pathologic polymerization of the variant AAT can occur, resulting in intrahepatocyte accumulation of AAT molecules, leading to cirrhosis, fibrosis, cholestasis, or hepatomegaly. Liver disease is more common in individuals with certain allele combinations. Gender and obesity may be risk factors for progression to advanced liver disease in adulthood among patients with severe AAT deficiency. In contrast, alcohol use and viral hepatitis do not appear to increase the risk of progressive hepatic failure (Stoller, 2024). AATD is a common genetic cause of liver disease in children (de Serres et al., 2003).

Skin manifestations of AATD are also recognized. The most associated skin condition is necrotizing panniculitis. In this condition, inflammatory skin lesions are thought to be a consequence of the AAT protein loss of function and subsequent unchecked proteolysis enzyme activity in the skin and subcutaneous tissue. Associations between alpha-1 antitrypsin (AAT) and vascular disease, inflammatory bowel disease, glomerulonephritis, and vasculitis have been proposed but not definitively established (Stoller, 2024).

Due to the numerous alleles associated with AAT, each allele has been given a letter code based on the "electrophoretic mobility of the protein produced". The normal allele is the "M" allele, and the most common mutation is the "Z" allele. This system applies for each individual allele; for example, a homozygous Z genotype would be denoted as "ZZ". Similarly, a wildtype (or "normal") genotype would be "MM". Besides the normal phenotype, the three other categories of AAT include "deficient" in which insufficient AAT is produced; "null" in which no AAT is produced at all; and "dysfunctional" in which a typical amount of AAT is produced, but the AAT protein does not function correctly (Stoller, 2023).

Laboratory testing for AATD is comprised of three strategies: serum or plasma AAT quantification, AAT protein phenotyping, and genotyping. Guidelines from national and international societies (e.g., World Health Organization, Spanish Society of Pneumology and Thoracic Surgery, European Respiratory Society) recommend testing for AATD at least once per lifetime for all individuals with liver disease of unknown etiology and for all individuals with chronic obstructive pulmonary disorder (COPD), emphysema, or adults with asthma and irreversible airflow obstruction (Belmonte et al., 2020).

Proprietary Testing

Initial testing often begins with serum quantification of AAT protein. This can be done through several methods, including immune turbidimetry and nephelometry (Stoller, 2023). A low level is generally represented by a serum level below 11 micromol/L (less than 57 mg/dl using nephelometry). Due to the variation of reference ranges in different testing methodologies, most labs will complete isoelectric phenotyping on any individual with a serum AAT levels of < 100 mg/dL (18.4 micromol/L). In fact, the American Thoracic Society suggests persons with borderline serum levels (defined as 12-35 micromoles or 90 to 140 mg/dL) have qualitative testing (ATS/ERS, 2003).

Isoelectric immunophenotype testing uses the difference in migration rates of allele variants under isoelectric focusing. For example, the M variant will migrate to the middle of the gel, Z will migrate the slowest, and F migrates quickly to the side closest to the anode. This is not a genetic test. On occasion the results can be inconclusive or discordant with quantitative testing, requiring genotype testing of the most-common variants (Stoller, 2023).

Genotype testing for the most common allele variants can be utilized where isoelectric immunophenotype testing is inconclusive. Usually polymerase chain reaction (PCR) or restriction fragment length polymorphism (RFLP) techniques are utilized to determine if the most common alleles are present. When dealing with the possibility of a rare

variant or null allele, full gene sequencing can be utilized as a final diagnostic measure (Stoller, 2023).

In 2017, Grifols won FDA approval for AAT Deficiency Test, which is capable of simultaneously analyzing 99% of the most prevalent known mutations causing alpha-1 antitrypsin deficiency. The molecular test analyzes simultaneously 192 samples per kit, and in a single reaction, identifies 14 of the most prevalent known mutations in the SERPINA1 gene, responsible for this genetic disorder (Grifols, 2017b).

Using Progenika's FDA-cleared A1AT Genotyping Test, Matrix Clinical Labs released the proprietary Alpha ID screening test, a comprehensive targeted genetic test assessing 14 common and rare alleles in the *SERPINA1* gene. The Alpha ID screening test utilizes a noninvasive cheek swab screen. If a positive result is found using this test, a follow-up test, Alpha ID Confirm, uses a finger stick and a blood spot card to asses A1AT protein levels as well a potential reflex to next-generation sequencing (NGS) to help physicians achieve an accurate diagnosis of Alpha-1 antitrypsin deficiency (A1ATD) (AlphaID, 2024).

Clinical Utility and Validity

The literature on the analytic and clinical validity of genetic testing for AATD is limited. In addition, few randomized controlled trials (RCTs) have evaluated the impact of AATD testing on patient outcomes. Current evidence-based guidelines (GOLD, 2024) for diagnosis and management of AATD recommend specific interventions for patients with emphysema and AATD. AAT augmentation therapy is often prescribed for patients with AATD and COPD. In addition, several studies have documented that the disease is under-recognized with delay in diagnosis of between five to eight years (Barrecheguren et al., 2016; Stoller et al., 2005).

Snyder et al. (2006) evaluated the laboratory methods of assessing AATD. Samples from 512 individuals were analyzed, and "A1AT concentrations were measured by nephelometry. Phenotype analysis was performed by isoelectric focusing electrophoresis. The genotype assay detected the S and Z deficiency alleles by a melting curve analysis." Of these 512 samples, 10 (2%) were discordant between genotype and phenotype. Of these 10 results, seven were attributed to phenotyping errors. Four percent of the samples submitted to genotype and quantitative analysis were "reflexed" to phenotyping, where phenotyping confirmed the genotype result 85% of the time. The investigators concluded, "The combination of genotyping and quantification, with a reflex to phenotyping, is the optimal strategy for the laboratory evaluation of A1AT deficiency" (Snyder et al., 2006).

Sorroche et al. (2015) examined a cohort of COPD patients and the prevalence of severe AATD. A total of 1002 patients were evaluated, and 785 (78.34%) had normal

AAT levels. The remaining 217 patients had low AAT levels, but only 15 patients had a genotype associated with severe AATD. Of these 15 patients, 12 were ZZ and three were SZ. Of the 202 other patients, 29 were a Z heterozygote, 25 were an S heterozygote, and four were an SS homozygote. Lastly, 144 patients could not be definitively diagnosed (Sorroche et al., 2015).

Corda et al. (2011) examined the prevalence of AATD in a supposed "high-risk" area. A total of 817 residents participated, and 67 had low AAT serum levels. Overall, 118 residents carried AATD-related alleles, 114 of which were heterozygotes "(46 Z, 52 S, 9 P(brescia), 4 M(wurzburg), 2 I, 1 P(lowell)". The authors concluded, "the large number of mostly asymptomatic individuals with AATD identified suggests that in high-risk areas adult population screening programs employing the latest genetic methods are feasible" (Corda et al., 2011).

Soriano et al. (2018) evaluated the prevalence of AATD testing in COPD patients. The patient sample came from "550 UK Optimum Patient Care Research Database general practices". Out of 107,024 COPD patients, only 2.2% had any record of being tested for AATD. Of those tested, 23.7% were diagnosed with AATD. The investigators also noted that between 1994 and 2013, the incidence of AATD diagnosis increased. The authors concluded "that AATD remains markedly underdiagnosed in COPD patients" (Soriano et al., 2018).

Greulich et al. (2016) evaluated the results of a large, targeted screening program for AATD. The samples were distributed by a German AAT laboratory over a period of 12 years, and 18,638 testing kits were obtained. Of this sample, 6919 carried at least one mutation, and 1835 patients were considered to have severe AATD. Overall, 194 of these patients had "rare" genotypes. The authors concluded that "among clinical characteristics, a history of COPD, emphysema, and bronchiectasis were significant predictors for Pi*ZZ, whereas a history of asthma, cough and phlegm were predictors of not carrying the genotype Pi*ZZ" (Greulich et al., 2016).

Mattman et al. (2020) compared the comprehensiveness and efficiency of pathogenic variant (PV) detection of four different protocols from 2011 to 2018 in laboratories across Canada. From 5399 index patients, 396 ZZ genotypes were identified. The protocol for serum A1AT concentration/DNA sequencing in the Ontario center (ON-CD) yielded the highest PV detection – "genotypes with at least one PV, other than S, Z, or F, were identified at 0.67/ZZ as compared to <0.2/ZZ (all others)." However, it also had the highest rates of undefined molecular variants (UMV) (0.16/ZZ vs <0.12/ZZ) or likely benign variants (LBV) compared to all others (0.08/ZZ vs <0.06/ZZ). The authors concluded the "strategies with readily detect variants across the full coding sequence of *SERPINA1* detect more PV as well as more UMV and LBV" (Mattman et al., 2020).

Hamesch et al. (2019) evaluated the clinical landscape of liver symptoms in patients with AATD, specifically the Pi*ZZ genotype. A total of 554 patients (403 exploratory cohort, 151 confirmatory cohort) were included and were compared to 234 controls without pre-existing liver disease. The authors found significantly higher levels of serum liver enzymes in the Pi*ZZ carriers compared to controls, further noting that "significant' fibrosis was suspected in 20%-36% of Pi*ZZ carriers. Signs of advanced fibrosis were 9 to 20 times more common in carriers compared to non-carriers. Controlled attenuation parameter of ≥280 dB/m, which suggests "severe" steatosis was detected in 39% of carriers compared to 31% of controls. Finally, Pi*ZZ carriers were found to have lower serum concentrations of triglyceride, low, and very-low density lipoprotein cholesterol compared to controls, which the authors suggested to represent impaired hepatic secretion of liquid. Overall, the authors concluded that they identified evidence of liver steatosis, impaired liver secretion, liver fibrosis, and that their data could assist in hepatologic management of Pi*ZZ carriers (Hamesch et al., 2019).

Strnad et al. (2019) investigated the impact of the Pi*Z and Pi*S genotypes on subjects with non-alcoholic fatty liver disease (NAFLD) or alcohol misuse. Separate cohorts of 1184 with NAFLD and 2462 with chronic alcohol abuse were included. The authors found Pi*Z genotypes in 13.8% of patients with cirrhotic NAFLD but only 2.4% of patients without liver fibrosis. From there, the increased risk of NAFLD subjects to develop cirrhosis was found to be 7.3 times higher in Pi*Z carriers. The Pi*Z variant was also found in 6.2% of alcohol abusers but only 2.2% of alcohol abusers without significant liver injury. The increased risk was found to be 5.2 times higher in Pi*Z carriers. The Pi*S variant was not associated with NAFLD-related cirrhosis and only mildly with alcohol-related cirrhosis (increased risk = 1.47 times). The authors concluded that the Pi*Z variant was the strongest "single nucleotide polymorphism-based risk factor for cirrhosis in NAFLD and alcohol misuse, whereas the Pi*S variant confers only a weak risk in alcohol misusers" and remarked that this finding should be considered in future genetic counseling of affected individuals (Strnad et al., 2019).

Carreto et al. (2020) examined the utility of routine screening for AATD among patients with bronchiectasis, due to the contradiction in guidelines from the British Thoracic Society, which recommend screening for bronchiectasis among patients with AATD, but not vice versa. After screening 1600 patients with bronchiectasis from two centers in the UK from 2012-2016, they found only eight patients with AATD. They concluded that because of the low prevalence of AATD as an etiology for disease presentation among patients with bronchiectasis, routine screening for AATD would not significantly impact clinical management through augmentation therapy, smoking cessation, and genetic counselling, among other methods. Despite this, the researchers did note that

higher rates of detection may be found in other geographical regions in the UK or in other countries (Carreto et al., 2020).

In 2021, Murray et al. evaluated the efficacy of a liquid chromatography-tandem mass spectrometry (LC-MS/MS) (proteotyping)-based algorithm for AATD detection (n=5474), as compared to the more traditional isoelectric focusing (IEF) phenotyping (n=16147). Here, the authors found that LC-MS/MS reduced the rate of IEF) phenotyping by 97% and the 3% of cases that were reflexed to IEF resulted in and addition 0.2% of phenotype findings. By retrospectively applying the proteotype-based algorithm to the IEF cohort, they demonstrated a 99.9% sensitivity for the detection of deficiency-associated phenotypes. The authors concluded that the "proteotype algorithm is a sensitive and cost-effective approach for the diagnosis of clinical AAT deficiency" (Murray et al., 2021).

Bellemare et al. (2021) studied the clinical utility of determining the allelic background of mutations causing alpha-1 antitrypsin deficiency. *SERPINA1* was DNA sequenced to identify rare variants that could confer the risk of developing emphysema. Seven carriers of a rare variant, Leu353Phe_fsTer24, known to lead to undetectable serum levels of AAT, were studied using an allele-specific DNA sequencing method that they developed. Results demonstrated that Leu353Phe_fsTer24 variant was transmitted on the same allele as the M3 variant in all the patients and two of the seven patients had either a S or Z allele. The lowest AAT serum levels were observed in compound heterozygotes for the S or Z allele, suggesting higher risk of developing emphysema. This study showed that understanding the clinical significance of genetic variants found in SERPINA1 can lead to better clinical outcomes (Bellemare et al., 2021).

Ashenhurst et al. (2022) conducted a study to examine whether direct-to-consumer genetic testing increased the identification of previously undetected individuals specifically with AATD, and whether it impacted clinical care. In this cross-sectional study using a survey from the 23andMe, Inc. research platform with 195,014 participants, researchers found that the allele frequency of PI*S was 15.1%, 6.5% for PI*Z, and 0.63% with PI*ZZ. Half of those with the PI*ZZ allele combination were able to confirm their diagnosis with a physician. Twenty seven percent of the participants were first made aware of their disease status through this test, and among these participants, "the diagnostic delay interval was 22.3 years." As a result of this finding, there was a 1.7 times increased odds of reporting smoking reduction and 4.0 times increased odds of reporting reduced alcohol consumption. This demonstrates that having convenient methods of detecting pathogenic variants of the *SERPINA1* gene in commercial testing could benefit patients in the long run in terms of reducing risks of complications from AATD (Ashenhurst et al., 2022).

Balcar et al. (2022) studied the association between the alpha-1 antitrypsin Pi∗Z allele and liver disease. The study included 1118 patients with advanced chronic liver disease, all of whom had undergone genotyping for the Pi*Z/Pi*S allele. Compared to non-carriers, Pi∗Z carriers had more severe portal hypertension and hepatic dysfunction. "Harbouring the Pi∗Z allele was significantly associated with an increased probability of liver transplantation/liver-related death," but "the Pi∗S allele was unrelated to liver disease severity" and "Pi∗S carriers had no increased risk of events." The authors concluded that "genotyping for the Pi∗Z allele identifies patients with ACLD at increased risk of adverse liver-related outcomes, thereby improving prognostication" (Balcar et al., 2022).

Clark et al. (2018) studied the clinical and histologic features of individuals with AATD. The study included 94 non-cirrhotic adults with Pi*ZZ AATD. "The prevalence of clinically significant liver fibrosis (F ≥ 2) was 35.1%. Alanine aminotransferase, aspartate aminotransferase and gamma-glutamyltransferase values were higher in the F ≥ 2 group." Metabolic syndrome, the presence of accumulated abnormal AAT in hepatocytes, portal inflammation, and hepatocellular degeneration were all associated with clinically significant fibrosis. The authors concluded that "over one-third of asymptomatic and lung affected adults with 'PI*ZZ' AATD have significant underlying liver fibrosis" and that "liver disease in this genetic condition may be related to a "toxic gain of function" from accumulation of AAT in hepatocytes" (Clark et al., 2018).

Eriksson et al. (1986) studied the association between AATD and cirrhosis and primary liver cancer. The study included 17 autopsy cases of individuals with AATD. Each autopsy was matched with four control cases. "The results indicated a strong relation between alpha 1-antitrypsin deficiency and cirrhosis and primary liver cancer" (Eriksson et al., 1986).

Fromme et al. (2022) studied the association between AATD and hepatobiliary phenotypes. The study included 1104 participants (586 Pi*ZZ, 239 Pi*SZ, 279 non-carriers). "Pi*ZZ individuals displayed the highest liver enzyme values, the highest occurrence of liver fibrosis/cirrhosis and primary liver cancer… Pi*SZ participants displayed higher liver enzymes, more frequent liver fibrosis/cirrhosis… Subjects with Pi*MZ genotype had slightly elevated liver enzymes and moderately increased odds for liver fibrosis/cirrhosis…Individuals with homozygous Pi*S mutation (Pi*SS genotype) harboured minimally elevated alanine aminotransferase values." The authors concluded that their findings classify hepatobiliary phenotypes with their most relevant AATD genotypes (Fromme et al., 2022).

The Childhood Liver Disease Research Network Longitudinal Observational Study of Genetic Causes of Intrahepatic Cholestasis (Teckman et al., 2020) is a longitudinal study about pediatric cholestatic liver disease. The study included 350 participants ages zero

to 25 with native livers. Overall, 18 participants developed hypertension, and two died, but "there was no difference in participants with or without preceding neonatal cholestasis progressing to transplantation or death during the study, or in experiencing portal hypertension." The authors concluded that, in youth with AATD, "progression to liver transplantation is slow and death is rare, but the risk of complications and severe liver disease progression persists throughout childhood." The authors also note that "A history of neonatal cholestasis is a weak predictor of severe disease" (Teckman et al., 2020). Teckman et al. (2023) then focused on neonatal cholestasis in children with AATD, using two subgroups: participants with neonatal cholestasis (n=46), and all participants who progressed to livre transplant (n=119). The authors reported "an association of neonatal gamma-glutamyl transpeptidase elevation to more severe disease, and a higher rate of neonatal cholestasis progression to portal hypertension than previously reported (41%) occurring at median age of 5 months." All participants, regardless of neonatal cholestasis, were at risk of progression to liver transplant, but of the participants that progressed to liver transplant, those with neonatal cholestasis were significantly younger at transplant than those without neonatal cholestasis. The authors further concluded that "patients with AATD and neonatal cholestasis are at risk of early progression to severe liver disease, but the risk of severe disease extends throughout childhood" (Teckman et al., 2023).

Lin et al. (2019) completed a systematic literature review of AATD deficiency-associated liver disease in children and put together diagnostic testing recommendations. The literature review revealed that "liver disease occurs in 10% of children, manifested by cholestasis, pruritus, poor feeding, hepatomegaly, and splenomegaly, but the presentation is highly variable." The authors recommend genetic testing for AATD in children with unexplained liver disease or suspected AATD, noting "consensus guidelines recommend diagnostic testing for all patients who have unexplained liver disease" (level of evidence for recommendations: A, based on consistent and good quality patient-oriented evidence) (Lin et al., 2019).

VI. Guidelines and Recommendations

American Thoracic Society/European Respiratory Society (ATS/ERS)

The ATS/ERS released joint guidelines on the "Diagnosis and Management of Individuals with Alpha-1 Antitrypsin Deficiency." These recommendations are as follows (ATS/ERS, 2003):

Policy Guidelines

Recommendations were classified as follows:

Type A: Genetic testing is recommended

Type B: Genetic testing should be discussed and could be accepted or declined

Type C: Genetic testing is not recommended, i.e., should not be encouraged

Type D: Recommend against genetic testing, i.e., should be discouraged

Type A recommendations for diagnostic testing in the following situations:

1. Symptomatic adults with emphysema, COPD or asthma with airflow obstruction that is not completely reversible with aggressive treatment with bronchodilators
2. Individuals with unexplained liver disease, including neonates, children, and adults, particularly the elderly
3. Asymptomatic individuals with persistent obstruction on pulmonary function tests with identifiable risk factors (e.g., cigarette smoking, occupational exposure)
4. Adults with necrotizing panniculitis
5. Siblings of an individual with known alpha-1 antitrypsin (AAT) deficiency

Type B recommendations for diagnostic testing in the following situations:

1. Adults with bronchiectasis without evidence etiology
2. Adolescents with persistent airflow obstruction
3. Asymptomatic individuals with persistent airflow obstruction and no risk factors
4. Adults with C-ANCA positive (anti-proteinase 3-positive) vasculitis
5. Individuals with a family history of COPD or liver disease not known to be attributed to AAT deficiency
6. Distant relatives of an individual who is homozygous for AAT deficiency
7. Offspring or parents of an individual with homozygous AAT deficiency
8. Siblings, offspring, parents or distant relatives of an individual who is heterozygous for AAT deficiency
9. Individuals at high risk of having AAT deficiency-related diseases
10. Individuals who are not at risk themselves of having AAT deficiency but who are partners of individuals who are homozygous or heterozygous for AAT deficiency

Type C recommendations for diagnostic testing in the following situations

1. Adults with asthma in whom airflow obstruction is completely reversible
2. Predispositional testing
3. Population screening of smokers with normal spirometry

Type D recommendations for diagnostic testing in the following situations:

1. Predispositional fetal testing
2. Population screening of either neonates, adolescents or adults*

* Population screening is not recommended currently. However, a possible exception (type B recommendation) may apply in countries satisfying all three of the following conditions: (1) the prevalence of AAT deficiency is high (about 1/1,500, or more); (2) smoking is prevalent; and (3) adequate counseling services are available.

The following features should prompt suspicion by physicians that their patient may be more likely to have AAT deficiency:

Clinical Factors

- Early-onset emphysema (age of 45 years or less)
- Emphysema in the absence of a recognized risk factor (smoking, occupational dust exposure, etc.)
- Emphysema with prominent basilar hyperlucency
- Otherwise unexplained liver disease
- Necrotizing panniculitis
- Anti-proteinase three-positive vasculitis (C-ANCA [anti-neutrophil cytoplasmic antibody]-positive vasculitis)
- Bronchiectasis without evident etiology

The ATS/ERS also made statements on serum testing for AATD. “Serum phenotyping by isoelectric focusing performed by a reliable laboratory is the accepted “gold standard” for diagnosing AAT deficiency”. The guidelines recommend “that all subjects with COPD or asthma characterized by incompletely reversible airflow obstruction should be tested once for quantitative AAT determination. Also, individuals with evidence of cirrhosis of the liver with no known etiology should be tested for candidate phenotypes (e.g., PI*ZZ, PI*MZ, PI*Mmalton) and testing should be considered in individuals with the syndrome of Wegener's granulomatosis (antiproteinase-3 vasculitis)” (ATS/ERS, 2003).

The ATS/ERS states that “Regarding hepatic presentations of AAT deficiency later in childhood, during adolescence, and in adulthood, reports indicate that patients may present with hepatosplenomegaly, ascites, upper gastrointestinal bleeding resulting from esophageal varices, chronic hepatitis, cirrhosis, or hepatic failure. The presentation of AAT deficiency may appear similar to other chronic liver diseases, including autoimmune hepatitis, drug-induced hepatitis, chronic viral hepatitis, and Wilson's disease. The weight of these reports suggests that patients with any unexplained features of chronic liver disease should be evaluated for AAT deficiency” (ATS/ERS, 2003).

American College of Gastroenterology (ACG)

The ACG notes that "defective production of the alpha-1 anti-trypsin protein may result in both panacinar emphysema and chronic obstructive pulmonary disease, as well as progressive liver disease, liver cirrhosis, and hepatocellular carcinoma" and recommends the following for AATD:

- "Patients with persistently elevated aspartate aminotransferase (AST) or alanine aminotransferase (ALT) should undergo screening for alpha-1 antitrypsin (A1AT) deficiency with alpha-1 anti-trypsin phenotype."
- Evaluation of hepatocellular injury (defined by the guidelines as "disproportionate elevation of AST and ALT levels compared with alkaline phosphatase levels") includes testing for A1AT deficiency" (Kwo et al., 2017).

National Organization for Rare Disorders

NORD publishes information on multiple rare disorders that may otherwise lack national guidelines and recommendations. One such disorder is neonatal cholestasis, which refers to impaired flow of bile from the liver cells into the intestine of a newborn. While neonatal cholestasis may be caused by viruses, metabolic disease, or rare disease that affect or impair the function of the liver, it can also be caused by genetic disorders. "The incidence of neonatal cholestasis is estimated to be ~1:2500 live births worldwide, and 25% to 50% are now known to be associated with changes (variants or mutations) in specific genes" (NORD, 2024b). These genetic disorders include "alpha-1-antitrypsin deficiency, PFIC and Alagille syndrome" (NORD, 2024b).

World Health Organization (WHO)

The WHO released a memorandum on AATD regarding AATD's association with conditions such as COPD and asthma. Their recommendation is as follows: "It is therefore recommended that all patients with COPD and adults and adolescents with asthma be screened once for AAT deficiency using a quantitative test. Those with abnormal results on screening should undergo PI typing" (WHO, 1997).

European Respiratory Society (ERS)

The ERS (Miravitlles et al., 2017) published updated guidelines which recommend:

- "The quantitative determination of AAT levels in blood is a crucial first test to identify AATD. Quantitative deficiency must be supported by qualitative tests to identify the genetic mutation(s) causing AATD."
- "Protein phenotyping by isoelectric focusing identifies variants where AAT is present in the sample including the rarer variants F, I and P *etc*."

- "Genotyping allows a rapid and precise identification/exclusion of S and Z alleles and other variants, where specific primers are available."
- "Gene sequencing remains necessary for those cases where a null variant or a deficient variant other than Z or S is suspected."
- "Testing of relatives of identified patients should be considered after appropriate counselling.
- "Genetic testing should be carried out only after informed consent is given and in accordance with the relevant guidelines and legislation."

The ERS has also noted that "there is no evidence to support efficacy of AAT augmentation therapy in PiSZ, PiMZ or current smokers of any protein phenotype" (Miravitlles et al., 2017).

Alpha-1 Foundation

The Alpha-1 Foundation (Sandhaus et al., 2016) sponsored a medical and scientific advisory committee of experts to examine all relevant, recent literature to provide concise recommendations for the diagnosis and management of individuals with AATD.

- "For family testing after a proband is identified, AAT level testing alone is not recommended because it does not fully characterize disease risk from AATD."
- "For diagnostic testing of symptomatic individuals, they recommend genotyping for at least the S and Z alleles. Advanced or confirmatory testing should include Pi-typing, AAT level testing, and/or expanded genotyping."
- "All patients with COPD, unexplained chronic liver disease, necrotizing panniculitis, granulomatosis with polyangiitis, or unexplained bronchiectasis should be tested for AATD."
- "Parents, siblings, and children, as well as extended family of individuals identified with an abnormal gene for AAT, should be provided genetic counseling and offered testing for AATD (see guideline document for special considerations about testing minors)."

The Foundation also noted the following (these statements were not labeled recommendations):

- "For primary diagnosis of AATD the most sensitive and specific method of diagnosis is direct identification of the Z allele by genotyping. By also including the S allele, genotyping for the S and Z allele is greater than 99% specific and sensitive. "

- "AAT levels are insufficient to identify at risk individuals because the AAT level changes with inflammation, pregnancy, and in children. "
- "The range of serum AAT levels among individuals with specific genotypes is sufficiently broad that there is overlap between different genotypes. Thus, serum AAT levels cannot discriminate between different genotypes and additional AAT testing is needed" (Sandhaus et al., 2016).

Global Initiative for Chronic Obstructive Lung Disease (GOLD)

The GOLD guideline notes that "The most relevant (albeit rare) genetic risk factor for COPD identified to date are mutations in *SERPINA1* gene leading to α-1 antitrypsin deficiency. A number of other genetic variables have also been associated with reduced lung function and risk of COPD, but their individual effect size is small."(GOLD, 2024).

Canadian Thoracic Society (CTS)

The CTS released guidelines on genetic testing for AATD, which are as follows:

- "We suggest targeted testing for A1AT deficiency be considered in individuals with COPD diagnosed before 65 years of age or with a smoking history of <20 pack years. (Grade of recommendation: 2C)"
- "We suggest targeted testing for A1AT deficiency not be undertaken in individuals with bronchiectasis or asthma. (Grade of recommendation: 2C)" (Marciniuk et al., 2012)

National Institute Health and Care Excellence (NICE)

NICE published a guideline discussing chronic obstructive pulmonary disease (COPD) in 2019. In it, they note that measurement of serum alpha-1 antitrypsin has a role in identifying deficiencies if the condition is "early onset, [of] minimal smoking history, or [has] family history" (NICE, 2019).

Government of British Columbia

The British Columbia guidelines on the diagnosis and management of COPD state that, "testing for A1AT deficiency is expensive, low yield, often duplicated and may not alter management in a meaningful way. Therefore, refer patients with high pre-test probability to a specialist" (BC Guidelines, 2024).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations

(LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: http://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration

On November 17, 2017, the FDA approved Grifols' (Grifols, 2017a) *SERPINA1* Variant Detection System as a qualitative in vitro molecular diagnostic system used to detect variants in *SERPINA1* gene in genomic DNA isolated from human specimens. On November 7, 2019, the FDA approved Grifols' AlphaID™, a cheek swab that can screen patients with COPD for alpha-1 antitrypsin deficiency. It "utilizes an FDA-approved genotyping assay to screen for the 14 most prevalently reported genetic mutations associated with Alpha-1, including the S, Z, F, I alleles, as well as rare and null alleles, helping detect patients who are at risk for this treatable condition" (Grifols, 2019).

On April 6, 2017 the FDA approved (FDA, 2017) the 23andMe PGS Genetic Health Risk Report for Alpha-1 Antitrypsin Deficiency (AATD) which determines if a person has variants associated with a higher risk of developing AATD-associated lung or liver disease. This report is based on a qualitative genetic test for single nucleotide polymorphism detection of the PI*Z (rs28929474) and PI*S (rs17580) variants in the *SERPINA1* gene by using the 23andMe Personal Genome Service.

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81332	SERPINA1 (serpin peptidase inhibitor, clade A, alpha-1 antiproteinase, antitrypsin, member 1) (eg, alpha-1-antitrypsin deficiency), gene analysis, common variants (eg, *S and *Z)
81479	Unlisted molecular pathology procedure
82103	Alpha-1-antitrypsin; total
82104	Alpha-1-antitrypsin; phenotype

82542	Column chromatography, includes mass spectrometry, if performed (eg, HPLC, LC, LC/MS, LC/MS-MS, GC, GC/MS-MS, GC/MS, HPLC/MS), non-drug analyte(s) not elsewhere specified, qualitative or quantitative, each specimen
83789	Mass spectrometry and tandem mass spectrometry (eg, MS, MS/MS, MALDI, MS-TOF, QTOF), non-drug analyte(s) not elsewhere specified, qualitative or quantitative, each specimen

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Initial Policy Effective Date:01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Colorectal cancer (CRC) involves the accumulation of genetic and epigenetic modifications within pathways that regulate proliferation, apoptosis, and angiogenesis resulting in carcinoma of the colon and rectum (Bardhan & Liu, 2013). Tumors originate in adenomas or flat dysplasia and evolve into different morphologic patterns with invasion and expansion (Compton, 2023a).

Monoclonal antibodies that bind the epidermal growth factor receptor (*EGFR*), such as cetuximab, and block its activation have led to significant clinical benefits for metastatic colorectal cancer (mCRC) patients (De Roock et al., 2010). Mutations in downstream effectors of the *EGFR* pathway have been associated with resistance to *EGFR* antibody chemotherapies (Allegra et al., 2009; Compton, 2023b; Sepulveda et al., 2017).

For guidance on microsatellite instability or tumor mutational burden testing in colorectal cancer, please refer to AHS-M2178- Microsatellite Instability and Tumor Mutational Burden Testing.

AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For all individuals with metastatic colorectal cancer, *KRAS, NRAS*, and *BRAF* mutation genotyping of the primary or the metastatic tumor **MEETS COVERAGE CRITERIA**.

2) For individuals with metastatic colorectal cancer for whom tumor tissue testing did not identify a mutation in *KRAS, NRAS*, **or** *BRAF*, HER2 amplification testing **MEETS COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

3) For all other situations not described above, testing for *KRAS, NRAS*, and *BRAF* mutations **DOES NOT MEET COVERAGE CRITERIA**.

4) For all other situations and/or mutations not described above, genotyping of the colorectal cancer tumor **DOES NOT MEET COVERAGE CRITERIA.**

5) To determine the prognosis of stage II colon cancer following surgery, gene expression profiling **DOES NOT MEET COVERAGE CRITERIA.**

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162-Reimbursement Policy.

IV. Table of Terminology

Term	Definition
ASCO	American Society of Clinical Oncology
ACS	American Cancer Society
BRAF	*B-Raf proto-oncogene*

CEA	Carcinoembryonic antigen
CLIA-1988	Clinical Laboratory Improvement Amendments of 1988
CNA	Copy number alteration
CRC	Colorectal cancer
ctDNA	Circulating tumor deoxyribonucleic acid
DFS	Disease free survival
dMMR	Deficient MMR
EGAPP	Evaluation of Genomic Applications in Practice and Prevention
EGFR	*Epidermal growth factor receptor*
ERBB2	*Erb-B2 Receptor Tyrosine Kinase 2*
ESCP	European Society of Coloproctology
ESMO	European Society for Medical Oncology
EWG	European Working Group
1F1CDx	Foundation One Cdx
FDA	Food and Drug Administration
FFPE	Formalin-fixed paraffin-embedded
FISH	Fluorescence in-situ hybridization
FOLFOX4	5-fluorouracil, leucovorin, and oxaliplatin
HER2	Human epidermal growth factor receptor 2
HR	Hazard ratios
ICI	Immune checkpoint inhibition
IHC	Immunohistochemistry
KRAS	*Kirsten rat sarcoma*
LDTs	Laboratory-developed tests
mAbs	Monoclonal antibodies
mCRC	Metastatic colorectal cancer
MMR	Mismatch repair
MMR-P	Mismatch repair proficient
MPFS	Median progression free survival
MSI	Microsatellite instability
NCCN	National Comprehensive Cancer Network
NGS	Next-generation sequencing
NICE	National Institute for Health and Care Excellence
NRAS	*Neuroblastoma rat sarcoma virus*
NSABP	National Surgical Adjuvant Breast and Bowel Project
OR	Odds ratio
ORR	Objective response rate
OS	Overall survival

PCO	Provisional clinical opinion
PCR	Polymerase chain reaction
PFS	Progression-free survival rate
PIK3CA	*Phosphatidylinositol-4,5-Bisphosphate 3-Kinase Catalytic Subunit Alpha*
PL	Plasma
PTEN	*Phosphatase and TENsin homolog deleted on chromosome 10*
QALY	Quality-adjusted life year
RAF	*Rapidly accelerated fibrosarcoma*
RAS	*Rat sarcoma virus*
RS	Recurrence score
T	Tissue
TMB	Tumor mutational burden
WT	Wild type

V. Scientific Background

Colorectal cancer (CRC) is the third leading cause of cancer-related deaths in the United States following lung cancer. The American Cancer Society (ACS) estimates 106,180 new cases of colon cancer and 44,850 new cases of rectal cancer for 2022. Overall, there is about a four percent lifetime risk of developing colorectal cancer (ACS, 2023). Metastatic colorectal cancer (mCRC), which occurs in 22% of patients with colorectal cancer, has a significantly poorer prognosis than colorectal cancer that hasn't metastasized. The five-year survival is 14% in patients with distant metastases from CRC, as compared to 71% for all CRC patients (El-Deiry et al., 2015; Wang et al., 2020).

Approximately one-quarter of the patients with colon cancer present with stage II disease (Kopetz, 2008). The current National Comprehensive Cancer Network (NCCN) guidelines include adjuvant chemotherapy as a treatment option in this setting, particularly for high-risk stage II patients, as determined by clinical and pathological parameters (NCCN, 2024). Although some of the routinely used parameters for estimating recurrence risk, such as T-stage and mismatch repair (MMR) status, are well established, they may not be reliable predictors of recurrence risk in this population (Gray et al., 2011; Gunderson et al., 2010; Harris et al., 2008; Ribic et al., 2003; Sargent et al., 2010; Venook et al., 2013).

Certain mutations may affect treatment of CRC. For example, the activation of the epidermal growth factor receptor (*EGFR*) signaling cascade is associated with colon tumorigenesis (Therkildsen et al., 2014); therefore, medications such as cetuximab or panitumumab that target the *EGFR* pathway may be used in treatment of CRC.

However, activating mutations in the *KRAS* oncogene will cause anti-*EGFR* resistance since these mutations can result in a constitutively active pathway, even with anti-*EGFR* treatment (Clark & Sanoff, 2024). Consequently, tumors with mutated *KRAS* are unresponsive to anti-*EGFR* therapy. As a result, testing for mutational status as a negative predictive factor for anti-*EGFR* therapy has become part of routine pathological evaluation for CRC. Other mutations in the RAS oncogene (primarily *NRAS*) may also lead to the same phenotype (Frucht & Lucas, 2023). Another gene that may be overexpressed within the *EGFR* pathway is *HER2* (human epidermal growth factor receptor 2). This gene plays a role in activating signal transduction pathways controlling epithelial cell growth. Although *HER2* is more traditionally known as a breast cancer-associated gene, up to five percent of colorectal cancer cases are found to overexpress *HER2* (Clark & Sanoff, 2024).

Another component of the RAS signaling pathway, *BRAF*, has also been found to affect anti-*EGFR* treatment. *BRAF* V600E mutations may also confer a lack of response to anti-*EGFR* treatment even when paired with a wild-type RAS oncogene. Mutations in this region occur in less than 10% of sporadic CRCs, and the mutation at position 600 is the primary polymorphism found in CRC. Non-V600 *BRAF* mutations are rarer (composing about 2.2% of patients with metastatic CRC) and confer a generally better prognosis than their V600 mutated counterparts; a study found non-V600 genotypes to lead to better median overall survival and fewer high-grade tumors (Jones et al., 2017).

Proprietary Testing

Gene expression assays have been commercially produced to predict prognosis of colon cancer. The 12-gene Oncotype DX Colon Cancer Assay (Genomic Health, Inc., Redwood City, CA) is a reverse transcriptase polymerase chain reaction–based assay that provides a Recurrence Score (RS) result (O'Connell et al., 2010). This test assesses the activity level of 12 genes (7 cancer-related genes, 5 reference genes), and this gene expression is scored from 1-100. This test is intended for resected stage II, MMR-P or stage III A/B colon cancer. Low risk is a score under 30, moderate risk is 31-40, and higher risk is ≥41 (Oncotype, 2024a, 2024b).

The ColDx assay (Almac Diagnostics, Craigavon, Northern Ireland) uses microarray technology for assessing the gene expression of 634 genes to stratify patients into low and high recurrence risk groups (Almac Group, 2024). ColDx identified 73 high risk patients with a hazard ratio of 2.62 during cross validation. In an independent validation, the assay identified high-risk patients with a hazard ratio of 2.53 (Kennedy et al., 2011).

ColoPrint (Agendia, Amsterdam, The Netherlands) is a gene expression classifier that uses whole-genome expression data of 18 key genes to distinguish patients with low

versus high risk of disease relapse. In a study using 206 fresh frozen tumor tissue samples from 188 patients with stage I through IV CRC, ColoPrint classified "60% of patients as low risk and 40% as high risk," and was "superior to American Society of Clinical Oncology criteria in assessing the risk of cancer recurrence without prescreening for microsatellite instability" (Salazar et al., 2011). In a study of 416 stage II colon cancer patients, "ColoPrint identified 63% of patients as low risk with a 5-year ROR of 10%, whereas high-risk patients (37%) had a 5-year ROR of 21%." Alternatively, the 2013 NCCN clinical risk factors could not distinguish low and high risk patients (Kopetz et al., 2015).

Analytical Validity

Cenaj et al. (2019) evaluated the correlation between "*ERBB2* amplification by next-generation sequencing (NGS) with HER2 overexpression by immunohistochemistry." NGS was performed on specimens with 20% or more tumor, and 1300 cases of colorectal cancer were included. *ERBB2* amplification was detected in 2% of cases. HER2 amplification was examined in "15 cases with *ERBB2* amplification (six or more copies), 10 with low gain (three to five copies), and 77 copy neutral." *ERBB2* amplification was found to have perfect concordance with HER2 immunochemistry at H-scores of 105 or more. Further, *ERBB2* amplification was found to inversely correlate with RAS/RAF mutations. The authors concluded that "NGS-detected *ERBB2* amplification highly correlates with HER2 overexpression in CRC," which may support authors' original hypothesis that ERBB2 amplification/overexpression may predict response to HER2 inhibitors (Cenaj et al., 2019).

Fan et al. (2021) analyzed the relationship between mismatch repair (MMR) protein, *RAS*, *BRAF,* and *PIK3CA* expression and clinicopathological characteristics in elderly patients with CRC. From 327 patients, the researchers found that "the mutation rates of the *KRAS, NRAS, BRAF* and *PIK3CA* genes in elderly CRC patients were 44.95% (147/327), 2.45% (8/327), 3.36% (11/327) and 2.75% (9/327), respectively." They also identified that "*KRAS* was closely related to tumor morphology ($P = 0.002$) but not to other clinicopathological features ($P > 0.05$), and there were no significant differences between *NRAS* gene mutation and clinicopathological features ($P > 0.05$).
The *BRAF* gene mutation showed a significant difference in pathological type, tumor location, differentiation degree and lymph node metastasis ($P < 0.05$), but was not correlated with sex, tumor size and tumor morphology ($P > 0.05$)" (Fan et al., 2021). This demonstrates the critical nature of mutation analysis for these specific genes to aid in identifying potential therapies that would better patient prognoses especially in such a vulnerable population like the elderly.

Formica et al. (2020) examined tumor tissue (T) mutational analysis in terms of discordance with circulating tumor DNA (ctDNA) obtained by liquid biopsy from plasma (PL) and assessed through real time polymerase chain reaction (PCR). Despite finding concordance for patients with *BRAF* mutations between the tissue and plasma samples, 20% of patients were *RAS* discordant. Mutations identified from ctDNA were able to refine the prognosis determined by tissue samples. "*RAS* wild type in T and mutated in PL had significantly shorter PFS than concordant *RAS* wild type in T and PL: mPFS [median progression free survival] 9.6 vs. 23.3 months, respectively, $p = 0.02$. Patients RAS mutated in T and wild type in PL had longer PFS than concordant RAS mutated in T and PL: 24.4 vs. 7.8 months, respectively, $p = 0.008$." This raises a limitation to using tumor tissue as the mainstay for mutational analysis and considering combining with or replacing tumor tissue genotyping with plasma ctDNA as a measure of prognosis going forward (Formica et al., 2020).

Pinheiro et al. (2022) studied the analytical validity of using ctDNA as a possible strategy to analyze *KRAS* and *NRAS* mutations from patients with metastatic colorectal cancer. The BEAMing Digital PCR (OncoBEAM) and Idylla ctDNA qPCR were compared and the concordance rate was reported. Blood samples from 47 mCRC patients were tested and the overall agreement and concordance rate were noted. "The overall agreement between tumor tissue and ctDNA analyses was 83% and 78.7% using the OncoBEAM and Idylla assays, respectively, with the concordance being 96.2% and 88.5% in naive treatment patients. The overall agreement between OncoBEAM and Idylla ctDNA analyses was 91.7%" (Pinheiro et al., 2022). The authors conclude that Idylla ctDNA qPCR method is a cheaper alternative with equivalent performance in comparison to the OncoBEAM assay. Analysis of ctDNA can be used to detect "RAS mutations in plasma, either at diagnosis or after progression when considering anti-EGFR treatment rechallenge" (Pinheiro et al., 2022).

Clinical Utility and Validity

In a meta-analysis by Xu et al. (2013), a total of 2875 patients were evaluated, with 246 patients having *BRAF* mutations. The objective response rate (ORR) to *EGFR* therapy was 18.4% (40/217) in mutant *BRAF* group and 41.7% (831/1993) in the wild-type *BRAF* group. The overall risk ratio for the ORR of *BRAF* mutations compared to wild-type *BRAF* patients was 0.58. The median progression free survival (hazard ratio 2.98) and overall survival (hazard ratio: 2.85) were significantly shorter of patients with *BRAF* mutations compared to patients with wild-type *BRAF* mutations (Xu et al., 2013).

Douillard et al. (2013) evaluated the effect of panitumumab plus oxaliplatin, fluorouracil, and leucovorin (FOLFOX4) compared to just FOLFOX4 on patients with varying RAS and *BRAF* mutations. A total of 639 patients with metastatic CRC without

mutations in *KRAS* exon 2 had at least one of the following: *KRAS* exon 3 or 4; *NRAS* exon 2, 3, or 4; or *BRAF* exon 15. 228 patients had neither RAS nor *BRAF* mutations, and this group was evaluated to have better survival metrics with panitumumab plus FOLFOX4 than the group with just FOLFOX4 (median of 10.8 months progression-free survival and 28.3 months overall survival for panitumumab group vs 9.2 and 20.9 respectively for the group without). However, 296 patients with either a *RAS* or *BRAF* mutation were treated with panitumumab plus FOLFOX4, and this group's survival metrics were lower than the group only treated with FOLFOX4. The *RAS*/*BRAF* group treated with panitumumab plus FOLFOX4 had a median of only 7.3 months progression-free survival and 15.3 months overall survival vs 8.0 and 18.0 for the 305 patients treated with only FOLFOX4). The authors concluded that additional RAS mutations predicted a lack of response to panitumumab plus FOLFOX4 (Douillard et al., 2013).

Therkildsen et al. (2014) performed a meta-analysis of the clinical impact of anti-*EGFR* treatment on patients with *KRAS*, *NRAS*, and *BRAF* mutations (as well as *PIK3CA* and *PTEN*). A total of 22 studies (2395 participants) were evaluated. Odds ratios for objective response rate (ORR) and hazard ratios (HR) for progression-free survival rate (PFS) and overall survival (OS) were calculated. Mutations in *KRAS* exons 3 and 4 and *BRAF* predicted poor ORR (0.26 and 0.29 respectively), *KRAS*, *NRAS*, and *BRAF* mutations all led to significantly lower progression-free survival (HR = 2.19, 2.30, and 2.95 respectively) and significantly lower overall survival (HR = 1.78, 1.85, and 2.52 respectively) (Therkildsen et al., 2014).

Rebersek et al. (2019) investigated the impact of molecular biomarkers on survival and response to first line therapy in metastatic colorectal cancer patients. The study included 154 patients with 42% harboring *KRAS* mutations and 3% harboring *BRAF* mutations. Median overall survival (OS) was found to be 56.5 months for wild-type *KRAS* patients and 58 months for mutated *KRAS* patients. Median OS for mutated exon 12 patients was 57 months compared to 44 months for mutated exon 13 patients. Wild-type *KRAS* was found to affect the response to first-line systemic therapy, whereas no other parameters were found to affect response (Rebersek et al., 2019).

Sartore-Bianchi et al. (2019) investigated the effect of *HER2* positivity on anti-*EGFR* treatment. A total of 100 patients HER2-positive (of 1485 wild-type *KRAS* exon 2 patients) with metastatic colorectal cancer were included. The authors found that HER2-positive patients had more frequent lung metastases (odds ratio [OR] = 2.04) and higher tumor burden (OR = 1.48). The 79 *HER2*-positive patients given anti-*EGFR* treatment were also found to have poorer clinical outcomes, with lower objective response rate (31.2% compared to 46.9% for all others) and lower progression-free survival (5.7 months vs seven months). The authors concluded that HER2 testing

should be offered because “occurrence of this biomarker is unlikely to be predicted based on main clinicopathological features” (Sartore-Bianchi et al., 2019).

The prognostic benefit was corroborated by Chang et al. (2021), who found that the *BRAF* gene mutation was “associated with cancer thrombosis in blood vessels” and was “negatively correlated with the OS [overall survival] rate of CRC patients” in their patient population (n=410) from Central China. Like Fan et al. (2021), *KRAS* also had the greatest mutation rate at 47.56% in this study, showing more awareness needed for tissue genotyping for mCRC (Chang et al., 2021).

Loree et al. (2021) characterized the clinical prevalence of atypical *KRAS/NRAS* mutations in metastatic colorectal cancer. The authors evaluated tissue and DNA samples from 9,485 patients to characterize atypical *RAS* variants using an in-vitro cell-based assay, studying the signaling changes across mutations. According to the results, "*KRAS* exon 2, extended *RAS*, and atypical *RAS* mutations were noted in 37.8%, 9.5%, and 1.2% of patients, respectively. Among atypical variants, *KRAS* L19F, Q22K, and D33E occurred at prevalence ≥0.1%, whereas no *NRAS* codon 117/146 and only one *NRAS* codon 59 mutation was noted. Atypical *RAS* mutations had worse overall survival than *RAS/BRAF* wild-type mCRC.” Of the 57 atypical *RAS* variants, 18 (31.6%) had signaling below wild-type, 23 (40.4%) had signaling between wild-type and activating control, and 16 (28.1%) were hyperactive beyond the activating control. The authors concluded that "*KRAS* L19F, Q22K, D33E, and T50I are more prevalent than many guideline-included RAS variants and functionally relevant” (Loree et al., 2021).

Benavides et al. (2022) studied how effective liquid biopsy-tailored assays were in identifying guideline-recommended biomarkers, including *RAS* and *BRAF*, in comparison to standard of care tissue genotyping for patients newly diagnosed with mCRC. To quantify the effectivity of liquid biopsy assays for biomarkers, the researchers utilized the Guardant360 for comprehensive ctDNA analysis, and OncoBEAM for targeted RAS and BRAF analysis. Among the 155 patients included in this prospective study, physician discretion standard of care tissue genotyping identified guideline-recommended biomarkers in 52.9% of patients, in comparison to the 56.8% from the comprehensive Guardant360 ctDNA analysis and 44.5% from targeted ctDNA analysis by OncoBEAM. An additional 19.5% more samples were included in the ctDNA assays “by rescuing those without tissue results either due to tissue insufficiency, test failure, or false negatives.” The complete processing of ctDNA assays was faster (10 days versus 27 days on median) and maintained accuracy even 10 days after sample collection (52.0% vs 10.2%). This could allow inclusion of ctDNA genotyping in the care of patients with mCRC and could enable accelerated personalized treatment regimens for patients with the quick turnaround and comparable results to current practices (Benavides et al., 2022).

Several studies have evaluated the impact of the gene expression profiling on clinical decision making in certain colon cancer subgroups. Brenner et al. (2016) assessed the clinical impact of the 12-gene Colon Cancer Recurrence Score Assay in treatment of T3 mismatch repair proficient (MMR-P) stage II colon cancer. Out of 269 patients, 102 patients had their treatment changed because of the assay's results. The authors concluded that testing significantly impacted adjuvant treatment decisions in clinical practice (Brenner et al., 2016).

Cartwright et al. (2014) performed a web-based survey evaluating the impact of the 12-gene Colon Cancer Recurrence Score Assay in stage II colon cancer patients. The authors surveyed 346 oncologists about their use of the Oncotype DX assay; the survey included questions about courses of treatment before and after using the assay and the stage of cancer their patient had. The authors found that 29% of treatment recommendations were changed for patients receiving Recurrence Score testing (Cartwright et al., 2014). Srivastava et al. (2014) conducted a prospective study assessing the impact of recurrence score results on physician recommendations regarding adjuvant chemotherapy in T3 MMR-P stage II colon cancer patients. A total of 141 patients were eligible for analysis, and the study concluded that treatment recommendation changes were made for 63 (45%) of patients (Srivastava et al., 2014).

Chang et al. (2020) reviewed the "entire database" of the OncoType Colon Recurrence Score test to identify any age-related differences in Recurrence Score (RS) and single-gene results. A total of 20478 Stage II and IIIA/B colon cancer patients were included. RS results were categorized into low, medium, and high risk, and single-gene results were organized by median and interquartile ranges. In total, 72.5% of all patients and 72.6% of patients under 40 years old were found to have a low-risk RS. However, there were no significant differences in either RS or single-gene results among the four age groups (<40, 40-54, 55-64, >65). Young-onset cancer was also not found to differ by gene expression in individual RS genes. Overall, most patients in stages II or III colon cancer were found to have low-risk disease per the OncoType assay (Chang et al., 2020).

Allar et al. (2022) evaluated how the OncoType Colon Recurrence Score influences clinical practice. The study included 105 patients with stage IIa colon cancer and investigated the association between the RS and the decision to offer adjuvant chemotherapy after resection. Fifty-two patients underwent RS testing, seven (13%) of whom received adjuvant chemotherapy. The authors found no significant effect or clear association of RS on the odds of undergoing chemotherapy. The authors conclude that "RS was not associated with the decision to start adjuvant chemotherapy" and suggest that "the RS should not be obtained in patients with stage IIa colon cancer" (Allar et al., 2022).

Chaudhari and Issa (2022) conducted a study to compare the cost-effectiveness of various genomic tests used to prognosticate stage II colorectal cancer patients. The researchers compared a 12-gene assay, 18-gene expression assay, 482-gene signature assay, and Immunoscore assay in a hypothetical cohort to investigate recurrence risk and death. Using a Markov model, the authors found that "the cost of the Immunoscore assay strategy in stage II colorectal cancer patients was estimated to be US $23,564 with a gain of 3.903 quality-adjusted life years (QALYs) as compared with the 12-gene assay strategy at US $24,545 and 3.903 QALYs; the 18-gene assay strategy at US $28,374 and 3.623 QALYs; and the 482-gene signature treatment strategy at US $33,315 with 3.704 QALYs." This, along with further analysis, led to the conclusion that the Immunoscore assay may be the "dominant strategy," in that it may reduce costs associated with treatment in long-term, but for the gene expression signature assays alone, the 12-gene assay may generate more cost savings than the 18-gene expression assay, equivalent to $3900 (Chaudhari & Issa, 2022).

Aoki et al. (2023) studied the validity of NGS-based ctDNA genotyping for *RAS* and *BRAF* V600E mutation assessment to guide therapy for metastatic colorectal cancer. The study included 212 mCRC patients. The authors compared NGS-cased ctDNA genotyping results with the results of validated PCR-based tissue testing, specifically looking at the concordance rate, sensitivity, and specificity. For *RAS,* the concordance rate was 92.5%, the sensitivity was 88.7%, and the specificity was 97.2%. For *BRAF* V600E, the concordance rate was 96.2%, the sensitivity was 88.0%, and the specificity was 97.3%. The authors then investigated efficacy of anti-EGFR and BRAF-targeted therapies based on ctDNA results. The progression-free survival pf anti-EGFT therapy was 12.9 months, and the progression-free survival of BRAF-targeted treatment was 3.7 months. The authors concluded that "ctDNA genotyping effectively detected RAS/BRAF mutations" and "clinical outcomes support ctDNA genotyping for determining the use of anti-EGFR and BRAF-targeted therapies in patients with mCRC" (Aoki et al., 2023).

VI. Guidelines and Recommendations

American Society of Clinical Oncology (ASCO)

The ASCO published an endorsement of the College of American Pathologist Guidelines, recommending:

- "For patients with CRC, being considered for immune checkpoint inhibitor therapy, pathologists should use MMR-immunohistochemistry (IHC) and/or microsatellite instability (MSI) by polymerase chain reaction (PCR) for the detection of DNA MMR defects. Although MMR-IHC or MSI by PCR is preferred, pathologists may use a validated MSI by next-generation sequencing (NGS)

assay for the detection of DNA MMR defects. Note: MSI by NGS assay must be validated against MMR-IHC or MSI by PCR and must show equivalency. (Strong recommendation)."

- "For all cancer patients being considered for immune checkpoint inhibitor therapy based on defective MMR, pathologists should not use tumor mutation burden (TMB) as a surrogate for the detection of DNA MMR defects. If a tumor is identified as TMB-high, pathologists may perform IHC and/or MSI by PCR to determine if high TMB is secondary to MMR deficiency. (Strong recommendation)."

- "For cancer patients being considered for immune checkpoint inhibitor therapy, if a MMR deficiency consistent with Lynch syndrome is identified in the tumor, pathologists should communicate this finding to the treating physician. (Strong recommendation)" (Vikas et al., 2023).

American Society for Clinical Pathology, College of American Pathologists, Association for Molecular Pathology, and the American Society of Clinical Oncology

These joint guidelines focus on "Molecular Biomarkers for the Evaluation of Colorectal Cancer." They list the following recommendations for *KRAS*, *NRAS*, and *BRAF* for CRC:

- "Patients with CRC considered for anti-*EGFR* therapy must receive RAS mutational testing. Mutational analysis should include *KRAS* and *NRAS* codons 12, 13 of exon 2; 59, 61 of exon 3; and 117 and 146 of exon 4 (expanded or extended RAS)."
- "*BRAF* p.V600 (*BRAF* c. 1799 [p.V600]) mutational analysis should be performed in CRC tissue in patients with CRC for prognostic stratification."
- "There is insufficient evidence to recommend *BRAF* c.1799 p.V600 mutational status as a predictive molecular biomarker for response to anti-*EGFR* inhibitors" (Sepulveda et al., 2017).

The joint guidelines state that further research is required to study the clinical validity and utility of gene expression profiling assays in colon cancer patients (Sepulveda et al., 2017).

National Comprehensive Cancer Network (NCCN)

The guidelines version 1.2024 recommend that "all patients with metastatic colorectal cancer should have tumor genotyped for *RAS* (*KRAS* and *NRAS*) and *BRAF* mutations individually or as part of a next-generation sequencing (NGS) panel (preferred). Patients with any known *KRAS* mutation (exons 2, 3, and 4) or *NRAS* mutation (exons 2, 3, and 4) should not be treated with either cetuximab or panitumumab, unless given as

part of a regimen targeting a *KRAS* G12C mutation. *BRAF* V600E mutation makes response to panitumumab or cetuximab highly unlikely unless given with a BRAF inhibitor."

The NCCN guidelines state that testing for *KRAS*, *NRAS* and *BRAF* mutations should be performed only in laboratories that are CLIA-1988 certified as qualified to perform "high complexity clinical laboratory (molecular pathology) testing." Testing can be performed on formalin fixed paraffin embedded tissue (preferred) or blood-based assay.

The NCCN further states that "testing can be performed on the primary CRCs and/or the metastasis, as literature has shown that the *KRAS, NRAS*, and *BRAF* mutations are similar in both specimen types."

BRAF genotyping of tumor tissue is recommended at stage IV disease. Allele-specific polymerase-chain reaction (PCR), NGS, or immunohistochemistry (IHC) may be used to determine *BRAF* status.

The NCCN notes that *HER2* may be overexpressed in *RAS*/*BRAF* wild-type tumors despite being rarely amplified/overexpressed in CRC (~3% overall). HER2-targeted therapies are now recommended in patients with tumors that are *RAS/BRAF* wild-type and with HER2 overexpression. Therefore, the NCCN now recommends testing for HER2 amplifications in patients with metastatic CRC. However, *HER2* testing is not indicated in patients with known *KRAS*/*NRAS* or *BRAF* mutations (NCCN, 2024).

Routine *EGFR* testing is not recommended (NCCN, 2024).

Overall, in patients with suspected or proven mCRC, the NCCN recommends "molecular testing, including: *RAS* and *BRAF* mutations; HER2 amplifications; MMR or MSI status (if not previously done). Testing should be conducted as part of broad molecular profiling, which would identify rare and actionable mutations and fusions such as *POLE/POLD1, RET,* and *NTRK*." (NCCN, 2024).

Regarding the OncoType DX colon cancer assay, the NCCN remarks that clinical validation in patients with stages II or III cancer from the QUASAR and NSABP clinical trials shows that "recurrence scores are prognostic for recurrence, DFS [disease free survival], and OS [overall survival] in stage II and stage III colon cancer but are not predictive of benefit to adjuvant therapy." ColoPrint, an 18-gene classifier for recurrence risk, was also found to independently predict recurrence risk and is currently being validated to predict 3-year relapse rates in patients with stage II colon cancer in a prospective trial. Similarly, ColDx, a microarray based multigene assay, was found to independently predict recurrence risk. However, despite these tests' ability to

further inform risk of recurrence, the panel questions the value added. The panel also noted that "evidence of predictive value in terms of the potential benefit of chemotherapy is lacking" and that "there are insufficient data to recommend the use of multigene assays, Immunoscore, or post-surgical ctDNA to estimate risk of recurrence or determine adjuvant therapy" (NCCN, 2024).

European Society for Medical Oncology (ESMO)

In its 2023 guidelines, ESMO recommends the following for mCRC genetic testing:

- "Determining the *RAS* mutational testing on a tumour biopsy [I, A] (or through a liquid biopsy in case no tumour sample is available [II, B]) is mandatory to guide the best treatment decision.
- Testing for mismatch repair (MMR) status and *KRAS, NRAS* exon 2, 3, and 4 as well as *BRAF* mutations is recommended in all patients at the time of mCRC diagnosis [I, A]
- Identification of human epidermal growth factor receptor (HER2) amplification by immunohistochemistry (IHC) or FISH [fluorescence in-situ hybridization] is recommended in *RAS* wild-type (wt) patients to detect those who may benefit from HER2 blockade [III, B]
- *RAS* testing is mandatory before treatment with anti-EGFR mAbs and can be carried out on either the primary tumour or other metastatic sites [III, A]
- *BRAF* mutation status should be assessed simultaneously with the evaluation of *RAS*, for prognostic assessment [I, B] and for the option of treatment with cetuximab-encorafenib [I, A].
- dMMR [deficient mismatch repair]/MSI testing in mCRC can assist in genetic counselling for Lynch syndrome [II, B].
- dMMR/MSI status is also recommended as the initial molecular work-up in metastatic disease for its predictive value for the use of ICIs [immune checkpoint inhibition] [I, A]" (Cervantes et al., 2023).

With regards to localized colon cancer, ESMO states that "besides MSI status, other genetic markers, e.g. *RAS* and *BRAF* mutations are not recommended for the routine assessment of risk of recurrence in non-metastatic patients, based on their lack of utility in the adjuvant decision-making process" (Argilés et al., 2020).

In their newly released guidelines, ESMO does not provide recommendations for using gene expression profiling assays for prognosticating patients with stage II colon cancer (Cervantes et al., 2023).

Choosing Wisely Canada

Choosing Wisely Canada lists "eleven tests and treatments to question" in their oncology recommendations. In this list, they recommend: "Don't perform routine colonoscopic surveillance every year in patients following their colon cancer surgery; instead, frequency should be based on the findings of the prior colonoscopy and corresponding guidelines" (Choosing Wisely Canada, 2023).

Research Committee and the Guidelines Committee of the European Society of Coloproctology (ESCP)

This systematic review was performed by the committee to assess the consensus levels "in guidelines from member countries of the European Society of Coloproctology, with supporting evidence." This review focuses on follow-up strategies for patients "after treatment with curative intent of nonmetastatic colorectal cancer" (Bastiaenen et al., 2019).

In this review, the committee concluded that "laboratory tests other than CEA [carcinoembryonic antigen] should not be part of follow-up," although it noted that only eight of 21 guidelines reviewed addressed this topic (Bastiaenen et al., 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Cetuximab and panitumumab have FDA marketing approval for treatment of metastatic colorectal cancer in the refractory disease setting, and ongoing studies are investigating the use of these *EGFR* inhibitors as monotherapy and as part of combination therapy in first, second, and subsequent lines of therapy.

On May 23, 2014, the FDA approved therascreen *KRAS* RGQ PCR Kit is a real-time qualitative PCR assay used on the Rotor-Gene Q MDx instrument for the detection of seven somatic mutations in the human *KRAS* oncogene, using DNA extracted from formalin-fixed paraffin-embedded (FFPE), colorectal cancer (CRC) tissue. The therascreen *KRAS* RGQ PCR Kit is intended to aid in the identification of CRC patients

for treatment with Erbitux (cetuximab) and Vectibix (panitumumab) based on a *KRAS* no mutation detected test result (FDA, 2014).

On May 7, 2015, the FDA approved cobas *KRAS* Mutation Test, for use with the cobas® 4800 System. Cobas is a real-time PCR test for the detection of seven somatic mutations in codons 12 and 13 of the *KRAS* gene in DNA derived from formalin-fixed paraffin-embedded human colorectal cancer (CRC) tumor tissue. The test is intended to be used as an aid in the identification of CRC patients for whom treatment with Erbitux (cetuximab) or with Vectibix (panitumumab) may be indicated based on a no mutation detected result (FDA, 2015).

On June 29, 2017, the FDA approved PraxisTM Extended RAS Panel as a qualitative in vitro diagnostic test using targeted high throughput parallel sequencing for the detection of 56 specific mutations in RAS genes [*KRAS* (exons 2, 3, and 4) and *NRAS* (exons 2, 3, and 4)] in DNA extracted from formalin-fixed, paraffin-embedded (FFPE) colorectal cancer (CRC) tissue samples. The Praxis™ Extended RAS Panel is indicated to aid in the identification of patients with colorectal cancer for treatment with Vectibix (panitumumab) based on a no mutation detected test result. The test is intended to be used on the Illumina MiSeqDx instrument (FDA, 2017).

On November 30, 2017, the FDA approved FoundationOne CDx, which is a next generation sequencing oncology panel. From the FDA website: "FoundationOne CDx™ (F1CDx) is a next generation sequencing based in vitro diagnostic device for detection of substitutions, insertion and deletion alterations (indels) and copy number alterations (CNAs) in 324 genes and select gene rearrangements, as well as genomic signatures including microsatellite instability (MSI) and tumor mutational burden (TMB) using DNA isolated from formalin-fixed paraffin embedded (FFPE) tumor tissue specimens. The test is intended as a companion diagnostic to identify patients who may benefit from treatment with the targeted therapies listed Table 1 in accordance with the approved therapeutic product labeling. Additionally, F1CDx is intended to provide tumor mutation profiling to be used by qualified health care professionals in accordance with professional guidelines in oncology for cancer patients with solid malignant neoplasms. The F1CDx test is a single-site assay performed at Foundation Medicine, Inc" (FDA, 2017).

In 2021, the ONCO/Reveal Dx Lung & Colon Cancer Assay (O/RDx-LCCA) was approved. O/RDx-LCCA is a highly accurate FDA approved IVD assay for the detection of clinically relevant KRAS variants in CRC and EGFR variants in NSCLC and determination of approved therapy. "The device is a qualitative next generation sequencing based in vitro diagnostic test that uses amplicon-based target enrichment technology for detection of single nucleotide variants (SNVs) and deletions in 2 genes

from DNA isolated from formalin-fixed paraffin-embedded (FFPE) non-small cell lung cancer (NSCLC) and colorectal cancer (CRC) tumor tissue specimens. The test is intended as a companion diagnostic to identify patients with NSCLC or CRC who may benefit from treatment with the targeted therapies" (FDA, 2021).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
81275	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; variants in exon 2 (eg, codons 12 and 13)
81276	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; additional variant(s) (eg, codon 61, codon 146)
81311	NRAS (neuroblastoma RAS viral [v-ras] oncogene homolog) (eg, colorectal carcinoma), gene analysis, variants in exon 2 (eg, codons 12 and 13) and exon 3 (eg, codon 61)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81479	Unlisted molecular pathology procedure
81525	Oncology (colon), mRNA, gene expression profiling by real-time RT-PCR of 12 genes (7 content and 5 housekeeping), utilizing formalin-fixed paraffin-embedded tissue, algorithm reported as a recurrence score
81599	Unlisted multianalyte assay with algorithmic analysis
0111U	Oncology (colon cancer), targeted KRAS (codons 12, 13, and 61) and NRAS (codons 12, 13, and 61) gene analysis utilizing formalin-fixed paraffin-embedded tissue Proprietary test: Praxis ™ Extended RAS Panel Lab/Manufacturer: Illumina
0471U	Oncology (colorectal cancer), qualitative real-time PCR of 35 variants of KRAS and NRAS genes (exons 2, 3, 4), formalinfixed paraffin-embedded (FFPE), predictive, identification of detected mutations Proprietary test: CRCdx® RAS Mutation Detection Kit

CPT	Code Description
	Lab/Manufacturera: EntroGen, Inc

Testing for Targeted Therapy of Non-Small-Cell Lung Cancer

Policy Number: AHS – M2030 – Testing for Targeted Therapy of Non-Small-Cell Lung Cancer	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Non-small cell lung cancer (NSCLC) is a heterogeneous group of cancers encompassing any type of epithelial lung cancer, other than small cell lung cancer (SCLC), which arise from the epithelial cells of the lung and include squamous cell carcinoma, large cell carcinoma, and adenocarcinoma (Thomas et al., 2023). Recently, oncogenesis in NSCLC has been associated with mutations in the epidermal growth factor receptor (*EGFR*), or rearrangements of the anaplastic lymphoma kinase (*ALK*) gene or *ROS1* gene (Sequist & Neal, 2024).

For guidance concerning the use of circulating tumor cells in NSCLC, please refer to AHS-G2054-Liquid Biopsy. For guidance concerning Tumor Mutational Burden Testing (TMB) and/or Microsatellite instability (MSI) analysis, please refer to AHS-M2178-Microsatellite Instability and Tumor Mutational Burden Testing policy.

II. Related Policies

Policy Number	Policy Title
AHS-G2054	Liquid Biopsy
AHS-M2029	Molecular Testing for Cutaneous Melanoma
AHS-M2078	Genetic Testing for Germline Mutations of the RET Proto-Oncogene
AHS-M2160	Molecular Testing for Pulmonary Disease
AHS-M2178	Microsatellite Instability and Tumor Mutational Burden Testing

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals with non-small cell lung cancer (NSCLC), molecular profiling to identify established actionable driver mutations (*ALK*, *BRAF*, *EGFR*, *ERBB2(HER2), KRAS*, *METex14* skipping, *NTRK 1/2/3*, *RET*, *ROS1)* **MEETS COVERAGE CRITERIA**.

2) To direct therapy in patients with NSCLC, analysis of PD-L1 expression by immunohistochemistry **MEETS COVERAGE CRITERIA**.

3) As a routine stand-alone assay and as a sole determinant of targeted therapy, *KRAS* molecular testing **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

4) To direct targeted therapy for individuals with NSCLC, analysis for genetic alterations in genes not mentioned above **DOES NOT MEET COVERAGE CRITERIA.**

NOTES:

Note: For 2 or more gene tests being run on the same platform, please refer to AHS-R2162 Reimbursement Policy.

IV. Table of Terminology

Term	Definition
AKT1	*AKT serine/threonine kinase 1 gene*
ALK	*Anaplastic lymphoma kinase*
AMP	Association for Molecular Pathology
ARMS	Amplification Refractory Mutation System
ASCO	American Society of Clinical Oncology
BRAF	*B-Raf proto-oncogene serin/threonine kinase gene*
CAP	College Of American Pathologists
CD74	*Cluster of differentiation 74*
cfDNA	Cell-free deoxyribose nucleic acid
CGP	Comprehensive genomic profiling
CLIA	Clinical Laboratory Improvement Amendment Of 1988

CMS	The Centers for Medicare and Medicaid
CNS	Central nervous system
DCB	Durable clinical benefit
DNA	Deoxyribose nucleic acid
EGFR	*Epidermal Growth Factor Receptor gene*
ERBB2	*Erythroblastic oncogene B*
ERBB2(HER2)	*Erythroblastic oncogene B (Human epidermal growth factor receptor 2)*
ESMO	European Society for Medical Oncology
FBXW7	*F-Box and WD repeat domain containing 7*
FDA	Food and Drug Administration
FIG	fluoroethyl-L-tyrosine (FET) in glioblastoma
FISH	Fluorescence in situ hybridization
HER2	*Human epidermal growth factor receptor 2*
HGF	Hepatocyte growth factor
IASLC	International Association for the Study of Lung Cancer
ICI	Immune checkpoint inhibitor
IHC	Immunohistochemistry
KRAS	*Kirsten rat sarcoma viral oncogene homolog*
LDTs	Laboratory-developed tests
MAPK	Mitogen-activated protein kinase
MET	*MET Proto-Oncogene, Receptor Tyrosine Kinase*
MSI	Microsatellite instability
NCCN	National Comprehensive Cancer Network
NDB	No durable benefit
NGS	Next-generation sequencing
NICE	National Institute for Health and Care Excellence
NOS	Not otherwise specified
NSCLC	Non-small cell lung cancer
NTRK	*Neurotrophic tyrosine receptor kinase gene*
OH	Ontario Health
PBRM1	*Protein Polybromo-1 gene*
PCR	Polymerase chain reaction
PD-L1	Programmed death-ligand 1
PFS	Progression-free survival
PI3K	Phosphatidyl 3-kinase (Pi3K)
PIK3CA	*Phosphatidylinositol-4,5-Bisphosphate 3-Kinase Catalytic Subunit Alpha gene*
PTEN	*Phosphatase and TENsin homolog deleted on chromosome 10 gene*
pts	Patients

RAS	*Rat sarcoma virus gene*
RET	*Rearranged during transfection gene*
ROS1	*ROS proto-oncogene 1*
RT-PCR	Real-time polymerase chain reaction
SCLC	Small-cell lung cancer
SETD2	*SET Domain Containing 2, Histone Lysine Methyltransferase*
STK11	*Serine/threonine kinase 11 gene*
TMB	Tumor mutational burden
TP53	*Tumor protein p53 gene*
TSC2	*TSC complex subunit 2 gene*

V. Scientific Background

Primary lung cancer is one of the most common malignancies. In the United States, approximately 235,000 individuals are diagnosed and more than 130,000 deaths occur annually. Approximately 95% of lung cancers are either non-small cell or small cell, and 80%-85% are non-small cell lung cancers (NSCLC) (ACS, 2024; Midthun, 2022).

Specific molecular treatments for patients based on certain genetic mutations have been developed. Currently, *EGFR-, ALK-, ROS1-, BRAF-*, and *NTRK*-positive cases of NSCLC have FDA-approved targeted therapies (i.e., specific treatments for specific mutations), whereas *HER2-, MET-*, and *RET*-positive cases are treated with off-label therapies. Therapies for other mutations such as *RAS, PTEN, AKT1*, and *PIK3CA* mutations are currently in development. Still, other genetic biomarkers, such as PD-L1 expression and microsatellite instability (MSI) testing may contribute to the management of NSCLC cases (Sequist & Neal, 2024).

EGFR tyrosine kinase mutations are observed in approximately 15% of NSCLC adenocarcinoma cases in the United States and occur more frequently in nonsmokers. The presence of an *EGFR* mutation usually confers a better prognosis and may be treated by EGFR tyrosine kinase inhibitors (TKIs) such as erlotinib (Sequist & Neal, 2024).

ALK tyrosine kinase translocations are present in approximately 4% of NSCLC adenocarcinoma cases in the United States and occur more frequently in nonsmokers and younger patients. In advanced-stage NSCLC, the presence of an ALK translocation may be treated by ALK TKIs such as crizotinib. Other effective TKIs include ceritinib, alectinib, brigatinib, and lorlatinib (Sequist & Neal, 2024). Studies have indicated that treatment with these therapeutic TKIs significantly prolongs progression-free survival.

ROS1 is a receptor tyrosine kinase that acts as a driver oncogene in 1 to 2% of NSCLC cases by a translocation between *ROS1* and other genes such as CD74. *ROS1* translocations are usually associated with younger patients and individuals who have never smoked tobacco. Since the ALK and ROS tyrosine kinases are significantly homologous, the ROS1 tyrosine kinase is treatable by ALK TKIs such as crizotinib (Sequist & Neal, 2024).

HER2 (ERBB2) is an EGFR family receptor tyrosine kinase. Mutations in *HER2* have been detected in approximately 1 to 3% of NSCLC tumors. These mutations are most frequent in exon 20, resulting primarily in adenocarcinomas and these mutations are more prevalent among individuals who have never smoked tobacco (Sequist & Neal, 2024).

BRAF is a downstream signaling mediator of KRAS that activates the mitogen-activated protein kinase (MAPK) pathway. Activating *BRAF* mutations have been observed in 1 to 3% of NSCLC cases and are usually associated with smokers. BRAF inhibition with oral small-molecule TKIs has been used to treat this version of NSCLC (Sequist & Neal, 2024).

MET is a tyrosine kinase receptor for hepatocyte growth factor (HGF). *MET* mutations include *MET* exon 14 skipping, *MET* gene amplification, and *MET* and *EGFR* co-mutations. Tepotinib has shown evidence of promise in treating *MET*-exon 14 skipping cases. Crizotinib, an ALK/ROS inhibitor, has also been used to treat *MET*-exon 14 skipping cases of NSCLC. Other MET-specific therapies are under investigation such as glesatinib and savolitinib. For those with *MET* amplification, capmatinib or crizotinib are suggested lines of treatment, but are not yet approved for this indication by the FDA and continue to be a line of active research (Sequist & Neal, 2024).

The *RET* gene encodes a cell surface tyrosine kinase receptor that may be translocated in adenocarcinomas. These mutations occur more frequently in younger patients and in individuals who have never smoked tobacco. Off-label RET inhibitors, such as alectinib, have been used to treat *RET*-positive cases of NSCLC. In addition, the FDA has approved selpercatinib and pralsetinib for advanced NSCLC in adult patients (Sequist & Neal, 2024).

RAS mutations, in either *KRAS* or *NRAS*, are associated with NSCLC. Activating *KRAS* mutations have been observed in approximately 20 to 25% of lung adenocarcinomas in the United States and are generally associated with smoking. The presence of a *KRAS* mutation has a limited effect on overall survival in patients with early-stage NSCLC. *NRAS* is homologous to *KRAS* and associated with smoking as well; however, *NRAS* mutations comprise only 1% of NSCLC cases. The clinical significance of *NRAS*

mutations is unclear, and no effective targeted therapies exist at this time (Sequist & Neal, 2024).

PIK3CA, AKT1, and *PTEN* are three genes involved in the same pathway. *PIK3CA* encodes the catalytic subunit of phosphatidyl 3-kinase (PI3K), AKT1 acts immediately downstream of PI3K, and phosphatase and tensin homolog (PTEN) inhibits AKT by dephosphorylation. Oncogenic alterations in this pathway include gain-of-function mutations in *PIK3CA* and *AKT1*, and loss of PTEN function. *PIK3CA* mutations may also cause resistance to EGFR TKIs in *EGFR*-mutated NSCLC. Small-molecule inhibitors of PI3K and AKT are being developed, but clinical efficacy of these agents against specific molecular alterations is unknown (Sequist & Neal, 2024).

Other genetic biomarkers include PD-L1 assessment and microsatellite instability (MSI) testing. Programmed death-1 ligand (PD-L1) expression testing via immunohistochemistry (IHC) is used to guide therapy for patients with NSCLC. Tumor cells present PD-L1 to T-cells to inhibit the immune response by downregulating cytokine production and T-cell proliferation, thereby allowing these tumor cells to evade immune system activity. Monoclonal antibody therapy (immune therapy) has been developed to inhibit this pathway and overcome this mechanism of immune system evasion (Teixidó et al., 2018). Tumor PD-L1 protein expression through immunohistochemistry can be ordered to pinpoint first-line treatment options for NSCLC outside of chemotherapy (Sequist & Neal, 2024).

Microsatellites are short tandem repeat sequences located throughout the genome. However, these sequences are subject to instability caused by faulty mismatch repair genes. This has historically been reported in other cancers, such as Lynch syndrome, and has been reported in NSCLC. MSI testing may be used to evaluate NSCLC cases (Fong et al., 1995).

Precision oncology is now the evidence-based standard of care for the management of many advanced NSCLCs. Expert consensus guidelines have defined minimum requirements for routine testing and identification of *EGFR* and *ALK* mutations in advanced lung adenocarcinomas. Targeted use of TKIs based on certain genetic mutations has consistently led to more favorable outcomes compared with traditional cytotoxic agents (Shea et al., 2016). The concept of targeted testing has been approved by the FDA, as package inserts for drugs such as erlotinib specify used for *EGFR* mutations and other drugs such as pembrolizumab have gained approval for specific types of tumors (in this case, high-MSI tumors) (Boyiadzis et al., 2018; FDA, 2004; Lemery et al., 2017). Proprietary tests are available for identification of relevant mutations, including larger genetic panels. FoundationOne's 324-gene panel and

Oncomine's 23-gene panel are both FDA-approved as companion diagnostics for non-small cell lung cancer targeted therapies (FDA, 2023). Recently, Guardant 360 CDx was FDA-approved for use as a companion diagnostic to identify NSCLC patients with *EGFR* mutations who may benefit from Tagrisso (osimertinib) (Guardant, 2021). The company Cobas has a diagnostic approved to identify patients with metastatic NSCLC who might benefit from Tarceva® (erlotinib) based on formalin-fixed tissue preparation to identify EGFR mutation; a Cobas assay was also FDA approved as a companion diagnostic using liquid biopsy and circulating-free tumor DNA (FDA, 2016).

Clinical Utility and Validity

Lin et al. (2017) evaluated the association between EGFR and EGFR-TKI efficacy in stage IV NSCLC patients. In this study, 94 patients were assessed. The authors calculated a 74.5% objective response rate and a 97.9% disease control rate for EGFR-TKI treatment. The authors concluded that EGFR-TKI therapy resulted in survival benefits for EGFR-mutant patients regardless of "gender, smoking history, pathologic type, type of EGFR mutations, brain metastasis and timing of targeted therapy" (Lin et al., 2017).

Li et al. (2017) examined the effect of number of *EGFR* mutations on the efficacy of EGFR TKIs. In this study, 201 patients with *EGFR* mutations were evaluated. These patients were quantitatively separated into "low" and "high" groups based on "amplification refractory mutation system (ARMS) method optimized with competitive blockers and specific mutation quantitation (ARMS+)." The cutoff value was determined by a receiving operating characteristic analysis in a training group and further validated in another group. The investigators found the median progression-free survival (PFS) to be 15 months in the high group compared to two months in the low group. Similar results were reported in the validation group. The authors concluded that the abundance of *EGFR* mutations was significantly associated with objective response to EGFR TKIs. However, they also noted the abundance of *EGFR T790M* mutation may adversely affect PFS rather than objective response rate (Li et al., 2017).

Wang et al. (2017) investigated the effect of *ALK* rearrangements on NSCLC patients. The authors reviewed 15 studies including 4981 patients. The study found that *ALK* positive (ALK+) patients faced better prognoses (hazard ratio 0.81 of ALK negative patients) except in the non-smoking population (hazard ratio 1.65). *ALK*+ patients also experienced a significantly higher objective response rate in pemetrexed-based chemotherapy, but not with EGFR-TKI treatment (Wang et al., 2017).

Gainor et al. (2016) performed a study evaluating the efficacy of PD-L1 blockades on EGFR and ALK positive patients. The study evaluated 58 patients; 28 had an *EGFR* or *ALK* mutation whereas 30 were wild-type. The investigators found only one of the 28

patients (3.6%) with either mutation had an objective response whereas seven of the 30 (23.3%) wild-type patients had an objective response (Gainor et al., 2016).

Planchard et al. (2016) evaluated the efficacy of the FDA-approved combination of daBRAFenib plus trametinib on previously treated BRAF-mutant metastatic NSCLC. The study included 57 patients; 36 of these patients achieved an overall response. However, serious adverse events were reported in 32 of these patients. The authors concluded that this combination may represent a robust therapy with a management safety profile in BRAF-positive NSCLC patients (Planchard et al., 2016).

A 2019 comprehensive study by Singal et al. (2019) examined the electronic health records (EHR) of 4064 individuals with NSCLC from 275 different oncology practices to explore "associations between tumor genomics and patient characteristics with clinical outcomes…." They note that 21.4% of these individuals had a mutation in *EGFR*, *ALK*, or *ROS1*, and that patients with driver mutations who had targeted therapies had significantly improved overall survival times than individuals who did not have targeted therapies (median of 18.6 versus 11.4 months, respectively); moreover, a tumor mutational burden (TMB) of 20 or higher was associated with improved overall survival for patients on PD-L1-targeted therapy than those patients with a TMB less than 20. The authors concluded that they replicated similar associations from previous research "between clinical and genomic characteristics, between driver mutations and response to targeted therapy, and between TMB and response to immunotherapy" (Singal et al., 2019).

Siena et al. (2019) reported integrated data from three clinical trials focusing on entrectinib. Patients had either *ROS1*-driven or *NTRK*-driven cases of NSCLC. Out of 53 patients with *ROS1* mutations, approximately 80% responded to entrectinib. Out of 54 patients with *NTRK* mutations, approximately 60% responded. The authors considered entrectinib to be "tolerable with a manageable safety profile", and concluded that "entrectinib induced clinically meaningful durable responses in [patients] with ROS1+ NSCLC or NTRK+ solid tumors with or without CNS disease" (Siena et al., 2019).

Volckmar et al. (2019) assessed the "feasibility and clinical utility of comprehensive, NGS-based genetic profiling for routine workup of advanced NSCLC." The authors based their study on the first 3000 patients seen in their facility. Of the patients tested, the authors identified 807 patients eligible for "currently approved, EGFR-/BRAF-/ALK- and ROS1-directed therapies," while 218 additional cases with *MET*, *ERBB2* (HER2) and *RET* alterations could "potentially benefit from experimental targeted compounds." Other co-mutations such as *TP53* and *STK11* were also frequently identified, which may be potentially useful predictive and prognostic tools. The authors also noted logistical successes, such as reliability, low dropout rate, fast turnaround times, and minimal

tissue requirements. Overall, the authors concluded that this diagnostic approach demonstrated "practicability in order to support individualized decisions in routine patient care, enrollment in molecularly stratified clinical trials, as well as translational research" (Volckmar et al., 2019).

Signorovitch et al. (2019) aimed to evaluate the "budget impact of increased use of CGP [comprehensive genomic profiling] using a 324-gene panel (FoundationOne) vs non-CGP (represented by a mix of conventional molecular diagnostic testing and smaller NGS hotspot panels) and the number needed to test with CGP to gain 1 life year." The authors developed a decision analytic model to assess the financial impact of increased CGP in advanced non-small cell lung cancer (NSCLC). The study included two million covered lives, of which 532 had advanced NSCLC. Of these patients, 266 underwent molecular diagnostic testing. An increased in CGP among those tested (from 2%-10%) was associated with a $0.02 per member per month budget impact, of which $0.013 "was attributable to costs of prolonged drug treatment and survival and $0.005 to testing cost." Overall, the addition of one life year was met with 12 patients tested. The authors concluded that a 2%-10% increase in CGP use was associated with a "modest budget impact, most of which was attributed to increased use of more effective treatment and prolonged survival" (Signorovitch et al., 2019).

In a prospective study, Peled et al. (2020) investigated the clinical utility of early cell-free deoxyribose nucleic acid (cfDNA) analysis using Guardant 360 CDx in treatment-naive NSCLC patients. Ten patients were studied and the median time from blood draw to receiving the cfDNA results was nine days. Actionable biomarkers were identified in four of the ten patients by both biopsy analysis and cfDNA analysis. Overall, three patients received biomarker-based treatment (one osimertinib, one alectinib, and one crizotinib). The authors concluded that "cfDNA analysis should be ordered by the pulmonologists early in the evaluation of patients with NSCLC, which might complement the tumor biopsy" (Peled et al., 2020).

Al-Ahmadi et al. (2021) studied the overall impact and racial differences of NGS testing in NSCLC patients. The study tested 295 patients with Stage IV NSCLC using the FoundationOne assay and genomic differences were compared by race. "Patients undergoing NGS testing had significantly longer survival of 25.3 months versus those who did not undergo sequencing with a median survival of 14.6 months (P=.002) irrespective if they received targeted therapy or not." In addition, there was no difference in NGS results based on race. However, African American patients had a higher rate of mutations in *PBRM1*, *SETD2*, *TSC2*, and *FBXW7*. Overall, there is no racial difference in NGS utilization and testing does increase survival (Al-Ahmadi et al., 2021).

Boeckx et al. (2020) convened a small study of 46 never-smoking, non-small cell lung cancer (NSCLC) patients to investigate genomic alterations in non-smoking individuals. There are few genomic studies focused primarily on this subgroup of patients with NSCLC who have never smoked. Whole exome and low-coverage whole genome sequencing was performed on tumors and matched germline DNA. Fewer somatic mutations, genomic breakpoints, and a smaller percentage of the genome with chromosomal instability in lung tumors were observed in non-smokers compared to smokers. In addition, *TSC22D1* was noted as a potential driver gene of NSCLC. The frequency of mutation of *TP53*, which is associated with negative long-term outcomes, was lower in those who were never-smokers than in smokers. That said, they found driver genes such as *EGFR* and *ERBB2*, as well as amplifications in *MET* were higher in never-smokers. The authors concluded there was a "more favorable prognosis for never smokers with NSCLC" (Boeckx et al., 2020).

VI. Guidelines and Recommendations

National Comprehensive Cancer Network (NCCN)

In the version 4.2023 update for NSCLC, NCCN states that "Numerous gene alterations have been identified that impact therapy selection. Testing of lung cancer specimens for these alterations is important for identification of potentially efficacious targeted therapies, as well as avoidance of therapies unlikely to provide clinical benefit" (NCCN, 2024). NCCN then expounds on their stance, providing a set of "several methodologies are generally considerations for use" that is delineated below.

- "Next-generation sequencing (NGS) is used in clinical laboratories. Not all types of alterations are detected by individual NGS assays and it is important to be familiar with the types of alterations identifiable in individual assays or combination(s) of assays."
- "It is recommended at this time that when feasible, testing be performed via a broad, panel-based approach, most typically performed by next generation sequencing (NGS). For patients who, in broad panel testing don't have identifiable driver oncogenes (especially in never smokers), consider RNA-based NGS if not already performed, to maximize detection of fusion event."
- "Real-time polymerase chain reaction (PCR) can be used in a highly targeted fashion (specific mutations targeted). When this technology is deployed, only those specific alterations that are targeted by the assay are assessed."
- "Sanger sequencing requires the greatest degree of tumor enrichment. Unmodified Sanger sequencing is not appropriate for detection of mutations in tumor samples with less than 25% to 30% tumor after enrichment and is not appropriate for assays in which identification of subclonal events (eg, resistance

mutations) is important. If Sanger sequencing is utilized, tumor enrichment methodologies are nearly always recommended."

- "Any method that interrogates sequences other than a subset of highly specific alterations (eg, NGS, Sanger) has the potential to identify variants of uncertain significance (VUS). Any variant classified as a VUS, even if in a gene in which other variants are clinically actionable, should not be considered as a basis for therapy selection."
- "Other methodologies may be utilized, including multiplex approaches not listed above (ie, SNaPshot, MassARRAY)."
- "Fluorescence in situ hybridization (FISH) analysis is utilized for many assays examining copy number, amplification, and structural alterations such as gene rearrangements. FISH may have better sensitivity for gene amplification events in some circumstances" (NCCN, 2024).

In order "To minimize tissue use and potential wastage, the NCCN NSCLC Panel recommends that broad molecular profiling be done as part of biomarker testing using a validated test(s) that assesses a minimum of the following potential genetic variants: *ALK* rearrangements, *BRAF* mutations, *EGFR* mutations, *KRAS* mutations, *METex14* skipping mutations, *NTRK* 1/2/3 gene fusions, *RET* rearrangements, and *ROS1* rearrangements. Both FDA and laboratory-developed test platforms are available that address the need to evaluate these and other analytes. Broad molecular profiling is also recommended to identify rare driver mutations for which effective therapy may be available, such as high-level *MET* amplifications and *ERBB2* mutations" (NCCN, 2024).

The NCCN also states that, "First-line targeted therapy options are recommended for eligible patients with metastatic NSCLC and positive test results for actionable driver mutations such as, *ALK*, *BRAF p.V600E*, *EGFR*, *MET*ex14 skipping, *NTRK 1/2/3*, *RET*, and *ROS1*. Second-line targeted therapy is recommended for patients with metastatic NSCLC and positive test results for *EGFR exon 20* insertions or *KRAS p. G12C mutations*" (NCCN, 2024).

In the 2022 NCCN update, the NCCN clarified that "any variant that is classified as VUS should not be used to select targeted therapy even if the VUS occurs in a gene in which other variants are clinically actionable" (NCCN, 2024).

The NCCN Panel added important information about general standards for biomarker testing in eligible patients with NSCLC. They noted that broad molecular profiling is molecular testing that "identifies all of the classic actionable driver mutations described in the algorithm [eg. *ALK*, *BRAF*, *EGFR*, *KRAS*, *MET*ex14 skipping, *NTRK 1/2/3*, *RET*, *ROS1*]–using either a single assay or a combination of a limited number of assays—and optimally also identifies the emerging actionable molecular biomarkers,

including high-level *MET* amplification and *ERBB2* mutations. Tiered testing approaches, based on the low prevalence of co-occurring biomarkers, are acceptable" (NCCN, 2024).

EGFR mutations

EGFR mutations are most often assessed using RT-PCR, Sanger sequencing, and NGS. *EGFR* mutation status is important for determining use of tyrosine kinase inhibitor (TKI) therapies. *EGFR* mutations include, but are not limited to, exon 19 deletions, p.L858R point mutation, p.L861Q, p.G719X, p.S768I0, exon 20 insertion variants, and p.T790M. As a category 1 recommendation, *EGFR* mutation testing is recommended for advanced or metastatic disease, including adenocarcinoma, large cell, and NSCLC NOS. As a category 2A recommendation, it is recommended to consider it for individuals with squamous cell carcinoma who have never been smokers, small biopsy specimens, or mixed histology (NCCN, 2024).

ALK gene rearrangements

ALK gene rearrangements are most often assessed using FISH, but IHC can also be effective. The NCCN states that NGS can detect *ALK* fusions, but PCR is less likely to detect any ALF fusion with a novel partner(s). The most common fusion partner for *ALK* is EML4; however, other partners have been isolated and identified. Like *EGFR*, *ALK* status is used in determining whether TKI therapies are appropriate. As a category 1 recommendation, *ALK* testing is recommended for advanced or metastatic disease, including adenocarcinoma, large cell, and NSCLC NOS. As a category 2A recommendation, it is recommended to consider it for individuals with squamous cell carcinoma who have never been smokers, small biopsy specimens, or mixed histology (NCCN, 2024).

ROS1 rearrangements

In NSCLC, *ROS1* rearrangements can result in inappropriate *ROS1* kinase signaling. Similar to *ALK*, FISH break-apart testing is often used, but this methodology "may under-detect the FIG-*ROS1* variant" (NCCN, 2024). IHC requires confirmatory testing because it has a low specificity for *ROS1*. PCR, if used, can be unlikely to detect novel fusion partners. The use of NGS can detect *ROS1* fusions, but DNA-based NGS is prone to under-detection of *ROS1* fusions. *ROS1* status is important for responsiveness to oral *ROS1* TKIs. As category 2A recommendations, *ROS1* testing should be performed for advanced or metastatic disease, including adenocarcinoma, large cell, and NSCLC NOS; it should be considered in individuals with squamous cell carcinoma with small biopsy specimens or mixed histology. Entrectinib has been noted as a preferred treatment option for *ROS1* rearrangements in advanced or metastatic NSCLC by the

NCCN since 2019. However, it should be noted that "Targeted real-time PCR assays are utilized in some settings, although they are unlikely to detect fusions with novel partners" (NCCN, 2024).

BRAF point mutations

Sequencing methods, especially NGS and Sanger (ideally paired with tumor enrichment), and rtPCR are most often used for detecting *BRAF* point mutations. *BRAF* V600 mutations are associated with responsiveness to certain combination therapies. Many *BRAF* mutations have been identified in NSCLC, but the impact of these mutations is not well-understood as of date. As category 2A recommendations, *BRAF* testing should be performed for advanced or metastatic disease, including adenocarcinoma, large cell, and NSCLC NOS; it should be considered in individuals with squamous cell carcinoma with small biopsy specimens or mixed histology (NCCN, 2024).

KRAS point mutations

Like *BRAF*, sequencing methods are used in the identification of point mutations within the *KRAS* gene. For NSCLC, the most common *KRAS* mutations are located in codon 12 even though other point mutations may occur elsewhere. *KRAS* mutations have been linked as a prognostic indicator of poor survival and can impact *EGFR* TKI therapy. The NCCN states, "*EGFR, KRAS, ROS1*, and *ALK* genetic alterations do not usually overlap; thus, testing for *KRAS* mutations may identify patients who will not benefit from further molecular testing." A newly designed oral KRAS G12C inhibitor was found to be effective in use against the *KRAS* p.G12C mutation, but this class of inhibitor has not been evaluated for any other mutations (NCCN, 2024).

MET exon 14 skipping variants

NGS-based testing, particularly RNA-based as it provides improved detection, is used to detect *METex14* skipping events. Immunohistochemistry is not used. Oral TKI therapy is used to address a *METex14* skipping mutation when detected. The NCCN states that "NGS-based testing is the primary method for detection of *METex14* skipping events; RNA-based NGS may have improved detection. IHC is not a method for detection of *METex14* skipping" (NCCN, 2024).

RET

FISH break-apart probe methodology is one appropriate method used to detect a RET mutation, though it may under-detect some fusions. NCCN also states that "Targeted real-time reverse-transcriptase PCR assays are utilized in some settings, although they are unlikely to detect fusions with novel partners. NGS-based methodology has a high

specificity, and RNA-based NGS is preferable to DNA-based NGS for fusion detection." Sequencing methods such as NGS and rtPCR are effective but rtPCR has difficulty detecting fusions with novel partners. RNA-based NGS has better fusion detection capability than DNA-based NGS. Regardless of fusion partner, *RET* mutations are responsive to oral *RET* TKI therapies (NCCN, 2024).

PD-L1

PD-L1 is expressed on tumor cells; its presence is used to determine possible pembrolizumab therapy. The FDA has approved IHC use for assessing PD-L1. The FDA-approved companion diagnostic for PD-L1 guides utilization of pembrolizumab in patients with NSCLC and is based on the tumor proportion score. As a category 1 recommendation, PD-L1 testing is recommended for all cases of advanced or metastatic disease, including adenocarcinoma, large cell, NSCLC NOS, and squamous cell carcinoma. NCCN states that, in comparison to TMB, "PD-L1 expression level is a more useful immune biomarker than TMB for deciding how to use immunotherapy, because test results are obtained more quickly, less tissue is needed for testing, and data demonstrate relative reproducibility across platforms and individuals." However, "While some clones for PD-L1 IHC are FDA-approved for specific indications, use of multiple IHC tests is not necessary, provided any individual IHC test has been internally validated for comparability for categorical results against the FDA-approved clone" (NCCN, 2024).

NTRK gene fusion

The NCCN has an *NTRK* gene fusion positive algorithm where larotrectinib is to be used as a first-line therapy if the gene fusion was discovered prior to first-line systemic therapy. If the *NTRK* gene fusion was discovered during a different first-line systemic therapy, then they recommend completing the planned systemic therapy, including maintenance therapy, and then follow this first-line therapy up with larotrectinib. As a category 2A recommendation, the NCCN recommends *NTRK* gene fusion testing to be included as part of molecular profiling for all forms of advanced or metastatic disease, including adenocarcinoma, large cell, NSCLC NOS, and squamous cell carcinoma. The NCCN NSCLC Panel recommends larotrectinib and entrectinib (both are category 2A) as either first-line or subsequent therapy options for patients with *NTRK* gene fusion-positive metastatic NSCLC based on data and the FDA approvals. As of the v3 2020 update, both agents are considered "preferred" first-line therapies for patients with *NTRK* gene fusion-positive metastatic disease (NCCN, 2024).

Tumor Mutational Burden (TMB)

NCCN reports that "In 2020, the NCCN Panel deleted tumor mutational burden (TMB)

as an emerging immune biomarker based on clinical trial data and other issues". Preliminary data from PFS from CHECKMATE 227, a phase 3 randomized trial with a complex design, had suggested that TMB might be a useful immune biomarker for deciding whether to use immunotherapy in patients with metastatic NSCLC, but updated data indicated that "overall survival was improved with nivolumab plus ipilimumab regardless of TMB or PD-L1 expression levels". Furthermore, "Several trials have shown that high TMB levels do not correlate with PD-L1 expression levels in patients with NSCLC". This lack of clinical data, coupled with technical problems with measuring TMB—including ": 1) lack of agreement on the definition of a cut off for designating high TMB levels; and 2) lack of standardization of TMB measurements across laboratories"—drives the NCCN Guidelines to "not recommend measurement of TMB levels before deciding whether to use nivolumab plus ipilimumab regimens or to use other ICIs, such as pembrolizumab" (NCCN, 2024).

Emerging biomarkers to identify novel therapies

The NCCN version 2.2022 also lists the following emerging biomarkers to identify novel therapies for patients with metastatic NSCLC.

Genetic Alteration (ie, Driver event)	**Available Targeted Agents with Activity Against Driver Event in Lung Cancer**
High-level *MET* amplification	Capmatinib Tepotinib Crizotinib
ERBB2 (HER2) mutations (Subsequent therapy)	Fam-trastuzumab deruxtecan-nxki Ado-trastuzumab emtansine

College of American Pathologists, the International Association for the Study of Lung Cancer (IASLC), and the Association for Molecular Pathology

The CAP/IASLC/AMP joint guidelines indicate that "*EGFR* molecular testing should be used to select patients for *EGFR*-targeted TKI [tyrosine kinase inhibitor] therapy" (Evidence Grade: A) (Lindeman et al, 2013). Testing is recommended for adenocarcinomas and mixed lung cancers "regardless of histologic grade." However, in the setting of fully excised lung cancer specimens, *EGFR* testing is not recommended for lung cancer without any adenocarcinoma component (Evidence Grade: A). In the setting of more limited lung cancer specimens where an adenocarcinoma component cannot be completely excluded, *EGFR* testing is recommended "in cases showing squamous or small cell histology but clinical criteria (eg, young age, lack of smoking

history) may be useful in selecting a subset of these samples for testing" (Evidence Grade: A)" (Lindeman et al, 2013). The 2018 CAP guidelines reaffirmed the 2013 guideline recommendations of universal testing of lung cancer patients with advanced-stage cancers with an adenocarcinoma component, using molecular diagnosis for activating ''hot-spot'' mutations in *EGFR* exons 18 to 21 with at least 1% prevalence (ie, codons 709 and 719, exon 19 deletion 768, and exon 20 insertions 790, 858, and 861) (Lindeman et al., 2018).

CAP also added the recommendation that: "In lung adenocarcinoma patients who harbor sensitizing *EGFR* mutations and have progressed after treatment with an *EGFR*-targeted tyrosine kinase inhibitor, physicians must use *EGFR* T790M mutational testing when selecting patients for third-generation *EGFR*-targeted therapy. Laboratories testing for *EGFR* T790M mutation in patients with secondary clinical resistance to *EGFR* targeted kinase inhibitors should deploy assays capable of detecting *EGFR* T790M mutations in as little as 5% of viable cells" (Lindeman et al., 2018).

The CAP recommendations were updated to include "3 categories into which genes should be placed. One set of genes must be offered by all laboratories that test lung cancers, as an absolute minimum: *EGFR*, *ALK*, and *ROS1*. A second group of genes should be included in any expanded panel that is offered for lung cancer patients: *BRAF*, *MET, RET, ERBB2* (*HER2*), and *KRAS*, if adequate material is available...All other genes are considered investigational at the time of publication." They elaborate to recommend: "In this context, institutions providing care for lung cancer patients have a choice: (1) offer a comprehensive cancer panel that includes all of the genes in the first 2 categories (*EGFR*, *ALK*, *ROS1*, *BRAF*, *MET, ERBB2* [*HER2*], *KRAS*, *RET*) for all appropriate patients, or (2) offer targeted testing for the genes in the must-test category (*EGFR*, *ALK*, *ROS1*) for all appropriate patients and offer as a second test an expanded panel containing the second-category genes (*BRAF*, *MET, ERBB2* [*HER2*], and RET) for patients who are suitable candidates for clinical trials, possibly after performing a single-gene *KRAS* test to exclude patients with *KRAS*-mutant cancers from expanded panel testing" (Lindeman et al., 2018). However, the CAP states that "*KRAS* molecular testing is not indicated as a routine stand-alone assay as a sole determinant of targeted therapy. It is appropriate to include *KRAS* as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative" and that "[*RET, MET*, *KRAS*, and *ERBB* (*HER2*)] molecular testing is not indicated as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include [*RET, MET, KRAS*, and

ERBB (*HER2*)] as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative" (Lindeman et al., 2018).

The guidelines indicate that "*ALK* molecular testing should be used to select patients for *ALK*-targeted TKI therapy" (Evidence Grade: B) (Lindeman et al., 2013). Testing is recommended for adenocarcinomas and mixed lung cancers "regardless of histologic grade." However, in the setting of fully excised lung cancer specimens, *ALK* testing is not recommended for lung cancer without any adenocarcinoma component (Evidence Grade: A). In the setting of more limited lung cancer specimens where an adenocarcinoma component cannot be completely excluded, *ALK* testing is recommended "in cases showing squamous or small cell histology but clinical criteria (eg, young age, lack of smoking history) may be useful in selecting a subset of these samples for testing" (Evidence Grade: A) (Lindeman et al., 2013).

The CAP recommends that "Multiplexed genetic sequencing panels are preferred over multiple single-gene tests to identify other treatment options beyond *EGFR*, *ALK*, and *ROS1*." They found that "NGS enables the simultaneous assessment of all 3 of the ''must-test'' genes in lung cancer—*EGFR*, *ALK*, *ROS1*—as well as each of the genes suggested for inclusion in larger panels—*BRAF*, *RET, ERBB2* (*HER2*), *KRAS*, *MET*—and hundreds to thousands of other genes that may have potential roles in cancer development. In addition to small mutations, NGS assays can detect fusions/rearrangements and copy number changes in the targeted genes, if designed with these alterations in mind. Numerous studies have demonstrated the excellent sensitivity of NGS methods relative to single-gene targeted assays, particularly for single-nucleotide–substitution mutations. Next-generation sequencing methods typically require less input DNA and can accommodate smaller samples with lower concentrations of malignant cells, and, although typically slower than 1 single-gene assay, can often be performed more rapidly than sequential multiple single-gene assays. A reduced need for repeat biopsy is an additional benefit of panel testing" (Lindeman et al., 2018).

When asked about new genes that should be tested for in lung cancer patients, CAP strongly recommends that "ROS1 testing must be performed on all lung adenocarcinoma patients, irrespective of clinical characteristics" (Lindeman et al., 2018).

Other guidance was backed by expert consensus opinion, and these recommendations include the following:

- "ROS1 IHC may be used as a screening test in lung adenocarcinoma patients; however, positive ROS1 IHC results should be confirmed by a molecular or cytogenetic method."
- "*BRAF* molecular testing is currently not indicated as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include *BRAF* as part of larger testing panels performed either initially or when routine *EGFR*, *ALK*, and *ROS1* testing are negative."
- ""RET molecular testing is not recommended as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include RET as part of larger testing panels performed either initially or when routine EGFR, ALK, and ROS1 testing are negative."
- "ERBB2 (HER2) molecular testing is not indicated as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include ERBB2 (HER2) mutation analysis as part of a larger testing panel performed either initially or when routine EGFR, ALK, and ROS1 testing are negative."
- "KRAS molecular testing is not indicated as a routine stand-alone assay as a sole determinant of targeted therapy. It is appropriate to include KRAS as part of larger testing panels performed either initially or when routine EGFR, ALK, and ROS1 testing are negative."
- "MET molecular testing is not indicated as a routine stand-alone assay outside the context of a clinical trial. It is appropriate to include MET as part of larger testing panels performed either initially or when routine EGFR, ALK, and ROS1 testing are negative" (Lindeman et al., 2018).

In 2018, CAP added the recommendation that "IHC is an equivalent alternative to FISH for *ALK* testing", and that "although at the time of writing RT-PCR and NGS are not approved by the FDA in the United States as first-line methods for determining *ALK* status in selection of patients for *ALK* inhibitor therapy, these approaches have shown comparable performance with IHC when designed to detect the majority of fusions, and are standard practice in many other countries. These methods are highly specific for most fusions, and patients with positive results should be treated with an *ALK* inhibitor, although patients with negative results may benefit from a more sensitive method to exclude the possibility of a variant fusion. Similarly, amplicon-based NGS assays of DNA may likewise fail to detect all fusion variants, and therefore a capture-based DNA or RNA approach is preferred for NGS testing for *ALK* fusions. Current data are still too limited to develop a specific recommendation either for or against the use of NGS for *ALK* fusions as a sole determinant of *ALK* TKI therapy" (Lindeman et al., 2018).

When performing molecular testing, CAP suggests that "Multiplexed genetic sequencing panels are preferred over multiple single-gene tests to identify other treatment options beyond *EGFR, ALK*, and *ROS1*" and that "Laboratories should ensure test results that are unexpected, discordant, equivocal, or otherwise of low confidence are confirmed or resolved using an alternative method or sample" (Lindeman et al., 2018).

Testing is indicated for patients with targetable mutations who have relapsed on targeted therapy. The CAP notes that

- "In lung adenocarcinoma patients who harbor sensitizing EGFR mutations and have progressed after treatment with an EGFR-targeted tyrosine kinase inhibitor, physicians must use EGFR T790M mutational testing when selecting patients for third-generation EGFR-targeted therapy" (strong recommendation); and
- "Laboratories testing for EGFR T790M mutation in patients with secondary clinical resistance to EGFR-targeted kinase inhibitors should deploy assays capable of detecting EGFR T790M mutations in as little as 5% of viable cells" (recommendation).

However, CAP also finds that "There is currently insufficient evidence to support a recommendation for or against routine testing for *ALK* mutational status for lung adenocarcinoma patients with sensitizing *ALK* mutations who have progressed after treatment with an *ALK*-targeted tyrosine kinase inhibitor" (Lindeman et al., 2018).

Regarding the use of circulating cell-free DNA, CAP claims that "There is currently insufficient evidence to support the use of circulating cell-free plasma DNA molecular methods for the diagnosis of primary lung adenocarcinoma." Moreover, "There is currently insufficient evidence to support the use of circulating tumor cell molecular analysis for the diagnosis of primary lung adenocarcinoma, the identification of EGFR or other mutations, or the identification of EGFR T790M mutations at the time of EGFR TKI resistance." However, CAP concedes that "In some clinical settings in which tissue is limited and/or insufficient for molecular testing, physicians may use a cell-free plasma DNA assay to identify EGFR mutations" and that "Physicians may use cell-free plasma DNA methods to identify EGFR T790M mutations in lung adenocarcinoma patients with progression or secondary clinical resistance to EGFR-targeted tyrosine kinase inhibitors; testing of the tumor sample is recommended if the plasma result is negative" (Lindeman et al., 2018).

American Society of Clinical Oncology (ASCO)

The ASCO published a joint update on "Therapy for Stage IV Non–Small-Cell Lung Cancer Without Driver Alterations" with Ontario Health (OH). These guidelines are intended for patients without alterations in *EGFR* or *ALK*. These recommendations divide PD-L1 expression into three categories: negative (0%), low positive (1-49%) and high (>50%). Pembrolizumab, carboplatin, pemetrexed, atezolizumab, paclitaxel, and bevacizumab are all listed as potential treatments, some of which may stand alone and some which are to be used in combination (Hanna et al., 2021).

Another joint update with Cancer Care Ontario remarked that "Mutations in *KRAS* are not predictive for benefit from adjuvant chemotherapy" (Kris et al., 2017).

ASCO published an endorsement of the joint guidelines from the CAP/IASLC/AMP with minor modifications. Relevant differences from the joint guidelines include:

- *BRAF* testing should be performed on all patients with advanced lung adenocarcinoma, irrespective of clinical characteristics.
- Physicians may use molecular biomarker testing in tumors with an adenocarcinoma component or nonsquamous non–small-cell histology (in addition to "any non–small-cell histology when clinical features indicate a higher probability of an oncogenic driver (eg, young age [50 years]; light or absent tobacco exposure)" (Kalemkerian et al., 2018).

European Society for Medical Oncology (ESMO)

According to ESMO, genetic alterations, which are key oncogenic events (driver mutations), have been identified in NSCLC, with two of these—*EGFR* mutations and the anaplastic lymphoma kinase (*ALK*) rearrangements—determining approved, selective pathway-directed systemic therapy. The ESMO guidelines do not specifically mention *KRAS* mutation testing. NGS is also mentioned for *ALK*, *RET*, *ROS1*, *MET, HER2*, and *BRAF* mutations (Novello et al., 2016).

ESMO remarks that the role of targeted agents in stages I-III NSCLC have not been evaluated properly. Therefore, they state that "there is no role for targeted agents in stage III NSCLC outside clinical trials" (Postmus et al., 2017).

ESMO published a guideline regarding metastatic NSCLC in 2020. In it, they note *EGFR, ALK, ROS1, BRAF*, and PD-L1 expression as usable biomarkers for "personalised medicine." *HER2, MET*, *NTRK*, and *RET* are considered "evolving targets/biomarkers". ESMO's specific recommendations are listed below.

- "*EGFR* mutation status should be systematically analysed in advanced NSCC [non-

small cell lung cancer] [level of evidence "I", strength of recommendation "A"]. Test methodology should have adequate coverage of mutations in exons 18–21, including those associated with resistance to some therapies [III, B]. At a minimum, when resources or material are limited, the most common activating mutations (exon 19 deletion, exon 21 L858R point mutation) should be determined"

- "The availability of TKIs effective against T790M-mutant recurrent disease makes T790M testing on disease relapse mandatory [I, A]"
- "Testing for *ALK* rearrangement should be systematically carried out in advanced non-squamous NSCLC [I, A]"
- "Testing for *ROS1* rearrangement should be systematically carried out in advanced NSCLC [III, A]. Detection of the *ROS1* translocation by FISH remains a standard; IHC may be used as a screening approach [IV, A]"
- "*BRAF* V600 mutation status should be systematically analysed in advanced NSCLC for the prescription of *BRAF*/MEK inhibitors"
- "Molecular *EGFR* and *ALK* testing are not recommended in patients with a confident diagnosis of SCC, except in unusual cases, e.g. never/former light smokers or long-time ex-smokers"
- "If available, multiplex platforms (NGS) for molecular testing are preferable [III, A]."
- "PD-L1 IHC should be systematically determined in advanced NSCLC [I, A]"
- "Testing is required for pembrolizumab therapy but may also be informative when nivolumab or atezolizumab are used" (Planchard et al., 2020).

In 2023, ESMO issued clinical practice guidelines focusing on oncogene-addicted metastatic non-small-cell lung cancer. These guidelines include

- "Adequate tissue material for histological diagnosis and molecular testing should be obtained to allow for individual treatment decisions [IV, A]."
- "Pathological diagnosis should be made according to the 2021 World Health Organization classification of lung tumours [IV, A].
- "Specific subtyping of all NSCLCs is necessary for therapeutic decision making and should be carried out wherever possible. IHC stains should be used to reduce the NSCLC-not otherwise specified rate to fewer than 10% of cases diagnosed [IV, A].
- The molecular tests below are recommended in patients with advanced non-squamous-cell carcinoma, and not recommended in patients with a confident diagnosis of squamous-cell carcinoma, except in unusual cases, e.g. young (<50 years) patients, never (<100 cigarettes in a lifetime)/former light smokers (≤15 pack-years, all kinds of tobacco) or long-time ex-smokers (quit smoking >15 years ago, all kinds of tobacco) [IV, A].

- *EGFR* mutation status should be determined [I, A]. Test methodology should have adequate coverage of mutations in exons 18-21, including those associated with resistance to some therapies [III, A]. At a minimum, when resources or material are limited, the most common activating mutations (exon 19 deletion, exon 21 L858R point mutation) should be determined [I, A].
- The availability of TKIs effective against T790M-mutated recurrent disease makes T790M testing on disease relapse on first- or second-generation EGFR TKIs mandatory [I, A].
- Testing for *ALK* rearrangements should be carried out [I, A].
- Detection of the *ALK* translocation by FISH remains a standard, but IHC with high-performance ALK antibodies and validated assays may be used for screening [III, A] and have been accepted as an equivalent alternative to FISH for ALK testing.
- Testing for *ROS1* rearrangements should be carried out [II, A]. Detection of the *ROS1* translocation by FISH remains a standard; IHC may be used as a screening approach [IV, A].
- *BRAF V600* mutation status testing should be carried out [II, A].
- Testing for *NTRK* rearrangements should be carried out [II, A]. Screening for NTRK rearrangements may use IHC or NGS, with appropriate testing follow-up to validate a positive result [II, A].
- Testing for *MET* exon 14 skipping mutations, MET amplifications, *RET* rearrangements, *KRAS* G12C mutations and *HER2* mutations should be carried out [II, A].
- If available, multiplex platforms (NGS) for molecular testing are preferable [III, A].
- RNA-based NGS is preferred for identifying an expanding range of fusion genes [III, B]. Whichever testing modality is used, it is mandatory that adequate internal validation and quality control measures are in place and that laboratories participate in, and perform adequately in, external quality assurance schemes for each biomarker test [III, A].
- cfDNA (liquid biopsy) can be used to test for oncogenic drivers as well as resistance mutations, but all patients with a negative cfDNA blood test still require tissue biopsy [II, A]" (Hendriks et al., 2023).

National Institute for Health and Care Excellence (NICE)

NICE has provided guidance for EGFR-TK mutation testing in adults with locally advanced or metastatic non-small-cell lung cancer.

"1.1 The tests and test strategies listed below are recommended as options for detecting epidermal growth factor receptor tyrosine kinase (EGFR-TK) mutations in the tumours of adults with previously untreated, locally advanced

or metastatic non-small-cell lung cancer (NSCLC), when used in accredited laboratories participating in an external quality assurance scheme. The laboratory-developed tests should be designed to detect the mutations that can be detected by one of the CE-marked tests as a minimum.

- therascreen EGFR RGQ PCR Kit (CE-marked, Qiagen)
- cobas EGFR Mutation Test (CE-marked, Roche Molecular Systems)
- Sanger sequencing of samples with more than 30% tumour cells and therascreen EGFR RGQ PCR Kit for samples with lower tumour cell contents
- Sanger sequencing of samples with more than 30% tumour cells and cobas EGFR Mutation Test for samples with lower tumour cell contents
- Sanger sequencing followed by fragment length analysis and polymerase chain reaction (PCR) of negative samples.

1.2 There was insufficient evidence for the Committee to make recommendations on the following methods:

- high-resolution melt analysis
- pyrosequencing combined with fragment length analysis
- single-strand conformation polymorphism analysis
- next-generation sequencing
- therascreen EGFR Pyro Kit (CE-marked, Qiagen)" (NICE, 2013).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81194	NTRK (neurotrophic receptor tyrosine kinase 1, 2, and 3) (eg, solid tumors) translocation analysis
81210	BRAF (B-Raf proto-oncogene, serine/threonine kinase) (eg, colon cancer, melanoma), gene analysis, V600 variant(s)
81235	EGFR (epidermal growth factor receptor) (eg, non-small cell lung cancer) gene analysis, common variants (eg, exon 19 LREA deletion, L858R, T790M, G719A, G719S, L861Q)
81275	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; variants in exon 2 (eg, codons 12 and 13)
81276	KRAS (Kirsten rat sarcoma viral oncogene homolog) (eg, carcinoma) gene analysis; additional variant(s) (eg, codon 61, codon 146)
81404	Molecular pathology procedure, Level 5 (eg, analysis of 2-5 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 6-10 exons, or characterization of a dynamic mutation disorder/triplet repeat by Southern blot analysis)
81405	Molecular pathology procedure, Level 6 (eg, analysis of 6-10 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 11-25 exons, regionally targeted cytogenomic array analysis)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons)
81479	Unlisted molecular pathology procedure
88342	Immunohistochemistry or immunocytochemistry, per specimen; initial single antibody stain procedure
88360	Morphometric analysis, tumor immunohistochemistry (eg, Her-2/neu, estrogen receptor/progesterone receptor), quantitative or semiquantitative, per specimen, each single antibody stain procedure; manual
88361	Morphometric analysis, tumor immunohistochemistry (eg, Her-2/neu, estrogen receptor/progesterone receptor), quantitative or semiquantitative, per specimen, each single antibody stain procedure; using computer-assisted technology
0414U	Oncology (lung), augmentative algorithmic analysis of digitized whole slide imaging for 8 genes (ALK, BRAF, EGFR, ERBB2, MET, NTRK1-3, RET, ROS1), and KRAS G12C and PD-L1, if performed, formalin-fixed paraffin-embedded (FFPE) tissue, reported as positive or negative for each biomarker

	Proprietary test: LungOI Lab/Manufacturer: Imagene
0448U	Oncology (lung and colon cancer), dna, qualitative, nextgeneration sequencing detection of single-nucleotide variants and deletions in egfr and kras genes, formalin-fixed paraffinembedded (ffpe) solid tumor samples, reported as presence or absence of targeted mutation(s), with recommended therapeutic options Proprietary test: oncoRevealTM DX Lung and Colon Cancer Assay Lab/Manufacturer: Pillar® Biosciences

Testing of Homocysteine Metabolism-Related Conditions

Policy Number: AHS – M2141 – Testing of Homocysteine Metabolism-Related Conditions	Initial Policy Effective Date: 01/01/2026

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Homocystinuria is a metabolic condition in which the body is unable to properly process certain amino acids, resulting in an abnormal accumulation of homocysteine and its metabolites in the blood and urine (NIH, 2023). Homocystinuria is primarily due to genetic causes; however, homocystinuria can also be due to nongenetic causes, including severe deficiency of vitamin B12, also known as cobalamin (Mudd et al., 2000).

Genetic counseling is strongly recommended for individuals pursuing genetic testing for homocystinuria.

II. Related Policies

Policy Number	Policy Title
AHS-G2014	Vitamin B12 And Methylmalonic Acid Testing
AHS-G2035	Prenatal Screening (Nongenetic)
AHS-G2050	Cardiovascular Disease Risk Assessment
AHS-M2041	Venous and Arterial Thrombosis Risk Testing
AHS-M2180	Genetic Markers for Assessing Risk of Cardiovascular Disease

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" of this policy document.

1) For individuals with signs and symptoms consistent with classic homocystinuria, genetic testing of *CBS* **MEETS COVERAGE CRITERIA**.

2) Genetic testing for variants of *MTHFR* known to cause homocystinuria **MEETS COVERAGE CRITERIA** for **either** of the following conditions**:**

   a) For symptomatic individuals that have tested negative for classic homocystinuria due to CBS deficiency.

   b) For individuals with a first-degree relative (see Note 1) positive for known variants of *MTHFR* that cause homocystinuria.

3) Newborn screening for homocysteine-related conditions **MEETS COVERAGE CRITERIA** in **any** of the following situations:

   a) Screening for classic homocystinuria due to CBS deficiency by performing quantitative plasma amino acids analysis and/or plasma or urine total homocysteine analysis.

   b) Screening for homocystinuria in dried blood spots.

   c) Screening for hypermethioninemia in dried blood spots.

4) When the initial screening test result exceeds the cut-off level of methionine, a repeat dried blood specimen submitted to the newborn screening program, **or** a quantitative plasma amino acid analysis and analysis of plasma total homocysteine **MEETS COVERAGE CRITERIA**.

5) For the diagnosis of phenotype variants of classic homocystinuria due to CBS deficiency, the pyridoxine (B6) challenge test **MEETS COVERAGE CRITERIA**.

6) For individuals over 18 years of age with homocystinuria suspected to be caused by CBS deficiency **and** for monitoring therapy in those with confirmed CBS deficiency, total homocysteine testing in plasma **MEETS COVERAGE CRITERIA**.

7) Plasma free homocysteine testing **DOES NOT MEET COVERAGE CRITERIA.**

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

8) Genetic testing for *MTR*, *MTRR*, and *MMADHC* genes **DOES NOT MEET COVERAGE CRITERIA.**

NOTES:

Note 1: First-degree relatives include parents, full siblings, and children of the individual.

IV. Table of Terminology

Term	Definition
3-MST	3-mercaptopyruvate
ACMG	American College of Medical Genetics
cblC	Homocystinuria type C
cblD	Cobalamin D
cblD-Hcy	Cobalamin D homocysteine
CblE	Methylcobalamin type E
cblF	Cobalamin F
cblG	Methylcobalamin type G
cblJ	Methylcobalamin type J
CBS	*Cystathionine β-synthase*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMS	Centers for Medicare and Medicaid
CT	Computed tomography
HT	Heterozygous state
CTH	Cystathionine
DNA	Deoxyribonucleic acid
EDTA	Chelating agentin deoxyribose nucleic acid extraction
E-HOD	European Network and Registry for Homocystinuria and Methylation Defects
FDA	Food and Drug Administration
FPIA	Fluorescence polarization immunoassay
GCLC	Glutamylcysteine
GC-MS	Gas chromatography–mass spectrometry
Hcy	Homocysteine
HHS	The U.S. Department of Health and Human Services
HPLC	High performance liquid chromatography
LC-MS	Liquid chromatography–mass spectrometry
LC-MS-MS	Liquid chromatography tandem mass spectrometry
LDTs	Laboratory-developed tests
MENA	Middle East and North Africa
Met	Methionine
MMA	Methylmalonic acid
MMADHC	Methylmalonic aciduria and homocystinuria type D protein

MRI	Magnetic resonance imaging
MTHFR	Methylene tetrahydrofolate reductase
MTR	Methionine synthase
MTRR	Methionine synthase reductase
NIH	National Institutes of Health
Phe	Phenylalanine
SAM	S-adenosyl methionine
tHcy	Total homocysteine
TT	Homozygous state
UPLC-MS/MS	Ultra performance liquid chromatography-tandem mass spectrometry

V. Scientific Background

Homocysteine (Hcy), a naturally occurring intermediary amino acid, is involved in multiple metabolic pathways, including the transsulfuration pathway as well as methionine (Met) metabolism. Classic homocystinuria, which results in an accumulation of Hcy and its metabolites in the blood and urine, is due to genetic mutations in *cystathionine-β-synthase* (*CBS*). CBS is the enzyme responsible for the rate-limiting step of the transsulfuration pathway and is dependent on pyridoxine (vitamin B6) (Zhu et al., 2018). If this enzyme is blocked, the transsulfuration of Hcy and the accumulation of both Hcy and Met will be limited, as Met concentration is enhanced by remethylation. The disruption of the Met metabolic pathway, as shown in Figure 1 below (Zhu et al., 2018), prevents Hcy from being used properly; this creates in a buildup of Hcy and toxic by-products in the blood, with excess Hcy excreted in urine (Mazaheri et al., 2017).

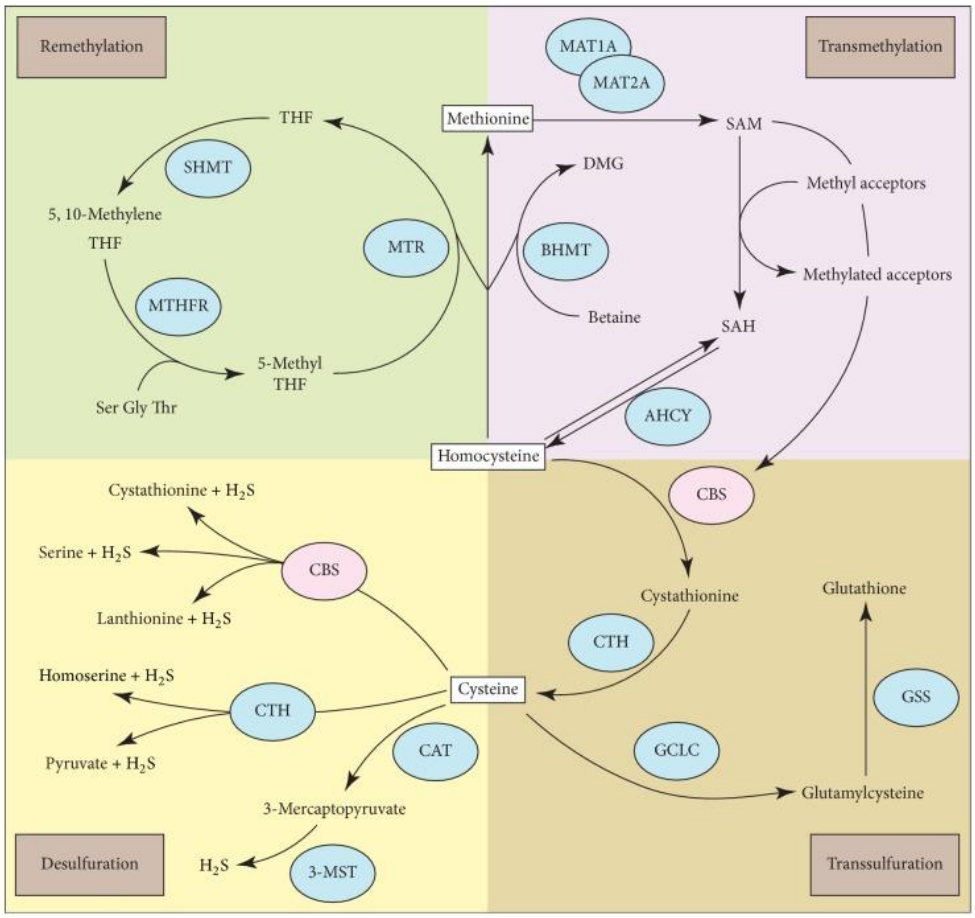

Figure 1: Homocysteine is a common metabolite linked to multiple metabolic pathways, including methionine/S-adenosyl methionine (SAM) metabolism, transsulfuration, and desulfuration. Figure taken from (Zhu et al., 2018).

Homocystinuria due to CBS deficiency can cause eye problems, skeletal abnormalities, an increased risk for blood clots, and developmental delay. Homocystinuria may also generate white matter abnormalities in the brain, potentially mimicking other disorders such as leukoencephalopathy when imaged with computed tomography (CT) and magnetic resonance imaging (MRI) scans (Ismayilova et al., 2019; Li et al., 2018).

The exact incidence of homocystinuria due to CBS deficiency is unknown. In 1985, the incidence was estimated to be around 1:344,000 worldwide (Mudd et al., 1985). However, the National Institutes of Health (NIH) is now estimating these rates to be much higher, around 1:150,000 worldwide, 1:200,000-300,000 in the United States, and 1:1,800 in Qatar (NIH, 2023). In European populations, incidence rates have been predicted by molecular epidemiological studies to be between 1:6,400 and 1:20,500 (Gaustadnes et al., 1999; Janosík et al., 2009). Higher prevalence in the MENA (Middle East and North Africa) region could be attributed to high consanguinity in those

communities (Al-Sadeq & Nasrallah, 2020). Infants with homocystinuria due to CBS deficiency are asymptomatic at birth, with symptoms slowly developing if left untreated. However, these symptoms are highly variable. Some affected patients may exhibit mild symptoms of the disorder while others may develop potentially life-threatening complications. Depending on the population affected and type of *CBS* gene mutation, symptoms can be as severe as ectopia lentis, Marfanoid features, mental retardation, idiopathic infertility, osteoporosis, and severe premature atherosclerosis (Al-Sadeq & Nasrallah, 2020; Rosenson et al., 2024). The phenotype of these patients mainly relates to pyridoxine-responsiveness: pyridoxine treatment responders exhibit a milder phenotype and a later onset than pyridoxine treatment nonresponders (Abbott et al., 1987; Mudd et al., 1985). Early detection and treatment is important in preventing or reducing the severity of the disorder. Screening for homocystinuria is frequently incorporated into state newborn screening programs (Rose & Dolan, 2012). While a newborn blood spot specimen for hypermethioninemia will detect homocystinuria due to CBS deficiency in some, not all affected individuals will be detected by this test (Sacharow et al., 2004).

According to Sacharow et al. (2004), the biochemical features of homocystinuria include:

- Markedly increased concentrations of total homocysteine, plasma homocysteine, homocysteine-cysteine mixed disulfide, and methionine
- Increased concentration of homocysteine in urine
- Reduced CBS enzyme activity

Classical biochemical findings establishing the diagnosis are summarized in the following table titled: Cardinal Biochemical Findings that Establish the Diagnosis of Homocystinuria (Sacharow et al., 2004).

Analyte	**Specimen**	**Expected Findings**		
		Neonate with homocystinuria	**Untreated older individual with homocystinuria**	**Control**
Total homocysteine (tHcy)	Plasma	50 to >100 µmol/L	>100 µmol/L	<15 µmol/L
Methionine (on amino acid analysis)	Plasma	200-1500 µmol/L (3-23 mg/dL)	>50 µmol/L (>0.7 mg/dL)	10-40 µmol/L (0.2-0.6 mg/dL)

Homocystinuria due to genetic causes is inherited in an autosomal recessive pattern. Many different forms of homocystinuria can occur and signs and symptoms vary depending on the gene mutation. *CBS* gene mutations cause the most common form of homocystinuria. This mutation is referred to as "classic" homocystinuria or CBS deficiency. Other gene mutations that can result in homocystinuria include *MTHFR*, *MTR*, *MTRR*, and *MMADHC*. The *MTHFR*, *MTR*, and *MTRR* genes all revolve around the remethylation pathway of Hcy, while the *MMADHC* gene plays a role in Vitamin B12 metabolism (Froese et al., 2015; Wang et al., 2016).

Homocystinuria may also be associated with a diagnosis of methylmalonic acidemia, when the body cannot efficiently break down specific fats or proteins, leading to a methylmalonic acid buildup in the blood. Methylmalonic aciduria and homocystinuria type C (cblC) is characterized by a vitamin B12 disorder initiated by a mutation in the *MMACHC* gene; symptoms of this disorder fall into several categories, including thromboembolic and neurological issues such as cognitive and psychiatric episodes (Collison et al., 2015).

Analytical Validity

This concentration of total homocysteine (tHcy) in blood plasma is the primary clinical analyte measured to diagnose homocystinuria. A study using liquid chromatography–mass spectrometry (LC-MS) calculated limits of detection (0.06 µmol/L) and quantification (0.6 µmol/Lu) of tHcy (Nelson et al., 2003). Another study using gas chromatography–mass spectrometry (GC-MS) found a detection limit of 0.4 µmol/L as well as intra- and inter-run variations of five and eight percent, respectively. Furthermore, this method was found to compare well with the LC-MS-MS method; the GC-MS method had a mean difference of -0.4 µmol compared to the LC-MS-MS method (Belkhiria et al., 2007). Fluorescence polarization immunoassay (FPIA) was found to compare favorably to the high performance liquid chromatography (HPLC) and MS approaches as well (five percent imprecision with negative two percent to three percent bias) so it is a practical option if the more precise approaches are not available; unfortunately, this study only measured levels up to 45 µmol/L, whereas severe homocystinuria can exceed 100 µmol/L (Nexo et al., 2000).

More recently, Concepción-Alvarez et al. (2016) have validated a method to quantify Hcy in plasma samples via HPLC. Hcy levels were measured in a total of 46 patients and the authors found that HPLC was able to "identify and quantify Hcy without interferences" and that the identified detection limit was 3.12 µM and quantification limit 6.25 µM (Concepción-Alvarez et al., 2016). This research has provided further

validation for Hcy plasma testing in ailments such as homocystinuria where this amino acid is increased.

For the detection of Hcy-related conditions, methylmalonic acid and tHcy are commonly measured in both plasma samples and dried blood spots. Using ultra performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS), de Sain-van der Velden et al. (2015) recently compared methylmalonic acid and tHcy levels collected either from a dried blood spot or from plasma concentration testing methods to determine which is the more efficient and accurate method. The authors note that the plasma assay performed better than the dried blood spot testing method in most areas, but that dried blood spot testing was superior for tHcy stability. Furthermore, a strong correlation of tHcy was found in both testing methods, ($y=0.46\pm1.12$ ($r(2)=0.91$)), leading to the authors suggestion that tHcy testing in plasma can be replaced by tHcy in dried blood spots (de Sain-van der Velden et al., 2015).

Clinical Utility and Validity

A diagnosis of classic homocystinuria (caused by CBS deficiency) is established by measurement of tHcy. The normal level is <15 µMol/L, whereas a newborn with homocystinuria is expected to measure at >50 µMol/L and an older, untreated individual will likely measure at >100 µMol/L (Sacharow et al., 2004). A measurement of Met in plasma can corroborate a diagnosis, as the metabolic pathway involves a buildup of Met in addition to the buildup of Hcy (Sacharow et al., 2004). While free Hcy composes about 15-25% of tHcy levels, separate free Hcy testing is unnecessary: tHcy measurement already includes all forms of Hcy (Rosenson et al., 2024).

The detection of biallelic pathogenic variants in CBS can substantiate a diagnosis of classic homocystinuria (Sacharow et al., 2004). There are two phenotypic variants in homocystinuria, both caused by *CBS*: B6-responsive and B6-non-responsive homocystinuria. The pyridoxine (B6) challenge test is performed to determine the variant and if vitamin B6 therapy will be beneficial (Sacharow et al., 2004). Testing for homocystinuria usually involves biochemical testing in urine and/or genetic testing for known mutations. Genetic testing can be done using a single gene or multi-gene panel which may include sequence analysis, deletion/duplication analysis, and/or other non-sequencing-based tests. Homocystinuria typically involves CBS deficiency and while the activity of the CBS enzyme could be performed in cultured fibroblasts when genetic tests are inconclusive, enzymatic testing for CBS deficiency is no longer available in USA (Sacharow et al., 2004).

Methylene tetrahydrofolate reductase (*MTHFR*) mutations are of interest in homocystinuria. The MTHFR enzyme catalyzes the reduction of 5,10-

methylenetetrahydrofolate to 5,10-methyltetrahydrofolate, the methyl donor for the conversion of Hcy to Met. Failure of this enzyme (<20% of normal levels) leads to increased Hcy and Met, as well as the production of other symptoms associated with homocystinuria (Long & Goldblatt, 2016). The two most common mutations in the *MTHFR* gene are 677T (changed from a C nucleotide) and 1298C (changed from an A). Both mutations can be heterozygotic or homozygotic, and both can lead to loss of enzymatic function (Gonzales et al., 2017). The 677T mutation is more severe, as in the homozygous state (TT) it results in up to 70% loss of enzymatic function, compared to only a 35% loss of function in the heterozygous state (CT) (Frosst et al., 1995). The 1298C mutation results in a loss of enzymatic function; 30% and 15% for its homozygous and heterozygous forms, respectively (Weisberg et al., 1998).

However, it is possible that dietary factors (notably low levels of folate or Vitamin B12) influence tHcy levels more than genetic factors. A study covering 452 young adults found tHcy variance to have a nine percent total genetic contribution (i.e. genetic polymorphisms) compared to a 35% contribution from dietary factors. The only polymorphism found to have a significant effect on tHcy levels was the 677T mutation, which interacted with low folate levels to produce a high tHcy phenotype. Compared to the authors earlier studies of genetic influence on tHcy levels, the younger cohort's genetic contribution on tHcy levels was measured out to be higher than the older cohort's (nine percent compared to seven percent for the older cohort). Furthermore, the authors suggest that genetic influence on tHcy levels are more pronounced during early life and environmental factors are more influential as time passes (Gaughan et al., 2001; Harmon et al., 1999; Kluijtmans et al., 2003).

Another study conducted by Gales et al. (2018) found that focal epilepsy presentation in the context of adult or adolescent onset could result from a mutation leading to *MTHFR* deficiency. It is critical that this mutation found in homocystinuria be detected early for treatment, as the neuropsychiatric syndrome could be easily treated with a combination of vitamin B9, vitamin B12, and betaine (Gales et al., 2018).

A novel newborn screening method has been developed by researchers: a two-tier algorithm using a methionine (Met) to phenylalanine (Phe) ratio. Data from 125,047 neonates was utilized to determine this accuracy of this method (Okun et al., 2017). It was reported that "Met to Phe ratio was found to be more effective for first sieve than Met, sorting out nearly 90% of normal samples. Only 10% of the samples would have to be processed by second-tier measurement of Hcy in dried blood spots" (Okun et al., 2017). This novel testing method resulted in 100% sensitivity and specificity for classic homocystinuria newborn screening (Okun et al., 2017).

Guo et al. (2022) investigated the effects of maternal Hcy concentrations, *MTHFR*, and *MTRR* gene presence on the occurrence of fetal aneuploidy through a retrospective case-control study. From the differences in the maternal *MTHFR* 677C>T, *MTHFR* 1298A>C and *MTRR* 66A>G genetic polymorphisms and maternal Hcy concentrations between aneuploidy and control mothers, they found that the mutations were associated with multiple trisomies, including Down syndrome (Trisomy 21), trisomy 15, and Turner syndrome. The 677C>T polymorphism was associated with the most trisomies and transfer genes. Lastly, there was an increased concentration of Hcy among mothers of fetuses with trisomies 22, 21, 18, 16, and 15 and Turner syndrome in comparison to the control mothers. Due to the identified associations, it becomes even more crucial to study effects of combining maternal genetic factors and body systemic factors like homocysteine concentration on spontaneous fetal aneuploidy formation that were not previously understood (Guo et al., 2022).

VI. Guidelines and Recommendations

The United States Department of Health and Human Services

The Secretary of the U.S. Department of HHS has developed a recommended uniform screening panel for every universal newborn screening program; the amino acid disorder homocystinuria is recommended as a core condition for newborn screening, and the organic acid condition methylmalonic acidemia with homocystinuria is recommended as a secondary screening condition. Methylmalonic acidemia due to methylmalonyl-CoA mutase or cobalamin disorders is included as a core condition as well (HHS, 2024).

American College of Medical Genetics (ACMG)

The ACMG recommends quantitative testing of plasma amino acids to determine increased levels of Hcy and Met; classic homocystinuria is characterized by increases in both Hcy and Met, while increased Met may be indicative of other disorders (ACMG, 2021b). Also, plasma Hcy analysis will show increased Hcy in classic homocystinuria and normal or only slightly increased Hcy in the other disorders. Urine Hcy will be significantly increased in classic homocystinuria (ACMG, 2021b).

In the Confirmatory Algorithms for Met, ACMG indicates that increased Met and increased tHcy are indicative of homocystinuria due to CBS deficiency (ACMG, 2021a).

European Network and Registry for Homocystinuria and Methylation Defects (E-HOD)

In 2015, a project by the E-HOD released the *Newborn Screening for Homocystinurias and Methylation Disorders: Systematic Review and Proposed Guidelines*. In this guideline, authors recommend newborn screening for CBS deficiency by detecting elevated Met, methionine-to-phenylalanine ratio, and/or tHcy in dried blood spots. Specificity is increased by analyzing tHcy as a second-tier marker and calculating Met/tHcy ratio is also suggested (Huemer et al., 2015)

Newborn screening for the cblD-Hcy, CblE, and cblG defects, and for *MTHFR* deficiency could be possible by measuring Met and methionine-to-phenylalanine ratio in dried blood spots followed by analysis of tHcy as a second-tier marker. However, it is stated that the efficacy and feasibility of screening for these disorders is largely unknown (Huemer et al., 2015).

As a part of E-HOD, the *Guidelines for Diagnosis and Management of The Cobalamin-Related Remethylation Disorders cblC, cblD, cblE, cblF, cblG, cblJ and MTHFR Deficiency* were released in 2017. Huemer et al. (2017) "strongly recommend measuring plasma total homocysteine in any patient presenting with the combination of neurological and/or visual and/or haematological symptoms, subacute spinal cord degeneration, atypical haemolytic uraemic syndrome or unexplained vascular thrombosis." For a "valid, timely laboratory diagnosis," the authors also add:

- "We strongly recommend that investigations in patients with a suspected remethylation disorder should start with the measurement of total homocysteine in blood. We recommend the blood sample for tHcy to be centrifuged within an hour and kept at four degrees or frozen until analysis. Immunoassays or chromatographic methods are suitable for tHcy measurement. (Quality of the evidence: moderate)
- We strongly recommend against measuring free homocysteine instead of total homocysteine. (Quality of the evidence: moderate)
- We strongly recommend that in the case of high total homocysteine, plasma and urine samples for determination of MMA, methionine, folate and vitamin B12 are to be obtained before treatment is started. (Quality of the evidence: moderate)" (Huemer et al., 2017).

Another guideline written as a part of E-HOD provides practical guides to recognition, diagnosis and management of CBS deficiency. The guideline presented 41 separate recommendations based on a literature review by the Guideline Development Group and the authors admitted that the quality of the identified data was poor and many of their recommendations were grade D; however, the highest recommendation was given to measuring the plasma total homocysteine concentrations in any patient whose signs and symptoms strongly suggest the diagnosis (Morris et al., 2017).

For the biochemical diagnosis, a tHcy test is recommended as "the frontline test" for the diagnosis of CBS deficiency. Plasma free Hcy is only detectable at tHcy concentrations above 50-60 µmol/L; its measurement is not particularly sensitive or even reproducible and is, therefore, not recommended. Untreated patients with a CBS deficiency typically have tHcy concentrations above 100 µmol/L and a diagnosis is likely if an elevated tHcy is found along with high or borderline high plasma Met concentrations. Further information such as low plasma cystathionine concentration or increased Met:Cystathionine ratio can support a diagnosis. Finally, tHcy measurement using dried blood spots can be done if plasma processing is not possible.

The European Network and Registry for Homocystinuria and Methylation Defects recommends confirming CBS deficiency by measuring cystathionine synthase activity in fibroblasts or plasma and/or by mutation analysis of CBS gene. The gold standard for confirming CBS deficiency is determination of cystathionine production of Hcy and serine in cultured fibroblasts. Either the enzyme or DNA can be analyzed and if one method does not confirm a diagnosis, the other method should be done. The grade of this recommendation is B-C.

Despite technical pitfalls of DNA testing, E-HOD recommends a molecular genetic analysis of the CBS gene for the confirmation of CBS deficiency and for carrier and prenatal testing (grade B). For the prenatal diagnosis, the molecular analysis is a preferred technique during the first trimester of pregnancy. If the mutations are known in the family, enzyme analysis can be performed in cultured amniocytes, but not in chorionic villi. Preimplantation analysis could also be done (grade C-D).

For newborn screening, it is recommended to increase specificity of Met testing by using tHcy as a second marker and calculating Met/tHcy ratio (grade C). Several other metabolic disorders can cause an increased Met concentration and the exact sensitivity of detecting Met in newborns with a CBS deficiency is unknown. Although the median Met concentration of CBS deficient patients is far greater than the median of a healthy neonate (103 µmol/L compared to 20 µmol/L), individual Met values may still vary.

Screening for family members at risk is recommended by measuring tHcy but molecular genetic testing may also be utilized in exceptional cases (grade D).

Monitoring of tHcy, amino acids, folate and vitamin B12 is recommended in all patients during therapy. The frequency of the monitoring is variable on a case-by-case basis (due to severity, treatment plan, age, etc). The targeted concentration ranges for total plasma homocysteine are proposed to be <50 ▪ mol/L in pyridoxine-responsive patients and at <11 ▪ mol/L free homocysteine (about 120 ▪ mol/L total homocysteine) in pyridoxine-unresponsive patients (Morris et al., 2017).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

On May 13, 2011, the FDA approved the Invader *MTHFR* 677 created by Hologic, Inc. The Invader *MTHFR* 677 is an in vitro diagnostic test intended for the detection and genotyping of a single point mutation (C to T at position 677) of the human 5,10-methylenetetrahydrofolate reductase (*MTHFR*) gene in isolated genomic DNA obtained from whole blood potassium EDTA samples from patients with suspected thrombophilia (FDA, 2011a).

On April 25, 2011, the FDA approved the Invader *MTHFR* 1298 created by Hologic, Inc. The Invader *MTHFR* 1298 test is an in vitro diagnostic test intended for the detection and genotyping of a single point mutation (A to C at position 1298) of the human 5,10-methylenetetrahydrofo late reductase (*MTHFR*) gene in isolated genomic DNA obtained from whole blood potassium EDTA samples from patients with suspected thrombophilia (FDA, 2011b).

On April 22, 2010, the FDA approved the eSensor Thrombophilia Risk Test on XT-8 System created by Osmetech Molecular Diagnostics. The *MTHFR*-specific portion is as follows: The eSensor *MTHFR* Genotyping Test is an in vitro diagnostic for the detection and genotyping of point mutations (C to T at position 677) and (A to C at position 1298) of the human 5,10-methylenetetrahydrofo late reductase (*MTHFR*) gene in isolated genomic DNA obtained from whole blood samples. The test is intended to be used on the eSensor XT-8 System (FDA, 2010).

On October 11, 2007, the FDA approved the Verigene System created by Nanosphere Inc. The *MTHFR*-specific portion is as follows: The Verigene *MTHFR* Nucleic Acid Test is an in vitro diagnostic for the detection and genotyping of a single point mutation (C to T at position 677) of the human 5,10-methylenetetrahydrofolate reductase gene (*MTHFR*) in patients with suspected thrombophilia, from isolated genomic DNA obtained from whole blood samples. The test is intended to be used on the Verigene System (FDA, 2007).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81291	MTHFR (5,10-methylenetetrahydrofolate reductase) (eg, hereditary hypercoagulability) gene analysis, common variants (eg, 677T, 1298C)
81401	Molecular pathology procedure, Level 2 (eg, 2-10 SNPs, 1 methylated variant, or 1 somatic variant [typically using nonsequencing target variant analysis], or detection of a dynamic mutation disorder/triplet repeat)
81406	Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)Molecular pathology procedure, Level 7 (eg, analysis of 11-25 exons by DNA sequence analysis, mutation scanning or duplication/deletion variants of 26-50 exons, cytogenomic array analysis for neoplasia)
81479	Unlisted molecular pathology procedure
82136	Amino acids, 2 to 5 amino acids, quantitative, each specimen
82139	Amino acids, 6 or more amino acids, quantitative, each specimen
82615	Cystine and homocysteine, urine, qualitative
83090	Homocysteine
83921	Organic acid, single, quantitative
84207	Pyridoxal phosphate (Vitamin B-6)

Current Procedural Terminology© American Medical Association. All Rights reserved.

Procedure codes appearing in Medical Policy documents are included only as a general reference tool for each policy. They may not be all-inclusive.

Transplant Rejection Testing

Policy Number: AHS – M2091 – Transplant Rejection Testing	Prior Policy Name and Number, as applicable: • AHS – M2091 – Heart Transplant Rejection
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Transplant rejection involves an immune response to a transplanted organ. The recipient's immune system recognizes the donated organ as "foreign," thereby initiating an immune response as if the transplanted organ was a foreign antigen. This response may cause the transplanted organ to fail (Vella, 2024). Gene expression profiling tests and serum cell-free DNA evaluation are possible ways to monitor organ transplant rejection (Carey et al., 2018; Crespo-Leiro et al., 2016; Gielis et al., 2015).

II. Related Policies

Policy Number	Policy Title
AHS-G2098	Immune Cell Function Assay

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For heart transplant recipients who are 15 years of age or older and who are 55 or more days post-transplant, the use of AlloMap® **MEETS COVERAGE CRITERIA** at the following frequency:
   a) Every month for individuals who are 2-12 months post-transplant.
   b) Every 3 months for individuals who are 12-36 months post-transplant.
   c) Every 6 months for individuals who are greater than 36 months post-transplant.

2) For heart transplant recipients who are 28 or more days post-transplant, the use of donor-derived cell-free DNA tests (e.g., AlloSure Heart, Prospera™ Heart) **MEETS COVERAGE CRITERIA** at the following frequency:
   a) Every month for individuals who are 1-12 months post-transplant.
   b) Every 3 months for individuals who are 12-36 months post-transplant.
   c) Every 6 months for individuals who are greater than 36 months post-transplant.

3) For single-kidney transplant recipients who are 18 years of age or older and who are at least 14 days post-transplant, the use of donor-derived cell-free DNA tests (e.g., AlloSure Kidney) to assess the probability of allograft rejection **MEETS COVERAGE CRITERIA** at the following frequency:
   a) Once per month for individuals who are 1-4 months post-transplant.
   b) Every 3 months for individuals who are greater than 6 months post-transplant.

4) For kidney transplant recipients with stable renal function, the use of peripheral blood microarray-based genomic tests that analyze gene expression profiles to rule out kidney transplant rejection (e.g., TruGraf) **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) For heart transplant recipients, testing for heart transplant rejection with simultaneous gene expression testing and donor-derived cell-free DNA testing (e.g., HeartCare®) **DOES NOT MEET COVERAGE CRITERIA.**

6) For any other organ transplant not listed above (e.g., lungs, liver), the use of donor-derived cell-free DNA tests **DOES NOT MEET COVERAGE CRITERIA**.

7) For any other organ transplant not listed above (e.g., kidneys, lungs, liver), the use of peripheral blood gene expression profiling tests **DOES NOT MEET COVERAGE CRITERIA**.

8) To assess for rejection and injury in transplanted organs, mRNA expression profiling of biopsied tissue from a transplanted organ (e.g., MMDx Heart, MMDx Kidney) **DOES NOT MEET COVERAGE CRITERIA.**

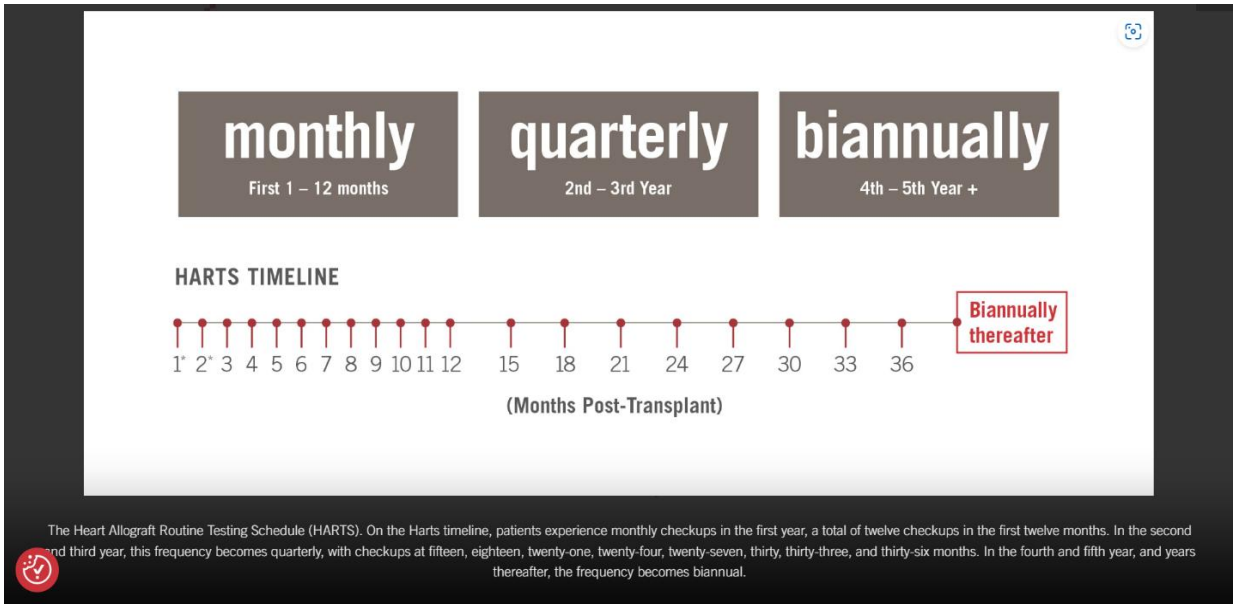
9) To assist in the detection of moderate grade 2R/grade 3 heart transplant rejection, the measurement of volatile organic compounds **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
AASLD	American Association for the Study of Liver Diseases
ACR	Acute cellular rejection
ALAD	Acute lung allograft dysfunction
AMR	Antibody-mediated rejection
AR	Active rejection
AST	American Society of Transplantation
ASTS	American Society of Transplant Surgeons
AUC	Area under curve
BAL	Bronchoalveolar lavage
BL	Borderline rejection
CARGO	Cardiac Allograft Rejection Gene Expression Observational
cfDNA	Cell-free deoxyribonucleic acid
CLAD	Chronic lung allograft dysfunction
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid
dd-cfDNA	Donor-derived cell-free deoxyribonucleic acid
DNA	Deoxyribonucleic acid
DSA	Donor-specific antibodies
EAU	European Association of Urology
EMA	European Medicines Agency
EMB	Endomyocardial biopsy
ESC	European Society of Cardiology
ESOT	European Society of Organ Transplantation
FCXM	Flow crossmatch
FDA	Food and Drug Administration
FEV1	Forced expiratory volume in one second
GEP	Gene expression profiling
HLA	Human leukocyte antigen
INTERCOMEX	International Collaborative Microarray Study Extension
IFN-γ ELISPOT	Interferon-γ enzyme-linked immunospot
ISHLT	International Society of Heart and Lung Transplantation
IVDMIA	In vitro diagnostic multivariate index assay
KDIGO	Kidney Disease: Improving Global Outcomes
LDT	Laboratory-developed test
LFT	Liver function test

MFI	Mean fluorescence intensity
MHC	Major histocompatibility complex
NGS	Next-generation sequencing
NPV	Negative predictive value
OI	Other injury
PBMC	Peripheral blood mononuclear cells
PPV	Positive predictive value
qRT-PCR	Quantitative real-time polymerase chain reaction methodology
RA	Renal Association
RNA	Ribonucleic acid
rsEMB	Routine surveillance endomyocardial biopsy
SAB	Single-antigen bead
STA	Stable
subAR	Subclinical acute rejection
TCMR	T cell-mediated rejection
TLC	Total lung capacity
VOCs	Volatile organic compounds

V. Scientific Background



Solid organ transplant is a delicate process, requiring much oversight and evaluation of every party involved. Rejection, or failure of the transplant, is a potential outcome of any transplant case. At the molecular level, rejection is primarily caused by a component of the adaptive immune system, the major histocompatibility complex (MHC) proteins. These proteins must match between donor and recipient, or the transplant can fail (Vella, 2024).

The primary function of MHC proteins is acting as the platform on which T cells identify antigens. Typically, these MHC proteins bind foreign antigens, which are then recognized as such by T cells. From there, the T cells can generate an immune response to handle the antigen. However, the MHC protein products must be identified as "self" by these T cells as well. If an organ donor's MHC protein does not match the recipient's, the recipient's T cells may identify the MHC of the donated organ as "foreign" and subsequently implement an immune response. This eventually starts the cascade of events that causes the transplant to fail (Vella, 2024).

Numerous methods mitigate this immune response. Immunosuppressants, which cause desensitization of the immune response, and more have been proposed as methods to circumvent this immune response (Vella, 2024).

Proprietary Tests – Gene Expression

AlloMap®

The AlloMap test is based on quantitative real-time polymerase chain reaction methodology (qRT-PCR) using RNA purified from peripheral blood mononuclear cells (PBMC). It is a gene expression test (11 informative genes, 9 control genes) that proposes to "aid in the identification of heart transplant recipients with stable allograft function who have a low probability of moderate/severe acute cellular rejection (ACR) at the time of testing in conjunction with standard clinical assessment" (FDA, 2008). Its FDA approval states that it is intended for heart transplant recipients, 15 years or older, and ≥55 days post-transplant (FDA, 2008). From CareDX, Inc., the makers of AlloMap: "The Heart Allograft Routine Testing Schedule (HARTS). On the Harts Timeline, patients experience monthly checkups the first year, a total of twelve checkups in the first year. In the second and third year, this frequency becomes quarterly, with checkups at fifteen, eighteen, twenty-one, twenty-four, twenty-seven, thirty, thirty-three, and thirty-six months. In the fourth and fifth year, and years after, the frequency becomes biannual" (CareDX, 2024d).

MMDx®

Gene expression profiles available through One Lambda for assessment of transplant rejection include MMDx Heart (1283 genes for heart transplants) and MMDx Kidney (1494 genes for kidney transplants). Whereas other tests are performed on a peripheral blood sample, MMDx Heart and MMDx Kidney requires a biopsy sample. The mRNA levels of a set number of genes (depending on the organ) are assessed in the biopsied

tissue and are then compared to the mRNA levels from a reference set of biopsies (One Lambda, 2024).

TruGraf® (Kidney and Liver)

The TruGraf assay is available for kidney and liver transplant recipients. TruGraf gene expression panels are intended for transplant patients and are based on microarray analysis of peripheral blood. TruGraf identifies if a patient is "immune activating" (potentially rejecting) or "immune quiescent" (stable), allowing a clinician to evaluate potential pre-symptomatic kidney damage without use of a biopsy (Eurofins Viracor, 2024; Peddi et al., 2020). According to Eurofins, "120 genes with the highest discriminatory power between the non-TX ["inadequately immunosuppressed"] and TX ["adequately immunosuppressed"] phenotypes are the IP incorporated in TruGraf" (Eurofins, 2023).

Proprietary Tests – Donor-derived Cell-free DNA & Combination

Tissue gene expression is not the only medium tested for rejection. The use of cell-free DNA has shown much promise as a minimally invasive detection method for allograft rejection, and may be used to complement or, ultimately, replace tissue biopsies in the future (Pattar & Greenway, 2020).

Viracor TRAC®

The Viracor TRAC® (Transplant Rejection Allograft Check) donor-derived cell-free DNA (dd-cfDNA) assay uses a non-invasive liquid biopsy to monitor the percentage of dd-cfDNA in transplant recipient plasma post-transplant using next generation sequencing (NGS). The test uses "a bioinformatics pipeline that analyzes NGS and genome-wide recipient genotype data to determine the percentage of dd-cfDNA present, which strongly correlates with allograft injury due to rejection. The licensed algorithm accurately quantifies the donor-derived fraction of cell-free DNA without need for donor genotype information, even when the donor is closely related (e.g., sibling kidney donors). The design of this test also enables the determination of dd-cfDNA concentrations over a much wider dynamic range than currently possible with other methods" (eurofins, 2024). As of 2023, this technology has not been approved by the FDA. Originally TRAC® was also offered as part of a dual-marker rejection panel by the name of OmniGraf; however, this test is no longer commercially available as of April 1, 2023.

AlloSure® Kidney

AlloSure Kidney, a test offered by the same parent company as AlloMap, evaluates cell-free DNA (cfDNA) in the blood for kidney transplant patients. The test states that when

graft injury occurs, donor-derived cell-free DNA is released into the blood where it can be measured as a marker of kidney transplant surveillance. Bloom et al. (2017) evaluated AlloSure Kidney with 102 kidney recipients. They concluded that a donor-derived cell-free DNA (dd-cfDNA) level of >1% indicated active rejection of the graft (Bloom et al., 2017). According to the manufacturer, AlloSure Kidney is validated for use in stable and high-risk patients, patients with allograft rejection, repeat kidney transplant patients, and pediatric patients (CareDX, 2024a).

A 2021 study from Pai et al. examined the clinical rationale behind a routine testing schedule utilizing dd-cfDNA. In this study, they found that dd-cfDNA surveillance was effective at months one, two, three, four, six, nine, and 12 during the first year following kidney transplantation and quarterly thereafter. They noted that these time points "coincide with major immunologic transition points after transplantation" and that these times points provide clinicians with "molecular information to help inform decision making" (Pai et al., 2021).

AlloSure® Heart

AlloSure Heart detects graft injury via a blood test; the test detects injury and rejection by measuring the amount of dd-cfDNA in the blood. Allosure Heart is covered by Medicare after 55 days when ordered in conjunction with AlloMap and with clinical suspicion of rejection. Heartcare by CareDx is another proprietary combination test that offers AlloMap gene expression profiling combined with next-generation sequencing to quantify dd-cfDNA in cardiac transplant recipients. This combination test includes an AlloMap score, the variability of the AlloMap score, and the percent of dd-cfDNA (using Allosure Heart) in one comprehensive single assessment of heart health (CareDx, 2024c).

AlloSure® Lung

AlloSure® Lung is another donor-derived cell-free DNA (dd-cfDNA) test used for transplant recipients that is now commercially available (CareDx, 2024b).

As evidence of its prowess, AlloSure cites what they describe as "the first and only multi-center study to clinically validate the use of dd-cfDNA in lung transplantation"(CareDx, 2024b). In a multicenter, retrospective cohort study, Keller et al. (2022) collected data from lung transplant recipients within three years of transplant and found that "dd-cfDNA was higher in patients with ALAD [acute lung allograft dysfunction] than stable patients" and that the estimated sensitivity of dd-cfDNA ≥1% was 73.9%, specificity of 87.7%, positive predictive value of 43.4% and negative predictive value of 96.5%." Consequently, the authors concluded that "dd-cfDNA identified acute lung allograft dysfunction in asymptomatic lung transplant patients

that may not have been identified by using a clinically indicated biopsy strategy alone," and as such may "support its use as a potential noninvasive marker for surveillance monitoring" (Keller et al., 2022).

Prospera™

Natera, a genetic testing company, has developed the Prospera test, which uses dd-cfDNA to assess kidney, heart, and lung transplant rejection. This blood test is now covered by Medicare for all kidney transplant recipients (Natera, 2024).

Proprietary Tests – Volatile Organic Compounds

Heartsbreath

Another medium used for assessment of rejection is breath. Heartsbreath is an FDA-approved test that purports to predict the probability of grade 3 rejection in heart transplant patients. The test detects "volatile organic compounds" (FDA, 2004a). The FDA notes that this test does not replace biopsy and is only intended as an adjunct to biopsies. The breath markers are considered to be markers of "oxidative stress" (FDA, 2004b).

Clinical Utility and Validity

Pham et al. (2010) conducted a randomized study comparing gene expression profiling and endomyocardial biopsies for monitoring heart transplant patients. A total of 602 patients who had undergone cardiac transplantation six months to five years previously were included. Both groups were found to have similar rates of primary outcomes, hazard ratios, and two year all-causes of mortality. Patients monitored with gene expression profiling underwent fewer biopsies. The researchers concluded that "Among selected patients who had received a cardiac transplant more than 6 months previously and who were at a low risk for rejection, a strategy of monitoring for rejection that involved gene-expression profiling, as compared with routine biopsies, was not associated with an increased risk of serious adverse outcomes and resulted in the performance of significantly fewer biopsies" (Pham et al., 2010).

Deng et al. (2014) evaluated the variability of a heart recipient's gene expression profiling test (AlloMap) scores. Variability was defined as the "the standard deviation of an individual's cumulative test scores." A total of 369 patients from the Invasive Monitoring Attenuation by Gene Expression Profiling (IMAGE) study were included, and "gene expression profiling score variability, but not ordinal scores or scores over threshold, was independently associated with future clinical events." The hazard ratio for a one unit increase in variability was found to be 1.76 (Deng et al., 2014).

Kobashigawa et al. (2015) conducted a single-center randomized controlled trial to evaluate gene expression profiling (GEP) versus endomyocardial biopsy (Moayedi et al.) starting at 55 days post-transplant. Sixty heart transplant patients meeting inclusion criteria were randomized beginning at 55 days post-transplant to either GEP or EMB arms. A positive GEP ≥30 between two and six months, or ≥34 after six months, prompted a follow-up biopsy. The primary end point included a composite of death/retransplant, rejection with hemodynamic compromise or graft dysfunction at 18 months post-transplant. The researchers concluded that "GEP starting at 55 days post-transplant seems comparable with EMB for rejection surveillance in selected heart transplant patients and does not result in increased adverse outcomes. GEP also seems useful to guide corticosteroid weaning" (Kobashigawa et al., 2015).

M. G. Crespo-Leiro et al. (2015) assessed the "prognostic utility of within-patient variability of GEP scores in predicting future significant clinical events, the negative predictive value (NPV) and the positive predictive value (PPV) of GEP score variability in predicting future significant clinical events." A total of 737 patients from the Cardiac Allograft Rejection Gene Expression Observational (CARGO) II trial were included. Estimated prevalence of events was found to be 17%, and events occurred at a median of 391 days after the final GEP test. The authors found that "the GEP variability area under the receiver operator characteristics curve for the prediction of a composite event was 0.72. The NPV for GEP score variability of 0.6 was 97% and the PPV for GEP score variability of 1.5 was 35.4%." The authors concluded that "The GEP score variability may be used in estimating the likelihood of events of death, re-transplantation or graft dysfunction occurring in patients beyond 315 days post-transplant" (M. G. Crespo-Leiro et al., 2015).

Furthermore, Crespo-Leiro et al. (2016) validated the clinical performance of the gene-expression profiling technology in an independent patient population from the CARGO II study. A total of 399 patients were included. The GEP score ranged from 0-39, and the authors identified the optimal cut-off to be 34. At this score (at ≥6 months after transplant), "95.5% (381/399) of GEP tests were true negatives, 4.5% (18/399) were false negatives, 10.2% (6/59) were true positives, and 89.8% (53/59) were false positives." Based on 938 paired biopsies, the area under the curve for distinguishing ≥3A rejection was found to be 0.70 and 0.69 for 2-6 months and ≥6 months, respectively. The authors concluded, "[T]he choice of threshold score for practical use of GEP testing should consider overall clinical assessment of the patient's baseline risk for rejection" (Crespo-Leiro et al., 2016).

Fujita et al. (2017) followed up on the CARGO study by investigating the long-term mortality of 46 patients. They found that 23 patients had an increased AlloMap score 6-9 months after heart transplant whereas the remaining 23 patients had a decreased

score. After a median follow-up time of 8.1 years, all-cause mortality was significantly elevated in patients with an AlloMap increase compared with patients with a decreased score. The authors concluded, "Dynamic changes of the AlloMap score between 6 and 9 months after HT [heart transplant] were strongly related to all-cause long-term survival after HT. These results suggest that AlloMap potentially displays a useful tool to estimate the patients' risk for long-term mortality" (Fujita et al., 2017).

Carey et al. (2018) analyzed 18 months of follow-up in a national cohort of 27 dual organ recipients (18 heart-kidney, eight heart-liver, one heart-lung) matched to 54 heart-only recipients for gender, age, and time to first GEP (AlloMap) test. They found that "during the first 90 days post-transplant, the mean GEP score for dual organ recipients was 25.2 ± 9.1, vs. 23.5 ± 7.7 for heart-only recipients (P = 0.48), with final GEP scores being 29.1 ± 6.1 and 32.3 ± 3.4, respectively (P = 0.34). GEP scores increased over time at a similar rate (P = 0.33) for both groups. During follow-up, mean GEP score among patients with cytomegalovirus infection was 32.3 (n = 14), compared to 26.7 in patients without cytomegalovirus. Only four (2%) of 233 biopsies were positive for mild antibody-mediated rejection; all occurring in two heart-only recipients (GEP scores = 18-33)" (Carey et al., 2018).

Bakir et al. (2018) analyzed time-dependent phenomapping of clinical and molecular data sets from 94 heart transplant patients (1557 clinical encounters) to determine its accuracy in guiding clinical management. Phenomapping's associations were analyzed with "immunosuppression therapy, biomarkers, and the combined clinical end point of death, allograft loss, retransplantation, and rejection," and these findings were further correlated with "clinical parameters, human leucocyte (*sic*) antigen antibody titers, and peripheral blood mononuclear cell gene expression of the AlloMap test genes" (Bakir et al., 2018). The authors found that patients in the group with higher event rates had "increased human leukocyte antigen class I and II antibody titers, higher expression of the *FLT3* AlloMap gene, and lower expression of the *MARCH8* and *WDR40A* AlloMap genes." The authors concluded that "time-dependent precision phenotyping is a mechanistically insightful, data-driven approach to characterize patterns of clinical care and identify ways to improve clinical management and outcomes" (Bakir et al., 2018).

Phillips et al. (2004) evaluated another novel marker of heart transplant rejection: volatile organic compounds (VOCs). A total of 1061 samples were taken from 539 patients prior to endomyocardial biopsy. The combination of nine VOCs in the algorithm "identified Grade 3 rejection (sensitivity 78.6%, specificity 62.4%, cross-validated sensitivity 59.5%, cross-validated specificity 58.8%, positive predictive value 5.6%, negative predictive value 97.2%). Site pathologists identified the same cases with sensitivity of 42.4%, specificity 97.0%, positive predictive value 45.2% and negative predictive value 96.7%" (Phillips et al., 2004). The authors concluded that "a breath test

for markers of oxidative stress was more sensitive and less specific for Grade 3 heart transplant rejection than a biopsy reading by a site pathologist, but the negative predictive values of the 2 tests were similar" (Phillips et al., 2004). However, the Centers for Medicare and Medicaid (CMS) determined that the evidence does not adequately define the technical characteristics of the test nor demonstrate that Heartsbreath testing to predict heart transplant rejection improves health outcomes (CMS, 2009).

Agbor-Enoh et al. (2019) assessed the donor-derived cell-free DNA (ddcfDNA or dd-cfDNA) levels in 106 lung transplant patients and monitored them for development of allograft failure ("defined as severe chronic lung allograft dysfunction [CLAD], retransplantation, and/or death from respiratory failure"). The average level of donor-derived cell-free DNA (%ddcfDNA) was measured and correlated with allograft failure. The authors separated the patients into three tertiles, with median values of 3.6% in the highest tertile, 1.6% in the middle, and 0.7% in the lowest. The highest tertile was calculated to have a 6.6-fold higher risk of allograft failure compared to the lowest and middle tertiles. The researchers concluded, "lung transplant patients with early unresolving allograft injury measured via %ddcfDNA are at risk of subsequent allograft injury, which is often clinically silent, and progresses to allograft failure" (Agbor-Enoh et al., 2019).

A 14-center post-transplant longitudinal study by Bromberg et al. (2017) published in *The Journal of Applied Laboratory Medicine* measured the dd-cfDNA at one, two, three, four, six, nine, and 12 months post-transplant. A total of 380 blood samples were taken during the study, and the median dd-cfDNA value was 0.21%. A value of 1.20% is at the 97.5th percentile. The authors conclude, "In a renal transplant recipient, a dd-cfDNA level above 1.2% is out of range and potentially abnormal" (Bromberg et al., 2017).

Huang et al. (2019) evaluated the ability of cell-free DNA to detect rejection in kidney transplant patients. A total of 63 kidney transplant patients with suspicion of rejection were included. Twenty-seven of these had donor-specific antibodies, and 34 were considered to have rejection by biopsy. The percentage of donor-specific cell-free DNA (dd-cfDNA) was higher in patients with antibody-mediated rejection (AMR) compared to those with no rejection and cell-mediated rejection (AMR: 1.35%, no rejection: 0.38%, cell-mediated rejection: 0.27%). A dd-cfDNA percentage of 0.74% was found to yield a sensitivity of 100%, a specificity of 71.8%, a positive predictive value of 68.6%, and a negative predictive value of 100%. The authors concluded that "the dd-cfDNA test did not discriminate CMR from no rejection among kidney transplant recipients, although performance characteristics were stronger for the discrimination of [AMR]" (Huang et al., 2019).

Schutz et al. (2017) evaluated graft-derived cell-free DNA (GcfDNA)'s ability as a marker for liver transplant rejection. A total of 115 patients were included, and 17 patients contributed samples (n = 31) during a biopsy-proven rejection episode; the remaining 88 contributed samples (n = 282) during stable periods. The samples from the rejection cohort were found to have a higher percentage of GcfDNA than the stable cohort (29.3% vs 3.3%). Liver function tests (LFTs) had low correlation rates with GcfDNA, and the area under the curve was 97.1% for GcfDNA. Overall, the authors concluded that "in this study, determination of GcfDNA allowed for earlier and more sensitive discrimination of acute rejection in liver transplant patients as compared with conventional LFTs" (Schutz et al., 2017).

A meta-analysis focusing on donor-derived cell-free DNA as a diagnostic tool in transplantation conducted by Oellerich et al. (2022) reported that the clinical validity of dd-cfDNA in kidney transplantation has been documented in over 20 studies, and that the exponential decline to a baseline level two weeks after transplantation can be used to discriminate graft injury. Moreover, "Although different concepts have been used to establish threshold values for detection of rejection median dd-cfDNA values in reference populations were very similar ranging from 0.21% to 0.40%," as such consistency is imputed to be evidence of its validity (Oellerich et al., 2022). Elevations of dd-cfDNA have also been observed in patients with TCMR and AMBR, and as such subclinical detection may enable earlier therapeutic interventions and improved outcomes (Halloran et al., 2022; Knight et al., 2019; Oellerich et al., 2022; Oellerich et al., 2021).

Grskovic et al. (2016) performed a validation of AlloSure. The authors included 1117 samples, and AlloSure was used to quantify the fraction of donor-derived cell-free DNA (dd-cfDNA) in both related and unrelated donor-recipient pairs. The quantifiable range was found to be linear from 0.2% to 16%, and the across-runs coefficient of variation was found to be 6.8%. The limit of blank was found to be 0.10%, limit of detection was 0.16%, and limit of quantification was 0.20%. The authors concluded that "application of the assay to clinical samples from heart transplant recipients demonstrated increased levels of dd-cfDNA in patients with biopsy-confirmed rejection and decreased levels of dd-cfDNA after successful rejection treatment" (Grskovic et al., 2016).

M. Crespo-Leiro et al. (2015) compared the levels of dd-cfDNA in heart transplant recipients with biopsy-confirmed rejection to recipients without rejection. A total of 151 plasma samples from 63 patients were evaluated, and 132 of these samples were biopsied. An AlloMap score was also taken. The dd-cfDNA levels were found to be higher in patients with rejection (1.7% vs 0.99%), and an area under curve (Halloran et al.) was measured to be 0.68. The mean AlloMap score was found to be 24.3 in non-

rejection patients and 28.3 for rejection patients. The authors found that the dd-cfDNA levels and AlloMap score were not significantly correlated, proposing that these tests may be complementary. Combining the AlloMap and plasma dd-cfDNA levels yielded an AUC of 0.78 (M. Crespo-Leiro et al., 2015).

Jordan et al. (2018) investigated the use of dd-cfDNA alongside donor-specific antibodies (DSA) testing in identifying antibody-mediated rejection (AMR) of renal allograft recipients (n = 87 patients). They note that the median level of dd-cfDNA was 2.9% in DSA+ patients who have active AMR whereas the dd-cfDNA was significantly lower in both DSA+ patients without AMR (0.34%) or DSA- patients (0.29%). "The positive predictive value of dd-cfDNA (at 1%) to detect active ABMR in DSA+ patients was 81%, whereas the negative predictive value was 83%. The positive predictive value for DSA+ alone was 48%... The combined use of dd-cfDNA and DSA testing may improve the noninvasive diagnosis of active ABMR in kidney transplant patients. Patients with dd-cfDNA+/ DSA+ results have a high probability of active ABMR" (Jordan et al., 2018).

Gielis et al. (2020) obtained samples from 107 kidney transplant recipients to investigate the role of cell-free DNA in acute kidney rejection. Samples were collected between one day and three months after transplantation. The authors noted that increases in cell-free DNA "above a threshold value of 0.88% were significantly associated with the occurrence of episodes of acute rejection (P = 0.017), acute tubular necrosis (P = 0.011) and acute pyelonephritis (P = 0.032)" (Gielis et al., 2020). However, the authors also note that "Although increases in plasma ddcfDNA% are associated with graft injury, plasma ddcfDNA does not outperform the diagnostic capacity of the serum creatinine in the diagnosis of acute rejection" (Gielis et al., 2020).

Peabody et al. (2020) researched the clinical utility of the dd-cfDNA Prospera test by Natera to lower the rate of kidney graft loss. Simulated cases of 154 nephrologists were analyzed for this study; some physicians used dd-cfDNA testing and some did not. Results show that at baseline, there were no differences between primary diagnosis, biopsy decisions, or therapeutic management. However, after use of the cc-cfDNA test, "intervention nephrologists were more likely to arrive at the diagnosis of rejection (OR 4.00, 95% CI 1.93-8.30), make a correct decision on biopsy/transplant center referral (OR 11.07, 95% CI 4.87-25.16), and properly adjust therapeutic management (OR 2.37, 95% CI 1.07-5.24)" (Peabody et al., 2020).

Sigdel et al. (2018) evaluated an SNP-based assay's accuracy in identifying allograft rejection or injury. The assay is intended to identify rejection through measurement of donor-derived cell-free DNA (dd-cf DNA). A total of 193 unique renal transplant patients were included, with a total of 300 plasma samples provided. Of the 300

samples, 217 were biopsy-matched, 38 had active rejection (AR), 72 had borderline rejection (BL), 25 had other injury (Breda et al.), and 82 were stable (STA). The authors found that median dd-cfDNA was higher in biopsy-proven AR (2.3%) compared to BL (0.6%), OI (0.7%), and STA (0.4%). The assay was found to discriminate active rejection from non-rejection at an area under curve of 0.87, 88.7% sensitivity, and 72.6% specificity (at a cutoff of 1% dd-cfDNA). Of 13 patients with AR findings after six months, 12 tested positive by the assay. The authors concluded that their data supported the "feasibility of using this assay to detect disease prior to renal failure and optimize patient management in the case of allograft injury" (Sigdel et al., 2018).

Altug et al. (2019) performed an analytical validation of a "single-nucleotide polymorphism [SNP]-based donor-derived cell-free [cf] DNA assay for detecting rejection in kidney transplant patients". This test measured 13962 SNPs and was validated using 66 unique samples with 1064 replicates. The authors measured the cf-DNA fraction in related and unrelated (genetically related) donor-recipient pairs. The authors identified a "limit of blank" of 0.11% and a limit of detection and quantitation of 0.15% for unrelated donors. For related donors, a limit of blank of 0.23% and a limit of detection and quantitation of 0.29% was identified. Other metrics such as precision and linearity were found to be identical for both categories. The coefficient of variance was found to be 1.8%. The authors concluded that their findings were an adequate analytical validation of the assay (Altug et al., 2019).

In a retrospective, observational study, Rodgers et al. (2023) evaluated the correlation, classification, and prediction for AR across two donor-derived cell-free DNA tests and a blood gene-expression profile test in heart transplantation. Looking at patients who had an EMB and both standard and expanded SNP dd-cfDNA testing in the 14 days preceding the EMB, the authors found that "Both standard and expanded SNP dd-cfDNA tests showed no significant difference in testing accuracy for AR," as the sensitivities of standard SNP and expanded SNP were reported to be 39% and 39%, respectively ($p = 0.66$). The authors also reported that "Specificity with standard SNP was 82% and expanded SNP testing 84% ($p = .26$). PPV with standard SNP was 6.2% and expanded SNP testing 7.0% ($p = .70$). NPV with standard and expanded SNP testing were both 98% ($p = .76$)". Moreover, the researchers evaluated the screening performance of combining GEP with standard SNP testing (standard dd-cfDNA + GEP), commercially packaged as HeartCare® and determined that "specificity of standard dd-cfDNA + GEP was 47%, which was significantly lower when compared to either standard or expanded SNP dd-cfDNA tests individually ($pc < .001$)". Regarding the use of GEP in the detection of ACR, "we [the authors] showed GEP specificity was significantly lower than standard SNP dd-cfDNA ($pc < .001$) but otherwise did not show a significant difference for sensitivity, PPV, and NPV for detection of ACR" and, most notably, "Standard dd-cfDNA + GEP similarly showed significantly reduced

specificity versus standard SNP testing alone for detection of ACR (pc < .001)" (Rodgers et al., 2023). As such, the results suggest that additional coverage offered by expanded SNP assay as compared to the standard SNP assay does "not show a direct impact on discrimination of AR in HTx patients in this study" and "that dd-cfDNA testing, without GEP, is sufficient" for the detection of ACR (Rodgers et al., 2023).

Henricksen et al. (2023) conducted a single center, retrospective analysis of adult heart transplant recipients. There, they focused on survival and rejection-free survival one-year post-transplant as primary endpoints for "A GEP cohort, transplanted from January 1, 2015 through December 31, 2017 and eligible for rejection surveillance with GEP was compared to a paired testing cohort, transplanted July 1, 2018 through June 30, 2020, with surveillance from both dd-cfDNA and GEP". The authors found that "At 1-year, there were no differences between the paired testing and GEP groups in survival (98.4% vs. 94.7%, P = .23) or rejection-free survival (81.3% vs. 73.7% P = .28)," concluding that "Compared to post-transplant rejection surveillance with GEP alone, pairing dd-cfDNA and GEP testing was associated with similar survival and rejection-free survival at 1 year," with the benefit of requiring significantly fewer biopsies (Henricksen et al., 2023).

The use of RNA microarray analysis has also begun to garner attention. The INTERCOMEX (International Collaborative Microarray Study Extension) explored the feasibility of real-time MMDx kidney transplant biopsy assessment by comparing the central MMDx assessment with local stand-of-care in 10 experienced North American and European centers that followed Banff 2013 guidelines. 519 samples from 491 patients were deemed sufficient for RNA microarray analysis (3mm), which was used to determine agreement between the histologic diagnoses. The distribution of the principal diagnoses was as follows: antibody-mediated rejection (ABMR, n=88, 17%), ABMR suspected (n=10, 2%), T cell-mediated rejection (TCMR, n=29, 6%), acute kidney injury (AKI, n=43, 8%), "borderline" (n=31, 6%), unexplained atrophy/fibrosis (n=84, 16%), and "no major abnormalities" (n=141, 27%). According to the authors, the report sign-out diagnosis of rejection agreed with histology with a normalized accuracy of 76-77% overall. However, dissecting the accuracy assessment for MMDx yielded PPVs of 51%, 45%, and 90% for ABMR, TCMR, and rejection, respectively, and NPVs of 92%, 96%, and 54% for the same (Halloran et al., 2017). Nevertheless, the authors concluded that "Feedback received for 451 biopsy samples indicates that clinicians agreed with MMDx more often than with their local biopsy assessment and indicated that MMDx would give them more confidence for clinical management" (Halloran et al., 2017).

Alam et al. (2022) evaluated whether MMDx performs in agreement with other validated modalities. Two hundred and twenty-eight corresponding endomyocardial biopsies and MMDx specimens from 135 adult heart transplant patients were

retrospectively reviewed with correlating donor-derived cell-free DNA (dd-cfDNA). "Rejection was classified on endomyocardial biopsies in 29 specimens (TCMR ≥ 2R and/or AMR ≥ 1), on MMDx in 56 specimens, and in 74 values with dd-cfDNA ≥0.20%. Despite moderate agreement between endomyocardial biopsies and MMDx (84% agreement, Cohen's kappa, 0.48, p < .001), systematic differences were observed (McNemar's test, p < .001) where MMDx classified 32 of 37 discordant cases as rejection. MMDx and dd-cfDNA demonstrated slight agreement (72% agreement, Cohen's kappa, 0.39, p < .001); however, systematic differences were also apparent where MMDx classified 12 of 50 discordant specimens as rejection when dd-cfDNA was <0.20% (McNemar's test, p < .001)" (Alam et al., 2022). Alam et al. (2022) findings provide insight on the performance of MMDx relative to other modalities in a heart transplant cohort and have implications on the surveillance and workup of allograft rejection in heart transplantation.

More recently, the TruGraf blood test has emerged as another possible alternative to expensive and invasive biopsies. This proprietary microarray-based test relies on specific gene expression in the peripheral blood as a means of providing information on the adequacy of immunosuppression in transplant candidates with stable renal function, who may manifest subclinical acute rejection (subAR). A study conducted at the Northwestern University Comprehensive Transplant Center and five participating clinical centers for the Genomics for Kidney Transplantation Project reported that in the 125 candidates demonstrating stable renal function, the TruGraf classifier boasted a PPV of 86% (95% CI: 83-89%) and an NPV of 28% (95% CI 13-49%) (First et al., 2017). In another study, simultaneous blood tests and clinical assessments were conducted on 192 patients from seven transplant centers to evaluate the predictive power of TruGraf v1. Researchers found that the accuracy of TruGraf—defined here as the agreement between TruGraf result and clinical and/or histologic assessment—was 74% (142/192), with an NPV of 90% (Marsh et al., 2019). Given the data, the researchers assert that the use of the TruGraf classifier will eschew unnecessary surveillance biopsies with high confidence and lead to personalization of management in patient care. However, though these results seem promising, the predictive power of TruGraf in patients with graft dysfunction has yet to be evaluated.

Moayedi et al. (2019) published results from the Outcomes AlloMap Registry (OAR) study, a multi-center prospective observational study. The OAR study was comprised of the largest group of patients – 1,504

patients – who had undergone gene expression profiling (GEP) for surveillance purposes to-date. Patients were aged ≥ 15 years and ≥ 55 days post-cardiac transplant with a median age of 54 years old. Results indicated the prevalence of "moderate to severe acute cellular rejection (≥2R) was 2.0% from 2 to 6 months and 2.2% after 6

months." Post-transplant survival at one, two, and five years was 99%, 98%, and 94%, respectively. The authors concluded that patients selected for GEP surveillance had excellent survival outcomes as well as low rates of acute rejection, graft dysfunction, readmission, and death (Moayedi et al., 2019).

As part of the D-OAR (utility of donor-derived cell free DNA in association with gene expression profiling) trials, Khush et al. (2019) reported overall that "dd-cfDNA levels differed significantly between patients with and without AR," such that the "median level of dd-cfDNA in patients with AR was significantly higher (0.17%) than in the group of patient specimens without rejection (0.07%, P < .001)" but that "Median dd-cfDNA levels were 0.17% for both ACR and AMR" (Khush et al., 2019). When considering only the planned biopsy samples, the authors found that "Statistically different median dd-cfDNA levels were observed in patients with and without rejection" (p = 0.02, n = 254), while the surveillance biopsy analysis sample size (n = 587) was purportedly "too small to detect a statistically significant difference in median dd-cfDNA levels" (p =0.140) (Khush et al., 2019). Consequently, the researchers conclude that "We [the authors] demonstrated that dd-cfDNA levels are significantly higher in patients with AR compared with patients with no biopsy evidence of rejection" and that "Surveillance with dd-cfDNA may therefore detect early rejection and thereby trigger augmentation of immunosuppression to prevent a more severe rejection event that may result in irreversible graft damage." However, it should also be noted that many patients were enrolled later than two months posttransplant and that the technique used to evaluate dd-cfDNA test performance (i.e., endomyocardial biopsy) is not a true "gold standard" for the diagnosis of AR (Khush et al., 2019).

Knüttgen et al. (2022) analyzed dd-cfDNA percentage in 87 heart transplant recipients. The study goal was to determine the clinical validity of using graft-derived cell-free DNA as well as the association of dd-cfDNA measurements with cardiac allograft rejection. Per the results, sensitivity was 76% and specificity was 83% for cardiac rejection with approximately a 95% confidence interval. Overall, the authors concluded that dd-cfDNA plasma values were "significantly associated with cardiac rejection", but that pericardial effusions and/or improper sampling "should be considered" as having the ability to confound results in a clinical setting (Knüttgen et al., 2022).

Kamath et al. (2022) evaluated 72 adult heart transplant patients with at least three concurrent AlloMap/AlloSure results in a single-center retrospective study. The aim of the study was to evaluate the performance of AlloSure, AlloMap, and a combination approach in predicting mortality. During the 480-day follow-up period, five patients died. Higher AlloSure variability (HR 1.66, 95%CI 1.14 – 2.41) was associated with increased mortality risk. However, there was not a strong association (of mortality) with higher AlloMap variability, or of combination AlloSure/AlloMap variability. The authors

concluded that, "increased variability of dd-cfDNA in heart transplant patients is associated with both mortality risk and the presence of donor specific antibodies" (Kamath et al., 2022).

An observational study by Kim et al. (2022) aimed to capture the performance of the Prospera dd-cfDNA test in detecting AR in adult heart transplant recipients. The authors reported that "Median dd-cfDNA fraction was significantly higher in samples with a matched biopsy showing AR (median 0.58%, IQR, 0.13%–1.68%) compared to samples where matched biopsies did not show AR (median 0.04%, IQR, 0.01–0.11%, pc < 0.001". This was confirmed for this study population through ROC analysis, where "the AUC-ROC of the dd-cfDNA test to distinguish AR from non-AR was 0.86" and using a dd-cfDNA fraction threshold of 0.15%, "dd-cfDNA detected histologically-proven rejection with a sensitivity of 78.5% (95% CI, 60.7%–96.3%) and a specificity of 76.9% (95% CI, 71.1%–82.7%). A PPV of 25.1% (95% CI, 18.8%–31.5%) and NPV of 97.3% (95% CI, 95.1%–99.5%) were calculated for this cohort (Kim et al., 2022). However, the authors acknowledge that "there may have been a selection bias for patients with previous history or suspicion of AMR, who would be more frequently biopsied at our [the chosen] centers," the higher prevalence of AR in the cohort making it difficult to generalize to patient cohorts with a different risk of rejection, and the limited number of sequential samples (Kim et al., 2022).

Other techniques may be also be worth noting in the future. Montero et al. (2019) analyzed 12 studies and 1181 patients and found that pretransplant interferon-γ enzyme-linked immunospot (IFN-γ ELISPOT) was "significantly associated with increased AR risk (odds ratio: 3.29; 95% confidence interval (CI), 2.34-4.60); hierarchical summary receiver operating characteristic jointly estimated sensitivity and specificity values were 64.9% (95% CI, 53.7%-74.6%) and 65.8% (95% CI, 57.4%-73.5%), respectively, with moderate heterogeneity across studies". But though this is the case, "Prospective randomized clinical trials are warranted" given the "suboptimal predictive ability at an individual level" (Montero et al., 2019).

Holzhauser et al. (2023) reviewed the evidence supporting both GEP and dd-cfDNA testing in heart transplant rejection and provided practical guidance for clinicians to allow for a transition to less invasive options for monitoring rejection after heart transplantation, as well as answering some of the common questions about GEP and dd-cfDNA. One important question they answered was when GEP and dd-cfDNA monitoring should begin post-transplant. As mentioned by previous sources, 55 days post-heart transplant is the earliest timepoint at which GEP monitoring should begin, as the performance of the GEP can be affected by the administration of corticosteroid therapy. In contrast, the dd-cfDNA assay results stabilize approximately 14 days post-

heart transplantation and many centers are using dd-cfDNA surveillance as early as three to four weeks post-transplantation (Holzhauser et al., 2023).

VI. Guidelines and Recommendations

International Society of Heart and Lung Transplantation (ISHLT)

In 2023, the International Society of Heart and Lung Transplantation issued guidelines for the care of heart transplant recipients (Velleca et al., 2023). Below are the recommendations relevant to this policy.

- "It is reasonable to utilize EMB in a HT candidate suspected of having an infiltrative cardiomyopathy or an inflammatory process, such as giant cell myocarditis, amyloidosis, or sarcoidosis. Class IIa, Level of Evidence C
- It is reasonable to perform periodic EMB during the first three to 12 postoperative months for surveillance of rejection **Class IIa, Level of Evidence: C**
- The standard of care for adolescents should be similar to adults, including surveillance EMB for heart allograft rejection for 3 to 12 months after HT. In younger children, especially infants, the risks associated with EMB and required general anesthesia may outweigh the surveillance benefit for comparably rare acute rejection; therefore, it is reasonable to use a combination of noninvasive screening methods (echocardiography, ECG, biomarkers) instead. **Class IIa, Level of Evidence: C**
- After the first postoperative year, it is reasonable to continue EMB surveillance in patients who are at higher risk for late acute rejection. This group includes HT recipients with donor-specific antibodies (DSA), a history of recurrent acute rejection, calcineurin-inhibitor free immunosuppression, reduced immunosuppression due to post-transplant malignancy or chronic infection, African American descent. **Class IIa, Level of Evidence: C**
- Routine EMB later than 5 years after HT are not recommended. EMB should be performed only for cause in patients with signs or symptoms of cardiac allograft dysfunction.
  Class III, Level of Evidence: C
- Children receiving ABO incompatible cardiac allografts in the first 2 years of life with isohemagglutinin titers toward the donor blood group below 1:32 and without elevated titers post-transplant do not require more frequent EMB or non-invasive monitoring compared to recipients of ABO compatible organs. **Class IIa, Level of Evidence: B**

- Ventricular evoked responses (VER) monitoring for rejection surveillance is no longer recommended as the technology has become obsolete. **Class III, Level of Evidence: C**
- Gene Expression Profiling (GEP) (i.e., Allomap) of peripheral blood can be used in low-risk patients between 2 months and 5 years after HT to identify adult recipients who have low risk of current ACR to reduce the frequency of EMB. Data in children does not allow a general recommendation of GEP as a routine tool at present.
  Class IIa, Level of Evidence: B
- It is reasonable to integrate biomarkers such as BNP and high-sensitivity troponins into a rejection monitoring strategy to identify higher risk patients who may benefit from additional evaluation for ACR, AMR, or CAV.
- **Class IIb, Level of Evidence C**
- Post-transplant monitoring for DSA should be performed at 1, 3, 6, and 12 months postoperatively and annually thereafter. Sensitized patients should be monitored more frequently. **Class IIa, Level of Evidence C**
- The use of systemic inflammatory markers such as C-reactive protein (CRP) for acute heart allograft rejection monitoring is not recommended. **Class III, Level of Evidence: C**
- In younger children, especially infants, the risks associated with EMB and required general anesthesia may outweigh the surveillance benefit for comparably rare acute rejection; therefore, it is reasonable to use a combination of noninvasive screening methods (echocardiography, ECG, biomarkers) instead. **Class IIa, Level of Evidence: C**
- Use of the immune cell function assay (ImmuKnow) cannot be recommended in adult and pediatric heart transplant recipients for rejection monitoring. **Class III, Level of Evidence B**
- **Patient Management During a Pandemic**: Efforts should be made to reduce visits by clinically stable heart transplant patients to medical facilities by shifting blood testing to the patients' homes. Remote drawing of blood samples can include screening tests to determine if patients require endomyocardial biopsies using gene expression profiling and donor derived cell-free DNA assays. **Class I, Level of Evidence C"** (Velleca et al., 2023)

In a 2016 guideline discussing antibody-mediated rejection (AMR) of the lung, the ISHLT noted the lack of specific diagnostic criteria for AMR and listed allograft dysfunction, positive histology, positive C4d staining, and donor-specific anti–human

leukocyte antigen (HLA) antibodies (DSA) as potential diagnostic items for AMR (ISHLT, 2016).

Regarding chronic lung allograft dysfunction (CLAD), the society recommended the following:

- "In stable CLAD patients with stable FEV1 [forced expiratory volume in 1 second] or a very slow decline in FEV1 (so-called plateau phase), it is advised to have lung function measured at least every 3 or 4 months."
- "We recommend measuring TLC [total lung capacity] in LTx patients at 3 and 6 months after transplant and annually thereafter. TLC measurements should also be obtained if changes ≥10% from previous values. The "gold standard" technique to assess TLC is body plethysmography."
- "The initial CT scans (inspiratory views with a maximum width of 3-mm sections, and expiratory sections as well) without contrast media are recommended in all LTx patients at 6-month follow-up (when spirometry is usually optimal). Repeat CT studies should be obtained when CLAD is initially diagnosed to better visualize air trapping and various subtle opacities."
- "Transbronchial biopsy and bronchoalveolar lavage (BAL) have a major role in the detection of treatable causes prior to the diagnosis of definite CLAD and should be performed at the start of the diagnostic process to investigate the decline in lung function not explained by obvious, non-CLAD causes."
- "BAL should also be assessed for signs of aspiration, which is suggested by the presence of multinucleated giant cells or foreign organic material (such as meat and plant material), and/or of lipid, as demonstrated on a lipid stain such as oil red-O or Sudan black and/or bile acids (detected by enzymatic assay)" (Verleden et al., 2019).

American Society of Transplant Surgeons (ASTS)

A positional statement on the role of dd-cfDNA in transplant surveillance was approved by the ASTS Executive Committee in March of 2023. The statement aims to provide clarity for clinicians and to advocate for access to molecular diagnostic techniques to support improvement in long term allograft function. ASTS recommends the following, particularly for adult individuals:

- "We suggest that clinicians consider measuring serial dd-cfDNA levels in kidney transplant recipients with stable renal allograft function to exclude the presence of subclinical antibody mediated rejection.

- We recommend that clinicians measure dd-cfDNA levels in kidney transplant recipients with acute allograft dysfunction to exclude the presence of rejection, particularly antibody-mediated rejection (ABMR).
- We do not recommend the use of blood gene expression profiling (GEP) in kidney transplant recipients for the purpose of diagnosing or excluding sub-clinical rejection, as adequate evidence supporting such use is still lacking.
- We do not recommend the use of blood GEP to diagnose or exclude the presence of acute graft rejection in kidney transplant recipients with acute allograft dysfunction given the paucity of data to support this practice.
- We recommend that dd-cfDNA may be utilized to rule out subclinical rejection in heart transplant recipients.
- We recommend that clinicians utilize peripheral blood GEP as a non-invasive diagnostic tool to rule out acute cellular rejection in stable, low-risk, adult heart transplant recipients who are over 55 days status post heart transplantation.
- We recommend that there is still insufficient evidence to recommend dd-cfDNA or GEP testing in liver transplant recipients" (ASTS, 2023).

American Society of Transplantation (ASTS)

The AST's Thoracic and Critical Care Community published a review of currently available and emerging biomarkers to aid in the management of heart transplant recipients. The panel expressed a need for larger and more sophisticated studies to rigorously validate the growing number of potentially useful biomarkers in heart transplant medicine; this need is underscored by the growing awareness that the current gold-standard for detecting rejection (endomyocardial biopsy) has several limitations.

Based on the currently available data, over half the members of the expert panel agreed that Donor-specific HLA antibodies (DSA) and dd-cfDNA used in combination may be the optimal biomarkers to assess clinical outcomes for heart transplant recipients. Despite this potential, however, the committee cautions that current dd-cfDNA assays lack tissue specificity, cannot distinguish between ACR and AMR, and have unproven clinical utility in the context of heart transplant medicine (due to a lack of clinical utility trials) (Kobashigawa et al., 2023).

Heart Failure Association of the European Society of Cardiology (ESC)

The Heart Failure Association of the European Society of Cardiology published a position statement on Advanced Heart Failure (Crespo-Leiro et al., 2018) which states: "Post-transplant patients should undergo a pre-defined regimen of graft biopsies, titration of immunosuppressive and other therapies, rejection monitoring, assessment for infections, transplant coronary artery disease and/or cardiac allograft vasculopathy,

immunosuppression side effects, and other potential complications including neoplasia, and co-morbidities that require comprehensive treatment."

A joint position statement on endomyocardial biopsy (Moayedi et al.) by the Heart Failure Association, Heart Failure Society of America, and Japanese Heart Failure Society Position elaborates, stating that "EMB remains the gold standard for the detection of HTx rejection. EMB after HTx can be scheduled according to a protocol for routine surveillance EMB (rsEMB) in asymptomatic patients, and it is also performed in patients with worsening clinical status, as a symptom triggered EMB." However, it is admitted that though this is the case, "there is a lack of consensus on the optimal timing and frequency of rsEMB" (Seferović et al., 2021).

European Association of Urology (M. Crespo-Leiro et al.)

The European Association of Urology published guidelines on renal transplantation. In it, they state that "the ultimate standard for the diagnosis of rejection is transplant biopsy, because it is impossible to differentiate acute rejection solely on clinical indicators from other causes of renal dysfunction (e.g. acute tubular necrosis, infection, disease recurrence or CNI nephrotoxicity). Therefore, all rejections should be verified by renal biopsy" (Breda et al., 2022).

The EAU also asserted that when it comes to matching donors with recipients, the following recommendations apply:

- "Determine the ABO blood group and the human leukocyte antigen A, B, C and DR phenotypes for all candidates awaiting kidney transplantation."
- "Test both the donor and recipient for human leukocyte antigen DQ. Human leukocyte antigen DP testing may be performed for sensitised patients."
- "Perform thorough testing for HLA antibodies before transplantation."
- "Perform adequate cross-match tests to avoid hyper-acute rejection, before each kidney and combined kidney/pancreas transplantation" (Breda et al., 2022).

Renal Association (RA)

The Renal Association published guidelines regarding post-operative care for kidney transplant patients. These guidelines have been endorsed by the British Transplant Society (BTS). The assessment of rejection recommendations is provided below:

- "We recommend that a transplant renal biopsy should be carried out before treating an acute rejection episode unless this will substantially delay treatment or pose a significant risk to the patient."

- "We recommend that a protocol transplant renal biopsy, defined as a biopsy performed in a stable graft without clinical evidence of acute rejection, be considered in the setting of persisting delayed graft function."

Furthermore, in the rationale, the RA states that "Rejection episodes are characteristically associated with loss of graft function but diagnosis is best established by a percutaneous biopsy since it differentiates rejection clearly from other causes of graft dysfunction. Recognition of different forms of rejection may inform different treatment regimens (e.g. antibody mediated rejection)" (Baker et al., 2017).

American Association for the Study of Liver Diseases (AASLD) and the American Society of Transplantation (ASTS)

These joint guidelines provide guidance on the long-term management of liver transplants. Their recommendations concerning assessment of rejection are as follows:

- "Rejection can be reliably diagnosed only on the basis of liver histology; a biopsy sample should be taken before treatment initiation and classified according to the Banff criteria."
- The guidelines also note that "Both forms of rejection are, until the late stages, asymptomatic, and the diagnosis is made through the investigation of abnormal liver tests; the diagnosis can be confirmed only on the basis of histology" (Lucey et al., 2013).

Kidney Disease: Improving Global Outcomes (KDIGO)

The KDIGO does not list any gene expression or cell-free DNA techniques in their guideline for evaluating and managing transplant recipient patients (KDIGO, 2010, 2020).

European Society for Organ Transplantation (ESOT)

A working group from the European Society for Organ Transplantation submitted a Broad Scientific Advice request to the European Medicines Agency (EMA) outlining the alloimmune and non-alloimmune factors driving allograft rejection. ESOT proposes the following for alloimmune risk stratification in CDC-negative kidney transplantation:

- Transplantation performed with an HLA-identical donor carries a significantly lower immunological risk than transplantation from a donor of another HLA status.
- For the same allogeneic eplet load, grafts from living donors, which are better preserved and are therefore less immunogenic than grafts from deceased donors, are associated with a lower immunological risk.

- Patients with anti-donor serological memory at the time of or short time before transplantation (i.e., those with the presence of HLA-DSA) should be clearly differentiated from the others:
  - Patients with donor reactivity are likely to have immune reactions to the allograft, with a heightened risk of post-transplant AMR and poor allograft outcome.
  - SAB testing is the gold standard to establish the repertoire of serologic memory and define the presence of a recipient's circulating anti-HLA DSA.
    - Local transplant physicians and immunologists should determine the appropriate cut-off point, with a focus on plausibility of immunization history.
    - In absence of clinical validation, non–HLA-DSA routine screening assays should not be considered when evaluating immunological risk of a transplantation.
  - Using SAB testing, three risk groups can be identified (patients with non–donor-specific HLA antibodies and no previous exposure to donor antigen are considered as naïve patients):
    - Group 1: Patients with no signs of anti-HLA immune sensitization at any time point (very low risk).
    - Group 2: Patients with previous exposure to donor antigens or history of HLA-DSA positivity, but without HLA-DSA at time of transplantation (intermediate risk due to likely presence of memory T and/or B alloimmune response): T/B ELISpot assays could identify anti-donor memory cells, but without clinical validation these assays should not be considered when evaluating immunological risk of a transplantation.
    - Group 3: Patients with HLA-DSA at time of transplantation (high risk). There is ongoing discussion on the utility of MFI in SAB or FCXM as a potential surrogate to estimate the DSA titer and for individual risk stratification.
    - Molecular HLA mismatch analysis is likely to play a future role in better allocating more compatible allografts, as well as in stratifying the primary alloimmune risk. However, in the absence of consensus regarding what algorithm (and which cut-off) should be used to quantify the eplet load and whether the quality of eplet should also be considered, it is difficult to integrate such information immediately into clinical practice and clinical trial design. Further consensus building is necessary.
    - Although it is a fast-evolving field, no reliable test is currently available to measure innate immune alloreactivity in routine clinical practice. (Bestard et al., 2022)

In reviewing these conclusions, the Committee for Medicinal Products for Human Use (CHMP) of the European Medicines Agency (EMA) "agreed that several important issues need to be considered in assessing the alloimmune risk following kidney transplantation. These include general characteristics of the recipient and donor, as well as issues related to the transplanted organ and issues requiring further studies and/or consensus before adapting into general guidelines" (Bestard et al., 2022).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

AlloMap was approved by the FDA on August 26, 2008, as an In Vitro Diagnostic Multivariate Index assay (IVDMIA) test service, performed in a single laboratory, assessing the gene expression profile of RNA isolated from peripheral blood mononuclear cells (PBMC). AlloMap Testing is intended to aid in the identification of heart transplant recipients with stable allograft function who have a low probability of moderate/severe acute cellular rejection (ACR) at the time of testing in conjunction with standard clinical assessment (FDA, 2008).

The Heartsbreath test received approval on February 24, 2004, through the FDA's humanitarian device exemption. The order is described as being "indicated for use as an aid in the diagnosis of grade 3 heart transplant rejection in patients who have received heart transplants within the preceding year. The heartsbreath test is intended to be used as an adjunct to, and not as a substitute for, endomyocardial biopsy. The use of the device is limited to patients who have had endomyocardial biopsy within the previous month" (FDA, 2004b).

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by

the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81479	Unlisted molecular pathology procedure
81595	Cardiology (heart transplant), mRNA, gene expression profiling by real-time quantitative PCR of 20 genes (11 content and 9 housekeeping), utilizing subfraction of peripheral blood, algorithm reported as a rejection risk score Proprietary test: AlloMap® Lab/Manufacturer: CareDx, Inc.
81599	Unlisted multianalyte assay with algorithmic analysis
84999	Unlisted chemistry procedure
0055U	Cardiology (heart transplant), cell-free DNA, PCR assay of 96 DNA target sequences (94 single nucleotide polymorphism targets and two control targets), plasma Proprietary test: myTAIHEART Lab/Manufacturer: TAI Diagnostics, Inc.
0087U	Cardiology (heart transplant), mRNA gene expression profiling by microarray of 1283 genes, transplant biopsy tissue, allograft rejection and injury algorithm reported as a probability score Proprietary test: Molecular Microscope® MMDx-Heart Lab/Manufacturer: Kashi Clinical Laboratories
0088U	Transplantation medicine (kidney allograft rejection), microarray gene expression profiling of 1494 genes, utilizing transplant biopsy tissue, algorithm reported as a probability score for rejection Proprietary test: Molecular Microscope® MMDx-Kidney Lab/Manufacturer: Kashi Clinical Laboratories
0118U	Transplantation medicine, quantification of donor-derived cell-free DNA using whole genome next-generation sequencing, plasma, reported as percentage of donor-derived cell-free DNA in the total cell-free DNA Proprietary test: Viracor TRAC™ dd-cfDNA Lab/Manufacturer: Viracor Eurofins
0319U	Nephrology (renal transplant), RNA expression by select transcriptome sequencing, using pretransplant peripheral blood, algorithm reported as a risk score for early acute rejection Proprietary test: Clarava™ Lab/Manufacturer: Verici Dx/Verici Dx, Inc

CPT	Code Description
0320U	Nephrology (renal transplant), RNA expression by select transcriptome sequencing, using posttransplant peripheral blood, algorithm reported as a risk score for acute cellular rejection Proprietary test: Tuteva™ Lab/Manufacturer: Verici Dx/Verici Dx, Inc

Use of Common Genetic Variants (single nucleotide polymorphisms) to Predict Risk of Non-Familial Breast Cancer

Policy Number: AHS – M2126 – Use of Common Genetic Variants (single nucleotide polymorphisms) to Predict Risk of Non-Familial Breast Cancer	Prior Policy Name and Number, as applicable:
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY |SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Single nucleotide polymorphisms (SNPs) are single-base pair changes that achieve a population frequency of at least one percent. They represent the most common form of genetic variation and are responsible for much of the heritable phenotypic variation observed in human populations, but are not clearly deleterious (Attia, 2024; MedlinePlus, 2024).

II. Related Policies

Policy Number	Policy Title
AHS-M2020	Molecular Diagnostics for Breast Cancer Prognosis

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

1) For all situations, testing for one or more single nucleotide polymorphisms (SNPs) to estimate an individual's risk for developing breast cancer (e.g., OncoArray,

TruSight®, and BREVAGenplus™ breast cancer tests; tests offered directly to consumers) **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
ASCO	American Society of Clinical Oncology
ATM	*ATM serine/threonine kinase*
AUC	Area under the curve
BCRAT	Breast cancer risk assessment tool
BCSC	Breast cancer surveillance consortium
BMI	Body mass index
BRCA1	*BRCA1 DNA repair associated*
BRCA2	*BRCA2 DNA repair associated*
CHEK2	*Checkpoint kinase 2*
CLIA '88	Clinical Laboratory Improvement Amendments Of 1988
CMS	Centers For Medicare and Medicaid Services
CRISPLD2	*Cysteine rich secretory protein LCCL domain containing 2*
DA	Dense tissue
ER	Estrogen receptor
FDA	Food and Drug Administration
GWAS	Genome-wide association studies
HER2	Human epidermal growth factor 2
IL-13	*Interleukin 13*
IQ-QR	Interquartile range odds ratio
LDT	Laboratory developed test
MD	Mammographic density
NCCN	National Comprehensive Cancer Network
NDA	Non-dense tissue
PALB2	*Partner and localizer of BRCA2*
PMD	Percent density
PR	Progesterone receptor
PRS	Polygenic risk score
SNP88	Single nucleotide polymorphism risk score
SNP	Single nucleotide polymorphism
SHOX2	*Short stature homeobox 2*
TWAS	Transcriptome-wide association study
USPSTF	United States Preventive Services Task Force
VUS	Variant of uncertain significance

V. Scientific Background

In the United States, breast cancer is the second most diagnosed cancer, following skin cancer, and, the second most common cause of cancer death in women, following lung cancer. Approximately one in eight women will develop breast cancer in their lifetime (ACS, 2024).

Breast cancer risk is strongly associated with both genetic and environmental factors. Familial aggregation and twin studies have shown that inherited susceptibility plays a substantial role in risk of developing breast cancer (Lichtenstein et al., 2000; Peto & Mack, 2000). Many genetic loci are known to contribute to this risk. These loci fall into three categories: genes with high-penetrance mutations (notably *BRCA1* and *BRCA2*), moderate-risk alleles in genes such as *ATM*, *CHEK2* and *PALB2*, and common lower penetrance alleles (Michailidou et al., 2013), of which almost 80 have been identified, principally through genome-wide association studies (GWAS) (Ahmed et al., 2009; Antoniou et al., 2010; Bojesen et al., 2013; Cox et al., 2007; Easton et al., 2007; Fletcher et al., 2011; French et al., 2013; Garcia-Closas et al., 2013; Ghoussaini et al., 2012; Haiman et al., 2011; Michailidou et al., 2013; Stacey et al., 2007; Stacey et al., 2008; Thomas et al., 2009; Turnbull et al., 2010; Vachon et al., 2015; Zheng et al., 2009). GWAS continues to identify additional risk loci, with 65 loci identified by Michailidou et al. (2017). Coupled with established risk factors, these loci are likely to increase the utility and accuracy of clinical risk prediction.

For sporadic (nonfamilial) breast cancer, the Breast Cancer Risk Assessment Tool (BCRAT), most often referred to as the Gail model (Gail et al., 1989) is commonly used to produce individual risk estimates in women. The model incorporates individual risk factors including age, family history (breast cancer among first-degree relatives), personal reproductive history (age at menarche and at first live birth), and personal medical history (number of previous breast biopsies and presence of biopsy-confirmed atypical hyperplasia) to identify women who have an increased 5-year risk and lifetime risk of invasive breast cancer and who may benefit from risk reduction with selective estrogen receptor (ER) modulators (Kinsinger et al., 2002; Visvanathan et al., 2009). While this model has implications for primary prevention of invasive breast cancer, both the discriminatory accuracy of the Gail model and its calibration in certain populations have been challenged (Mealiffe et al., 2010). In 2018, Wang et al. (2018) systematically reviewed and analyzed the performance of different versions of the Gail model. They did find that the original Gail model 1 and the Caucasian-American Gail model was well calibrated in American and European women. However, in contrast, the Caucasian-American and Asian-American Gail models likely overestimate the risk in Asian females, providing a risk roughly double that of their actual risk (Wang et al., 2018).

It has been noted that the "effect of single SNPs in complex disease to date has been small (i.e., odds ratios in the 1.1-1.6 range)" (Attia, 2024). However, previous studies have analyzed the potential impact of adding genetic information from a panel of single nucleotide polymorphisms (SNPs) associated with breast cancer risk to the Gail model (Gail, 2008, 2009). SNPs are specific locations in the genome where a nucleotide differs between individuals. A study that compared classification of risk using the Gail model or the Gail model plus 10 common genetic susceptibility variants, excluding those associated with *BRCA1* or *BRCA2*, found that inclusion of these genetic factors only modestly improved performance of the BCRAT (Wacholder et al., 2010). Another study evaluated the inclusion of a SNP risk score combined with the Gail model, basing the SNP risk score on seven SNPs associated with risk for breast cancer (Mealiffe et al., 2010). These showed that real gains, albeit modest, could be achieved in reclassification of risk. Other studies have found modest potential clinical gains from combining SNP information with clinical risk factors (Gail, 2008, 2009; Pharoah et al., 2008; Wacholder et al., 2010). However, these studies have either been theoretical in nature (Gail, 2008, 2009; Pharoah et al., 2008) or they combined model building with evaluation (Wacholder et al., 2010), which may complicate evaluating the results in a clinical context. Incorporating genetic information has the greatest improvement in risk assessment in subsets of women that are at an intermediate risk based on their clinical risk factors (Mealiffe et al., 2010). Moreover, it should be cautioned that though "Success in creating risk scores with a handful of SNPs has led some to try creating risk scores with tens or hundreds of thousands of SNPs, hoping to increase predictive power", the predictive power of these attempts tend to level off very rapidly. In one instance, increasing the number of SNPs examined from tens to millions only explained two to four percent of the variance in disease risk (Attia, 2024; Khera et al., 2018).

Proprietary Testing

Proprietary tests exist for the assessment of SNPs in breast cancer risk. TruSight evaluates 94 genes and 284 SNPs related to common and rare cancers, including breast cancer (Illumina, 2024b); BREVAGen*plus*, now GeneType for Breast Cancer, measures 66 genes and 77 loci for Caucasian women, 74 for African American women, and 71 for Hispanic women (GeneType, 2019, 2024); Infinium OncoArray-500k covers over 500,000 SNPs associated with many types of cancer, as well as other features such as ancestry and pharmacogenetics (Illumina, 2024a). Additionally, companies, such as 23andMe, can offer direct-to-consumer SNP testing for risk of breast cancer (23andme, 2024; Begley, 2018; FDA, 2024). The number of possible assessments and combinations of SNPs are virtually infinite.

Clinical Utility and Validity

A 76-locus polygenic risk score (PRS) was incorporated into the Breast Cancer Surveillance Consortium (BCSC) risk-prediction model to assess its attributable risk, comparing five-year absolute risk predictions between models within three studies (1643 case patients, 2397 control patients). The PRS was found to be an independent risk factor across all three studies and improved discriminatory accuracy for area under the curve (AUC) from AUC = 0.66 to AUC = 0.69. The study concluded that the set of 76 SNPs improves the identification of women at the highest risk. Along with the increase seen in AUC, there was a net-reclassification of 11% of case patients (95% CI = 7% to 15%) to a risk level where women are more likely to benefit from chemoprevention. This suggests that SNPs could be clinically useful. However, independent cohort data are needed to test calibration in the general population (Vachon et al., 2017; Vachon et al., 2015).

Michailidou et al. (2017) performed a GWAS on breast cancer, encompassing "122,977 cases and 105,974 controls of European ancestry and 14,068 cases and 13,104 controls of East Asian ancestry." Overall, they identified 65 new loci associated at a genome-wide level with overall breast cancer risk (defined as $P < 5 \times 10^{-8}$). The authors concluded that "these results provide further insight into genetic susceptibility to breast cancer and will improve the use of genetic risk scores for individualized screening and prevention" (Michailidou et al., 2017).

Cuzick et al. (2017) developed a SNP risk score (SNP88) using the Illumina OncoArray, which includes most known breast-cancer risk SNPs (previously validated and directly available or with close surrogates on the OncoArray) in women receiving preventative treatment. They found that "SNP88 was predictive of breast cancer risk overall (interquartile range odds ratio [IQ-OR], 1.37), but mainly for estrogen receptor-positive disease (IQ-OR, 1.44) versus estrogen receptor-negative disease. However, the observed risk of SNP88 was only 46% of expected. No significant interaction was observed with treatment arm. SNP88 was independent of TC (Spearman rank-order correlation, 0.012) and when combined multiplicatively, a "substantial" improvement was seen (IQ-OR, 1.64)" (Cuzick et al., 2017).

Mavaddat et al. (2015) evaluated the value of using 77 breast cancer related SNPs for risk stratification. A total of 33,673 breast cancer cases and 33,381 controls were analyzed. All possible pair-wise multiplicative interactions were examined, and a 77-SNP polygenic risk score (PRS) was created for estrogen receptor (ER) status, as well as breast cancer overall. The authors found that women in the highest 1% of the PRS had a "three-fold increased risk" compared to women in the middle quintile (odds ratio = 3.36). Lifetime risk of breast cancer for women without a family history that had a PRS in the lowest and highest quintiles were 5.2% and 16.6%, respectively (Mavaddat et al., 2015).

Rudolph et al. (2018) investigated the integration of PRS into risk prediction models, combining PRS and environmental risk factors. The authors performed a retrospective review of 20 studies and evaluated joint associations of the 77-SNP PRS with several environmental factors such as body mass index (BMI) and alcohol use. They found that "the strongest evidence for a non-multiplicative joint association with the 77-SNP PRS was for alcohol consumption, adult height, and current use of combined menopausal hormone therapy in ER-positive disease. Risk associations for these factors by percentiles of PRS did not follow a clear dose-response. In addition, global and tail-based goodness of fit tests showed little evidence for departures from a multiplicative risk model, with alcohol consumption showing the strongest evidence for ER-positive disease (P = 0.013 for global and 0.18 for tail-based tests)" (Rudolph et al., 2018). They concluded that "the combined effects of the 77-SNP PRS and environmental risk factors for breast cancer are generally well described by a multiplicative model" (Rudolph et al., 2018).

Schuetz et al. (2019) researched genetic variants and the relationship between inflammation, apoptosis, and autophagy in breast cancer risk. In total, 206 SNPs were tested in 54 genes related to inflammation, apoptosis, and autophagy in a population-based breast cancer study; this study included women of both European descent (658 with breast cancer and 795 controls) and East Asian descent (262 with breast cancer and 127 controls). The researchers report that "although no SNP was associated with breast cancer risk among women of European descent, we found evidence for an association among East Asians for rs1800925 (IL-13) and breast cancer risk (OR = 2.08; 95% CI: 1.32-3.28; p = 0.000779), which remained statistically significant after multiple testing correction" (Schuetz et al., 2019). The researchers also report that "This association was replicated in a meta-analysis of 4305 cases and 4194 controls in the Shanghai Breast Cancer Genetics Study" (Schuetz et al., 2019).

Kapoor et al. (2020) assessed potential interactions between 205 breast cancer susceptibility loci and 13 established breast cancer risk factors. A total of 28,176 cases and 32,209 controls were analyzed with the iCOGS array (a custom SNP genotyping array), and 44,109 cases and 48,145 controls were genotyped using the OncoArray. An interaction with less than or equal to 1% prior probability was found with three different SNP risk factor pairs. "SNP rs4442975 was associated with a greater reduction of risk of ER-positive breast cancer… in current users of estrogen-progesterone therapy compared with non-users. This finding was supported by replication using OncoArray data of the previously reported interaction between rs13387042 (r2 = 0.93 with rs4442975) and current estrogen-progesterone therapy for overall disease (Pint = 0.004). The two other interactions suggested stronger associations between SNP rs6596100 and ER-negative breast cancer with increasing parity and younger age at first birth" (Kapoor et al., 2020).

Shu et al. (2020) performed a meta- analysis of data from GWAS conducted in Asians (24,206 cases, 24,775 controls) and European descendants (122,977 cases, 105,974). The focus of their study was identifying additional genetic susceptibility loci for breast cancer, as currently known risk variants only explain a small portion of breast cancer heritability, particularly in Asian women. In this study, they identified 31 potential novel risk loci, with the lead variant showing an associate with breast cancer risk at $p<5x10^{-8}$. Of note, "the associations for 10 of these loci were replicated in an independent sample of 16,787 cases and 16,680 controls of Asian women ($P < 0.05$). In addition, we replicated the associations for 78 of the 166 known risk variants at $P < 0.05$ in Asians. These findings improve our understanding of breast cancer genetics and etiology and extend previous findings from studies of European descendants to Asian women"(Shu et al., 2020).

Zhang et al. (2020) note that "breast cancer susceptibility variants frequently show heterogeneity in associations by tumor subtype... defined by combinations of ER, [progesterone receptor] PR, [human epidermal growth factor 2] HER2 and grade: (1) luminal A-like, (2) luminal B/HER2-negative-like, (3) luminal B-like, (4) HER2-enriched-like and (5) triple-negative or basal-like." To identify novel breast cancer loci, they performed a GWAS (133,384 breast cancer cases, 113,789 controls, plus 18,908 *BRCA1* mutation carriers, 9,414 of them with breast cancer) on patients with European ancestry. They identified 32 novel susceptibility loci ($p<5x10^{-8}$), 15 of which showed associations with at least one tumor feature. Five loci showed opposite associations ($p<0.05$) between luminal- and non-luminal subtypes. They also found that "the genetic correlations between five intrinsic-like subtypes ranged from 0.35 to 0.80. The proportion of genome-wide chip heritability explained by all known susceptibility loci was 37.6% for triple-negative and 54.2% for luminal A-like disease. The odds ratios of polygenic risk scores (PRSs), which included 330 variants, for the highest 1% quantiles compared to middle quantiles were 5.63 and 3.02 for luminal A-like and triple-negative disease, respectively. These findings provide an improved understanding of genetic predisposition to breast cancer subtypes and will inform the development of subtype-specific polygenic risk scores"(Zhang et al., 2020).

Adedokun et al. (2021) used a cross-ancestry GWAS approach to describe breast cancer risk loci. They identified breast cancer variants in individuals from African ancestry GWAS (9,421 cases, 10,193 controls) and meta-analyzed them with European ancestry GWAS data (122,977 cases, 105,974 controls). The identified "four loci for overall breast cancer risk [1p13.3, 5q31.1, 15q24 (two independent signals), and 15q26.3] and two loci for estrogen receptor-negative disease (1q41 and 7q11.23) at genome-wide significance." This study suggests that replication across multiple ancestry populations will "help improve the understanding of breast cancer genetics and identify causal variants" (Adedokun et al., 2021).

Chen et al. (2022) conducted a "genome-wide association study, as well as a transcriptome-wide association study (TWAS), of age- and BMI- adjusted DA, NDA, and PMD in up to 27,900 European-ancestry women from the MODE/BCAC consortia." In their results they identified 28 genome-wide significant loci for MD phenotypes and found that 45% of all known breast cancer SNPs were associated with at least one MD phenotype. Also, "TWAS identified two novel genes (*SHOX2* and *CRISPLD2*) whose genetically predicted expression was significantly associated with MD phenotypes." In conclusion, their findings provided insight into the genetic background of MD phenotypes, and further demonstrated their shared genetic basis with breast cancer (Chen et al., 2022).

Jia et al. (2023) studied the association between SNPs and overall breast cancer risk in the Chinese female population, stating that "frequencies vary across ethnic group." Thirty-four SNPs were included in the study, all of which had been previously identified by GWAS. The authors conducted an association analysis, including 1848 patients with breast cancer and 709 healthy controls. The authors identified a a significant association between SNP rs12493607 and breast cancer risk, as well as invasive carcinoma, estrogen receptor (ER)-positive, progesterone receptor (PR)-positive, HER2-negative, and young (aged younger than 45) breast cancer. The authors also identified "less conservatively" significant association with rs4784227 and rs2046210 and breast cancer risk. Overall, the authors concluded that the results "shed light on the relationship between SNPs and breast cancer susceptibility within a vast Chinese cohort, supporting the development of polygenetic risk scores for the Chinese population" (Jia et al., 2023).

VI. Guidelines and Recommendations

American Society of Clinical Oncology (ASCO)

An update from the ASCO included recommendations for genetic and genomic testing for cancer susceptibility. These guidelines state, "ASCO recognizes that concurrent multigene testing (i.e., panel testing) may be efficient in circumstances that require evaluation of multiple high-penetrance genes of established clinical utility as possible explanations for a patient's personal or family history of cancer. Depending on the specific genes included on the panel employed, panel testing may also identify mutations in genes associated with moderate or low cancer risks and mutations in high-penetrance genes that would not have been evaluated based on the presented personal or family history. Multigene panel testing will also identify variants of uncertain significance (VUSs) in a substantial proportion of patient cases, simply as a result of the multiplicity of genes tested. ASCO affirms that it is sufficient for cancer risk

assessment to evaluate genes of established clinical utility that are suggested by the patient's personal and/or family history" (Robson et al., 2015).

National Comprehensive Cancer Network (NCCN)

Prior to 2020, the NCCN guidelines focused largely on testing *BRCA1/2*. However, the NCCN has since updated their guidelines based on "strong evidence that genes beyond *BRCA1/2*, *TP53*, and *PTEN* confer markedly increased risk of breast and/or ovarian cancers" (NCCN, 2024). These NCCN guidelines acknowledge that "Multi-gene testing can detect P/LP variants not found in single-gene testing", but "Since more than one gene can explain an inherited cancer syndrome, phenotype-directed testing based on personal and family history through a multi-gene panel test is often more efficient and/or cost-effective" (NCCN, 2024). Furthermore, "Multi-gene testing may also be considered for those who tested negative for one particular syndrome, but whose personal and family history is suggestive of an inherited susceptibility." The NCCN also stated that "Multi-gene tests also increase the likelihood of detecting a VUS." The NCCN recommends that "for individuals potentially meeting established criteria for one or more of the hereditary cancer syndromes, genetic testing should be considered along with appropriate pre- and post-test counseling" (NCCN, 2024).

The NCCN Panel recommends that "Multi-gene testing may be considered for individuals who meet testing criteria and who previously underwent single-gene and/or absent deletion duplication analysis but tested negative. Both first- and second-degree relatives of individuals who meet these testing criteria are also eligible for testing, except for second-degree relatives of individuals with pancreatic cancer or prostate cancer, for whom prior probability of a high-penetrance cancer susceptibility gene is low in the absence of additional family history of cancer; only first-degree relatives of these affected individuals should be offered testing, unless indicated based on additional family history" (NCCN, 2024). It should be noted that "Carriers of a P/LP variant should be encouraged to participate in clinical trials or genetic registries. Carriers should be encouraged to recontact their genetics providers every few years for updates, as laboratories may issue amended reports as the knowledge base surrounding hereditary cancer risk expands" (NCCN, 2024).

However, "A major dilemma regarding multi-gene testing is that there are limited data and a lack of clear guidelines regarding degree of cancer risk associated with some of the genes assessed, and how to communicate and manage risk for carriers of these genes." This issue is exacerbated by the "low incidence rates of hereditary disease, leading to a difficulty in conducting adequately powered studies," and the fact that "Multi-gene tests include moderate-penetrance genes, and they often also include

low-penetrance genes for which there are little available data regarding degree of cancer risk and guidelines for risk management"(NCCN, 2024).

The NCCN states, "Reports regarding germline findings that may impact medical management should come from laboratories that are certified by the College of American Pathologists (CAP) and Clinical Laboratory Improvement Amendments (CLIA), with some U.S. states (eg, New York) having additional reporting requirements.. The testing typically used by companies providing ancestry information directly to consumers is microarray-based single nucleotide polymorphism (SNP) testing that has not been validated for clinical use. These companies do not provide comprehensive genetic analysis that includes gross deletion or duplication analysis. Third-party services are available to assist patients with interpreting their raw data, but these services are not government-regulated. In addition to the errors inherent in working with raw data from DTC labs, other limitations of these services include inadequate informed consent process, uncertain clinical validity and utility, and lack of medical oversight" (NCCN, 2024). As such, "Given the limitations of the information obtained from DTC services, confirmatory germline testing by a certified laboratory is clinically indicated, and changes to medical management based solely on DTC testing results are not recommended" (NCCN, 2024).

Finally, "Confirmatory germline testing through an appropriately certified laboratory is clinically indicated when a potential P/LP variant is identified through various data sources" as listed below:

- "Commercial entities providing ancestry (and sometimes health) information typically do so through microarray-based single nucleotide polymorphism (SNP) testing that has not been validated for clinical use. Third-party software applications can be used by consumers to obtain an interpretation of the raw data provided by these companies. Raw data and third-party software are not able to provide information that is appropriate for medical management, as these services are not subject to quality-control processes and recent research suggests that the error rate (40%) is substantial. In addition, the current tests only provide limited founder pathogenic variants results without the benefit of family history. More comprehensive genetic counseling and testing for pathogenic variants in other inherited cancer risk genes may be appropriate at the time of confirmation testing."
- "Commercial laboratories utilizing consumer-initiated or direct-to-consumer (DTC) marketing of DNA sequence-based cancer predisposition tests vary substantially in providing information necessary to make informed decisions regarding results and may vary in accuracy in their variant interpretation"

- "Research: Patients may have participated in research studies that included germline genomic analysis. In such cases, it is clinically indicated to review the patient's findings with a genetics professional and/or the reporting laboratory to establish whether the original report was generated by an appropriately certified laboratory, or whether confirmatory testing is clinically indicated" (NCCN, 2024).

The United States Preventive Services Task Force (USPSTF)

The USPSTF published recommendations related to genetic testing for breast cancer. In particular, "The USPSTF found adequate evidence that the benefits of risk assessment, genetic counseling, and genetic testing are moderate in women whose family history is associated with an increased risk for harmful mutations in the BRCA1/2 genes," whereas for women without such family history, it stated that the benefits are small to none (USPSTF, 2019). They concluded with moderate certainty that the net benefit of these procedures outweighs the harms in women both with and without a familial risk of potentially harmful mutations. The USPSTF does not address the use of SNPs as a screening method for cancer (USPSTF, 2019).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

Venous and Arterial Thrombosis Risk Testing

Policy Number: AHS – M2041 – Venous and Arterial Thrombosis Risk Testing	Prior Policy Name and Number, as applicable: • AHS – M2041 – Venous Thrombosis Risk Testing
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

A thrombosis, also known as a blood clot, occurs within blood vessels in the body. The two main types of thrombosis include venous thrombosis, which is when a vein is blocked due to a blood clot, and arterial thrombosis, which is when an artery is blocked due to a blood clot. Thrombophilias refer to hereditary and/or acquired abnormalities of hemostasis that predispose patients to thrombosis (Stevens et al., 2016). The most common presentations of venous thromboembolism (VTE) are deep vein thrombosis (DVT) and pulmonary embolism (PE) (Bartholomew, 2017).

Terms such as male and female are used when necessary to refer to sex assigned at birth.

II. Related Policies

Policy Number	Policy Title
AHS-M2141	Testing of Homocysteine Metabolism-Related Conditions
AHS-M2180	Genetic Markers for Assessing Risk of Cardiovascular Disease

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For individuals without recurrent venous thromboembolism (VTE) risk factors (e.g., surgery, prolonged immobilization, collagen vascular disease, malignancy, certain hematologic disorders), genetic testing for Factor V Leiden and prothrombin gene G20210A mutations and plasma testing for protein C deficiency, protein S deficiency, and antithrombin III deficiency (see Note 1) **MEETS COVERAGE CRITERIA** in **any** of the following situations:
    a) For individuals less than 50 years of age who have experienced any deep venous thrombosis (DVT) or pulmonary embolism (PE).
    b) For individuals who have experienced a DVT in unusual sites (e.g., hepatic, mesenteric, or cerebral veins).
    c) For individuals who have experienced a DVT and who have a strong family history of thrombotic disease.
    d) For individuals who are pregnant or taking oral contraceptives and who have experienced a DVT.
    e) For first- and second-degree relatives (see Note 2) of individuals who experienced a DVT before 50 years of age.
    f) For women under the age of 50 who smoke and who have suffered a myocardial infarction.
    g) Before the administration of oral contraceptives, targeted testing of individuals with a personal or family history of DVT.
    h) For pediatric individuals who have suffered from a pediatric arterial ischemic stroke.
2) For individuals with warfarin-induced skin necrosis or for infants who develop neonatal purpura fulminans, plasma testing for protein C deficiency and protein S deficiency (see Note 1) **MEETS COVERAGE CRITERIA**.
3) For individuals with a first-degree relative (see Note 2) with a known Factor V Leiden or prothrombin gene G20210A mutation, genetic testing for the known familial mutation **MEETS COVERAGE CRITERIA** in any of the following situations:
    a) For individuals who are considering the use of oral contraceptives.
    b) For individuals who were assigned female at birth and who are considering hormone replacement therapy.
4) For hypercoagulable evaluation or for "at risk" family members, *MTHFR* genetic testing **DOES NOT MEET COVERAGE CRITERIA**.

5) For individuals with recurrent thrombotic events who are receiving a lifelong anticoagulation regimen, genetic testing for Factor V Leiden and prothrombin gene G20210A mutations **DOES NOT MEET COVERAGE CRITERIA**.

6) Venous thrombosis risk testing for superficial venous thrombosis (including superficial thrombophlebitis and varicosities) **DOES NOT MEET COVERAGE CRITERIA**.

7) For all situations, activated protein C (aPC) resistance assay **DOES NOT MEET COVERAGE CRITERIA**.

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

8) Genetic testing for inherited thrombophilia **DOES NOT MEET COVERAGE CRITERIA** for any of the following situations:
   a) For the evaluation of recurrent fetal loss, placental abruption, preeclampsia, or fetal growth restriction.
   b) For the evaluation of arterial thrombosis not attributable to paradoxical emboli.
   c) As a routine screen for the general population.
   d) As a routine screen for asymptomatic individuals considering oral contraceptive use or hormone replacement therapy.
   e) As a routine screen for asymptomatic pregnant individuals.
   f) For prenatal or preimplantation testing.
   g) As a routine newborn screen.

9) Genetic testing for inherited thrombophilia more than once per lifetime **DOES NOT MEET COVERAGE CRITERIA**.

10) Testing for other genetic thrombophilia risk factors (e.g., factor V HR2 variant, prothrombin G1199A variant, factor VII R353Q variant, factor 13B V34L variant, PAI-1), as well as multi-gene panel testing **DOES NOT MEET COVERAGE CRITERIA**.

11) DVT risk testing as part of a pre-transplant evaluation test DOES NOT MEET COVERAG**E CRITERIA**.

12) To determine arterial thrombosis risk, genetic testing for Factor V Leiden mutation and prothrombin gene G20210A mutation **DOES NOT MEET COVERAGE CRITERIA**.

NOTES:

Note 1: Plasma testing for protein C deficiency, protein S deficiency, and antithrombin III deficiency should be performed at least six weeks after the acute thrombotic event and while the patient is not taking anticoagulants. Assays for clotting inhibitors amount and function should be performed prior to any molecular testing.

Note 2: First-degree relatives include parents, full siblings, and children of the individual. Second-degree relatives include grandparents, aunts, uncles, nieces, nephews, grandchildren, and half-siblings of the individual.

IV. Table of Terminology

Term	Definition
ACC	American College of Cardiology
ACMG	American College of Medical Genetics and Genomics
ACOG	American College of Obstetricians and Gynecologists
ACR	American College of Radiology
AHA/ASA	American Heart Association/American Stroke Association
aPC	Activated protein C
APS	Antiphospholipid syndrome
ASCP	American Society for Clinical Pathology
ASH	American Society of Hematology
COC	Combined oral contraceptives
CTPA	Computed tomography pulmonary angiography
DVT	Deep vein thrombosis
EGAPP	Evaluation of genomic applications in practice and prevention
ESC	European Society of Cardiology
FVL	Factor V Leiden
HRT	Hormone replacement therapy
NAFT	The North American Thrombosis Forum
OC	Oral contraceptives
PE	Pulmonary embolism
PGM	Prothrombin 20210A gene mutation
SIGN	Scottish Intercollegiate Guidelines Network

SPESI	Simplified pulmonary embolism severity index
SVM	Society for Vascular Medicine
VQ	Ventilation perfusion
VTE	Venous thromboembolism
VUS	Variant of unknown significance

V. Scientific Background

A thrombus is "an aggregate of coagulated blood within the vascular system or heart which contains platelets, fibrin, leukocytes, and red blood cells in varying amounts" (Herrmann, 2018). This aggregate of blood can be problematic as it may obstruct normal blood circulation throughout the body and even travel to peripheral areas. The primary manifestations of venous thromboembolisms (VTE) are deep vein thrombosis and pulmonary embolism. These conditions affect an estimated one million individuals in the United States annually (Bartholomew, 2017).

Thrombosis is widely theorized to develop due to Virchow's Triad, which consists of abnormalities in blood flow, a vascular endothelial injury, and alterations in the blood constituents. Changes in any of these characteristics may cause the clot to form (Bauer & Lip, 2024). For example, sickle red blood cells may cause increased clumping or decreased adhesion to the vessel walls (Byrnes & Wolberg, 2017). There are two main types of thrombosis: venous thrombosis (when a vein is blocked due to a blood clot) and arterial thrombosis (when an artery is blocked due to a blood clot).

A deep vein thrombosis (DVT) refers to a thrombus in a "deep" vein whereas a pulmonary embolism (PE) refers to an obstruction of the pulmonary artery (or one of its branches) by foreign material (Bauer, 2024a; Thompson, 2023). DVT of the lower extremities may cause symptoms, such as swelling or edema in the lower extremities, pain, and warmth in the affected area (Bauer, 2024a). This thrombus may travel to the lungs (becoming an embolus) and cause a PE. A PE has similar symptoms to DVT but may include pulmonary issues, such as shortness of breath. The risk factors for VTE, PE, and DVT are similar (Thompson, 2023). The two primary categories of risk factors for VTE are hereditary and acquired, and the genetic tendency toward VTE is referred to as inherited thrombophilia. Hereditary risk factors include genetic mutations such as Factor V Leiden (FVL) mutations. The five most common genetic risk factors for VTE are FVL mutations, prothrombin mutations, protein S defect, protein C defect, and antithrombin defect (Bauer & Lip, 2024). Approximately 50–60% of the variance in VTE incidence are attributed to genetic effects (Crous-Bou et al., 2016).

A modified activated partial thromboplastin time (aPTT) assay detects the anticoagulant activity of activated protein C (aPC). FVL mutations cause coagulation

factor V to be unresponsive to aPC and initially, these changes were termed "aPC resistance" due to the reduced activity of aPC on a modified aPTT assay. A single nucleotide change (G1691A) results in a point mutation of glutamine to arginine at position 506. Approximately 99% of carriers of this mutation are heterozygous, and only 5% of these heterozygotes will experience a VTE in their lifetime. These mutations are often suspected in patients experiencing a VTE at a young age (under 50), a VTE in unusual areas such as a portal vein, or recurrent VTEs (Bauer, 2023a). Protein C may also be genetically deficient, but this mutation is only seen in 2-5% of individuals with a VTE (Bauer, 2024a). Protein S, a cofactor for the aPC control mechanism, and deficiencies in this protein may also confer additional risk for VTE (Bauer, 2024b).

The second most common inherited thrombophilia is the G20210A mutation of prothrombin. This mutation is a gain of function mutation where clotting activity is increased by creating more thrombin and fibrin. The overall prevalence of this mutation is about 2% (Bauer, 2023c). Genetic defects of antithrombin (an inhibitor of thrombin) may also occur, but the estimated prevalence of antithrombin defects is only a maximum of 0.2% (Bauer, 2023b).

Acquired risk factors or predisposing conditions for thrombosis include a prior thrombotic event, recent major surgery, presence of a central venous catheter, trauma, immobilization, malignancy, pregnancy, the use of oral contraceptives or heparin, myeloproliferative disorders, antiphospholipid syndrome (APS), and a number of other major medical illnesses (Bauer & Lip, 2024). Patients with acquired hypercoagulability have an increased risk of venous thrombosis, arterial thrombosis, or both; however, there is a low risk of recurrence, regardless of thrombophilia status (Connors, 2017). A rare complication of warfarin treatment, warfarin-induced skin necrosis is commonly due to protein C deficiency, with rare cases of protein S deficiency or PVL having been reported (Bauer & Lip, 2023).

Risk factors for arterial thrombosis are lesser known. The relationship between FVL and arterial thrombosis is controversial with studies reporting varying results; overall, FVL is not currently considered a major risk factor for arterial thrombosis (Carroll & Piazza, 2018; Kujovich, 2011). Kujovich (2018) states that FVL testing should not be performed on persons with any type of arterial thrombosis including myocardial infarction and stroke in children or adults. It has also been reported that while inherited antithrombin, protein S and protein C deficiencies are important risk factors for venous thrombosis, "they have little or no effect on arterial thrombosis" (Previtali et al., 2011). Further, prothrombin gene mutation is not consistently shown to increase the risk of an arterial thromboembolism, and "There is no association of antithrombin deficiency with arterial thrombosis" (Carroll & Piazza, 2018).

It has been proposed that venous thrombosis risk testing may be beneficial as a pre-transplant evaluation test. However, no studies have been identified suggesting this. The North American Thrombosis Forum (NAFT) states that even though certain genetic conditions predispose a small proportion of the population to the development of blood clots, "few people with thrombophilias develop symptoms"; further, there is no cost-effective, safe or long-term method to prevent a blood clot from forming even if a genetic predisposition is identified (NATF, 2019).

Thrombotic events such as thrombophilia and stroke have become increasingly documented in hospitalized pediatric patients with underlying medical conditions such as prematurity, cancer, and congenital heart disease, but they are rarely identified in healthy children. Furthermore, in most cases of pediatric venous thromboembolism, there exist other underlying risk factors such as indwelling central venous catheter and inherited thrombophilia that are worthy of further investigation. The incidence of venous thromboembolisms is highest in neonates and infants, but there is a second peak recorded in adolescence, coinciding with the use of oral contraceptives. However, as in the case with adults, little to no evidence suggests that the use of venous thrombosis risk testing in children will affect the acute management of venous thromboembolisms. In a study including a total of 271 children with VTE, it was found that the relative frequencies of individually inherited thrombophilias were low—for example, the highest recorded frequency of IT disorders was of Factor V Leiden, occurring in only five to 10 percent of the samples. Moreover, a study of 52 children with thromboembolic events during the acute phase did not urge any changes to acute management, regardless of the result of the test (Raffini et al., 2023).

Venous thrombosis risk testing has also been entertained as a manner of combatting pediatric stroke, which can be characterized in a variety of ways, such as by age and by presentation. Arterial ischemic infarctions are the most common, comprising approximately 80% of all perinatal strokes, and this form of stroke can occur in up to one in 3500 of newborns. However, though it would seem reasonable for venous thrombosis risk testing to be employed here, recent prospective case-control studies suggest that routine thrombophilia testing is not warranted. The study showed that conditions associated with thrombophilia rarely coincided with arterial ischemic strokes, and these conditions included, but were not limited to, decreased levels of protein C, protein S, or prothrombin, and genotyping of factor V Leiden (FVL) and factor II (FII, prothrombin) G20210A. Of the 14 parameters examined, 12 showed no difference, including all common thrombophilias examined, with specific mention that FVL and FII were comparable to population norms (Curtis et al., 2017; Ferriero et al., 2019). Subsequent evaluation deemed thrombophilia evaluation in neonates as having limited clinical utility because "levels of protein C, protein S, antithrombin, and factor XI are normally decreased to 30% of adults levels, and these levels only approach adult

levels at various time points during childhood". Therefore, the use of thrombophilia testing for these proteins may be misleading in the neonatal period, and MRIs instead should be used to diagnose the thrombosis (Ferriero et al., 2019). Moreover, studies focusing on the roles of thrombophilia, arteriopathy, and cardiac abnormalities in perinatal ischemic stroke find that these risk factors were at best unclear, weakening what predictive power they were believed to contain for even recurrent events after perinatal stroke and leading researchers to conclude that thrombophilia evaluation should rarely be considered in cases of perinatal stroke (Lehman et al., 2017).

While the initial aPTT assays used unaltered plasma (first-generation assays), some versions were neither sensitive nor specific for FVL. Modifications to this test resulted in second generation functional aPC resistance assays that correlate well with the presence of FVL. However, in rare cases, functional assays for aPC resistance can give misleading results (e.g., the presence of a lupis anticoagulant can cause falsely abnormal results in some assays; therapy with a direct thrombin inhibitor or oral factor Za inhibitor can cause falsely normal results). In addition, while FVL can be detected by genetic testing or a second-generation functional coagulation test for aPC resistance, individuals with a positive aPC resistance assay would still need to receive genetic testing to confirm a diagnosis (Bauer, 2023a). Due to difficulty with interpretation, a need for confirmatory genetic testing, and the overall declining cost of genetic testing, aPC resistance assays are performed infrequently. When performed, they are simply reported as positive, borderline, or negative (Middeldrop, 2023).

The term FVL paradox describes the different risk of DVT and PE in FVL carriers; there is data to suggest that FLV carriers are less likely to experience isolated PE (without DVT) than the general population (Bauer, 2023a). de Moerloose et al. (2000) studied the prevalence of FVL in people suspected of DVT and/or PE. The 99 participants with PE were categorized based on "those with PE but without DVT (n = 57) and those with PE and DVT (n = 42)." The odds ratio for the prevalence of FVL was higher (19.1%) in patients with DVT and PE than the odds ratio for the prevalence of FVL in patients with only PE (10.5%), suggesting that "patients with primary PE are less often affected by the factor V Leiden mutation." In another study by (Mäkelburg et al., 2010), the relative risk of DVT in FVL carriers compared to non-carriers was 7.0, while the relative risk of PE in FVL carriers compared to non-carriers was 2.8.

Analytical Validity

Murphy and Sabath (2019) have compared the accuracy and reliability of two tests: a genotypic assay which identifies FVL mutations, and a phenotypic aPC resistance assay. Data from 1596 patients was analyzed; each patient had received both types of testing. The authors state that the phenotypic testing exhibited both high sensitivity and

specificity compared to genotypic testing. “Phenotypic assays had close to total concordance with genotypic assays over 16 years of testing. Changing ordering practices could result in up to an 80% reduction in testing costs” (Murphy & Sabath, 2019).

A systematic review and meta-analysis by Chiasakul et al. (2019) researched the relationship between inherited thrombophilia and the risk of arterial ischemic stroke in adults. Inherited thrombophilias included FVL, protein C and S deficiency, antithrombin deficiency and prothrombin G20210A mutation. For this study, 11,916 stroke patients and 96,057 controls were identified. The authors concluded that “Compared with controls, patients with arterial ischemic stroke were significantly more likely to have the following inherited thrombophilias: factor V Leiden (OR, 1.25; 95% CI, 1.08-1.44; I2=0%), prothrombin G20210A mutation (OR, 1.48; 95% CI, 1.22-1.80; I2=0%), protein C deficiency (OR, 2.13; 95% CI, 1.16-3.90; I2=0%), and protein S deficiency (OR, 2.26; 95% CI, 1.34-3.80; I2=8.8%)” (Chiasakul et al., 2019). Antithrombin deficiency did not reach statistical significance in this study. Hence, in this review, inherited thrombophilias were found to be associated with an increased risk of arterial ischemic stroke in adults.

In a systematic review, Ortega studied the predictive value of D-dimer testing for venous thrombosis diagnosis in unusual locations. 3378 patients from 23 articles with thrombosis in unusual sites, such as upper extremity deep vein thrombosis (DVT), cerebral vein thrombosis (CVT) and splanchnic vein thrombosis (SVT), were studied. 12 articles on CVT concluded that timing of D-dimer testing is important and patients with short duration of symptoms displayed higher D-dimer levels. Sensitivity and specificity in these patients ranged from 58% to 97% and from 77% to 97.5%, respectively. The authors conclude that "D-dimer testing should not be currently recommended for the diagnosis of thrombosis in unusual sites as a first line diagnostic tool. The development of algorithms combining biomarkers such as D-dimer and clinical decision tools could improve the diagnosis" (Ordieres-Ortega et al., 2020).

Clinical Utility and Validity

A D-dimer assay is a blood test that is used in clinical practice to assist in identifying if a patient has a DVT or PE; this test may also help patients experiencing unprovoked VTE to determine if anticoagulation treatment should continue or halt after initial treatment is complete (Linkins & Takach Lapner, 2017). A D-dimer assay may vary greatly based on the type of antibody used, the method of capture, calibration, and instrumentation. Currently, 30 different assays as available which use 20 different monoclonal antibodies; various studies have reported a broad sensitivity and specificity range for D-dimer assays from 69-97% and 43-99% respectively (Linkins & Takach

Lapner, 2017). Hence, all D-dimer assays differ and need to be validated within the population of interest. Because of this, comparing study results is challenging.

Factor VIII is a blood clotting protein encoded by the F8 gene. A case report by Algahtani and Stuckey (2019) suggests that high factor VIII levels may also assist in risk factor determination for thrombosis or ischemic heart disease. "We conclude that high factor VIII levels are a risk factor for thrombosis, with a greater impact on venous than on arterial thrombosis. However, due to a lack of international consensus on methods for the laboratory testing of factor VIII levels in plasma, we would not currently recommend the measurement of factor VIII levels as part of routine thrombophilia screening" (Algahtani & Stuckey, 2019). This relationship has been shown previously as elevated levels of coagulation factor VIII:C were identified in a retrospective study of 584 first-degree relatives of 177 patients with high coagulation factor VIII:C levels; the researchers found that 40% of first degree relatives also had high VIII:C levels and were at an increased risk for VTE and arterial thrombosis when compared to other first-degree relatives with normal VIII:C levels (Bank et al., 2005).

Lee et al. (2017) performed whole exome sequencing on 64 patients with VTE to assess the types of mutations of inherited thrombophilias. Of these 64 patients, 39 of them were found to have a pathogenic variant or variant of unknown significance (VUS). Further, eight were found to have a Factor V mutation (six with FVL and two with less common mutations), two were found to have a prothrombin G20210A mutation, six were found to have a protein S mutation, two were found to have a protein C mutation, and three were found to have an antithrombin mutation (Lee et al., 2017).

Segal et al. (2009) reviewed the utility of FVL and prothrombin G20210A testing. The authors reviewed 124 articles and concluded that although genetic testing for these two risk factors is very accurate (valid), the clinical utility is lacking due to lack of evidence demonstrating improvement in clinical outcomes (Segal et al., 2009).

Onda studied the clinical utility of a new diagnostic algorithm based on serum D-dimer levels for VTE after hepatectomy. A total of 742 patients who underwent hepatectomy were enrolled in the study and measured for serum D-dimer levels post-op. CT scan was performed for patients who had a D-dimer level of greater than 20 µg/mL. Based on D-dimer and CT scan, VTE was diagnosed in 26 patients and pulmonary embolism (PE) was diagnosed in 18 patients. Multivariate analysis also showed that a resected liver weight of more than 120 grams is a significant predictor of VTE. Overall, "patients who undergo hepatectomy are at high risk for VTE, especially when the resected liver weight is high. The proposed diagnostic algorithm based on serum D-dimer levels for VTE after hepatectomy can be useful for early diagnosis" (Onda et al., 2021).

VI. Guidelines and Recommendations

American Heart Association/American Stroke Association (AHA/ASA)

The AHA/ASA has issued a scientific statement for the management of stroke in neonates and children, wherein testing for thrombophilic abnormalities are discussed. The AHA/ASA admits that due to the lack of "an adequately powered study to detect the impact of genetic thrombophilia on recurrence risk in pediatric AIS [arterial ischemic stroke], definite recommendations about evaluation remain challenging", but acknowledges that "laboratory testing outside of clinical studies may provide guidance for long-term management of the patient". For cases of thrombophilia the AHA/ASA provides an algorithm for the "Targeted Evaluation of a Child With AIS for Rare Causes or Causes Requiring Additional Evaluation" that includes the examination of Factor VIII level, Lipoprotein(a),
MTHFR mutation, and homocysteine levels, and it is suggested that "non-DNA testing may need to be repeated when the child is older to ensure that adult levels of proteins have been attained" and "measurement of proteins or homocysteine levels in the acute phase of stroke may not be accurate and should be repeated after the acute event". Finally, for the evaluation of a child with AIS, it is believed that "A thrombophilia evaluation is helpful in every case of childhood stroke, especially if there is no identifiable cause, medical history of thrombosis, or a first-degree relative with thrombosis history" (Ferriero et al., 2019).

In 2021, the AHA released guidelines on stroke prevention. The AHA brushes on testing for hematologic traits in the context of secondary stroke prevention. "If in certain clinical scenarios (eg, paradoxical emboli caused by venous thrombosis or recurrent venous thrombosis) testing for thrombophilic states is considered, testing for protein C, protein S, or antithrombin levels should be deferred or repeated at least 4 to 6 weeks (or up to 6 months for factor VIII609) after the acute stroke given that these protein levels may be altered during the acute stroke phase" (Kleindorfer et al., 2021).

American College of Medical Genetics and Genomics (ACMG)

ACMG has released guidelines for laboratory testing of venous thromboembolism (VTE). This 2018 edition superseded the 2005 edition. The guidelines are as follows:

Testing for factor V Leiden and factor II c.*97G>A (this mutation is also known as G20210A) is recommended in the following circumstances:

- A first unprovoked VTE, especially <50 years old
- VTE at unusual sites (such as hepatic portal, mesenteric, and cerebral veins)
- Recurrent VTE
- Personal history of VTE with (a) two or more family members with a history of VTE or (b) one first-degree relative with VTE at a young age

- Patients with low aPC resistance activity

Testing may be considered in the following circumstances:

- Females under the age of 50 who smoke tobacco and have a history of acute myocardial infarction
- Siblings of individuals known to be homozygous for factor V Leiden or factor II c.*97G>A, because they have a one in four chance of being a homozygote
- Asymptomatic pregnant individual or individual contemplating pregnancy, with a first-degree relative with unprovoked VTE or VTE provoked by pregnancy or contraceptive use
- Pregnant individual or individual contemplating pregnancy or estrogen use who has a first-degree relative with a history of VTE and is a known carrier for factor V Leiden and/or factor II c.97*G>A variant
- Pregnant individual or individual contemplating pregnancy with a previous non-estrogen-related VTE or VTE provoked by a minor risk factor, because knowledge of the factor V Leiden or factor II c.*97G>A status may alter pregnancy related thrombophylaxis (Zhang et al., 2018).

The ACMG found several clinical scenarios requiring special considerations worth mentioning, involving different populations. One involved the testing of asymptomatic versus symptomatic individuals, in which they assert that "It is generally not recommended to test asymptomatic minors as VTE rarely occurs before young adulthood even in the homozygous state." For prenatal testing and population screening, the ACMG suggests that "prenatal testing and population screening are not indicated due to the low penetrance of these variants, later age of onset, and lack of genotype-directed prophylaxis". Lastly, in individuals considering taking estrogen-containing oral contraceptives (OC) or hormone replacement therapy (HRT), the ACMG indicates that "A family and personal history of thrombosis should be carefully evaluated for all women before initiating HRT and a positive history may warrant thrombophilia screening" (Zhang et al., 2018).

ACMG does not support testing for *MTHFR* variants in thrombophilia assessment due to the lack of correlation with negative pregnancy outcomes (Hickey et al., 2013). This statement was reaffirmed in 2020 (Bashford et al., 2020).

American Society of Hematology (ASH)

The 2013 ASH recommends against testing "for thrombophilia in adult patients with venous thromboembolism (VTE) occurring in the setting of major transient risk factors (surgery, trauma or prolonged immobility)" (ASH, 2013).

In 2018, ASH released their guidelines for management of venous thromboembolism, which included the following recommendations (Lim et al., 2018). These guidelines were reviewed in 2022 by an ASH expert working group and agreed to "continue monitoring the supporting evidence rather than revise or retire these guidelines at this time."

- "*Recommends* using a strategy starting with D-dimer for excluding PE in a population with low prevalence/PTP (≤5%), followed by ventilation-perfusion (VQ) scan or computed tomography pulmonary angiography (CTPA) for patients requiring additional testing.
- *Recommends against* using a positive D-dimer alone to diagnose PE, and against additional testing following negative CTPA or normal VQ scan in a population with low prevalence/PTP (≤5%).
- S*uggests* using a strategy starting with D-dimer for excluding PE in a population with intermediate prevalence/PTP (~20%), followed by VQ scan or CTPA for patients requiring additional testing.
- *Recommends against* using a positive D-dimer alone to diagnose PE, and against additional testing following negative CTPA or normal VQ scan in a population with intermediate prevalence/PTP (~20%).
- *Recommends against* using a positive D-dimer alone to diagnose PE, and against using D-dimer as a subsequent test following a negative CT scan in a population with high prevalence/PTP (≥50%).
- *Suggests* using a strategy starting with D-dimer for excluding recurrent PE in a population with unlikely PTP.
- *Recommends* using a strategy starting with D-dimer for excluding DVT in a population with low prevalence/PTP (≤10%), followed by proximal lower extremity ultrasound or whole-leg ultrasound for patients requiring additional testing.
- *Recommends against* using a positive D-dimer alone to diagnose DVT, and against additional testing following negative proximal or whole-leg ultrasound in a population with low prevalence/PTP (≤10%).
- *Recommends against* using a positive D-dimer alone to diagnose DVT in a population with intermediate prevalence/PTP (~25%).
- *Recommends against* using a positive D-dimer alone to diagnose DVT in a population with high prevalence/PTP (≥50%).
- *Suggests* using a strategy starting with D-dimer for excluding recurrent DVT in a population with unlikely PTP.
- *Suggests* a strategy starting with D-dimer for excluding upper extremity DVT in a population with low prevalence/unlikely PTP (10%), followed by duplex ultrasound if D-dimer is positive.

- *Recommends against* using a positive D-dimer alone to diagnose upper extremity DVT in a population with low prevalence/unlikely PTP (10%).
- *Suggests* a strategy of either D-dimer followed by duplex ultrasound/serial duplex ultrasound, or duplex ultrasound/serial duplex ultrasound alone for assessing patients suspected of having upper extremity DVT in a population with high prevalence/likely PTP (40%).
- *Recommends against* using a positive D-dimer alone to diagnose upper extremity DVT in a population with high prevalence/likely PTP (40%)" (Lim et al., 2018).

In 2020, the ASH released guidelines on management of venous thromboembolism. ASH suggest "against the routine use of prognostic scores, D-dimer testing, or venous ultrasound to guide the duration of anticoagulation" (Ortel et al., 2020).

In 2023, the ASH released guidelines thrombophilia testing for the management of venous thromboembolism. "The panel issued a strong recommendation against testing the general population before starting combined oral contraceptives (COCs) and conditional recommendations for thrombophilia testing in the following scenarios: (a) patients with VTE associated with nonsurgical major transient or hormonal risk factors; (b) patients with cerebral or splanchnic venous thrombosis, in settings where anticoagulation would otherwise be discontinued; (c) individuals with a family history of antithrombin, protein C, or protein S deficiency when considering thromboprophylaxis for minor provoking risk factors and for guidance to avoid COCs/hormone replacement therapy; (d) pregnant women with a family history of high-risk thrombophilia types; and (e) patients with cancer at low or intermediate risk of thrombosis and with a family history of VTE. For all other questions, the panel provided conditional recommendations against testing for thrombophilia." The panel also listed the following 23 recommendations (Middeldorp et al., 2023):

- "For patients with unprovoked VTE who have completed primary short-term treatment, the ASH guideline panel suggests not to perform thrombophilia testing to guide the duration of anticoagulant treatment (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with VTE provoked by surgery who have completed primary short-term treatment, the ASH guideline panel suggests not to perform thrombophilia testing to determine the duration of anticoagulant treatment (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with VTE provoked by a nonsurgical major transient risk factor who have completed primary short-term treatment, the ASH guideline panel suggests testing for thrombophilia to guide anticoagulant treatment duration. The panel suggests indefinite anticoagulant treatment for patients with thrombophilia and

stopping anticoagulant treatment for patients without thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."

- "For women with VTE provoked by pregnancy or postpartum who have completed primary treatment, the ASH guideline panel suggests thrombophilia testing to guide anticoagulant treatment duration. The panel suggests indefinite anticoagulant treatment for women with thrombophilia and stopping anticoagulant treatment for women without thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For women with VTE associated with COCs who have completed primary short-term treatment, the ASH guideline panel suggests testing for thrombophilia to guide anticoagulant treatment duration. The panel suggests indefinite anticoagulant treatment for women with thrombophilia and stopping anticoagulant treatment for women without thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with an unspecified type of VTE who have completed primary short-term treatment, the ASH guideline panel suggests not performing thrombophilia testing to guide anticoagulant treatment duration (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with CVT who have completed primary treatment in a setting where anticoagulation would be discontinued, the ASH guideline panel suggests thrombophilia testing to guide anticoagulant treatment duration. The panel suggests indefinite anticoagulation for patients with thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with CVT who have completed primary treatment in a setting where anticoagulation would be continued indefinitely, the ASH guideline panel suggests not to perform thrombophilia testing to guide anticoagulant treatment duration (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with splanchnic venous thrombosis who have completed primary treatment in a setting where anticoagulation would be discontinued, the ASH guideline panel suggests thrombophilia testing to guide anticoagulant treatment duration. The panel suggests indefinite anticoagulation for patients with thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For patients with splanchnic venous thrombosis who have completed primary treatment in a setting where anticoagulation would be continued indefinitely, the ASH guideline panel suggests not performing thrombophilia testing to guide anticoagulant treatment duration (conditional recommendation based on very low certainty in the evidence about effects)."

- "For individuals with a family history of VTE and known FVL or PGM [prothrombin 20210A gene mutation] (low-risk thrombophilia) who have a minor provoking risk factor for VTE (eg, immobility or minor injury, illness, or infection), the ASH guideline panel suggests not testing for the known familial thrombophilia to guide thromboprophylaxis (conditional recommendation based on very low certainty in the evidence about effects). For individuals with a family history of VTE and known antithrombin, protein C, or protein S deficiency (high-risk thrombophilia) who have a minor provoking risk factor for VTE, the ASH guideline panel suggests testing for the known familial thrombophilia. The panel suggests thromboprophylaxis in individuals with thrombophilia and no thromboprophylaxis in individuals without thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For individuals with a family history of VTE and known FVL or PGM (low-risk thrombophilia) who have a minor provoking risk factor for VTE (eg, immobility or minor injury, illness, or infection), the ASH guideline panel suggests not testing for all hereditary thrombophilias to guide thromboprophylaxis (conditional recommendation based on very low certainty in the evidence about effects). For individuals with a family history of VTE and known antithrombin, protein C, or protein S deficiency (high-risk thrombophilia) who have a minor provoking risk factor for VTE, the ASH guideline panel suggests testing for all hereditary thrombophilias (using a panel of tests). The panel suggests thromboprophylaxis in individuals with thrombophilia and no thromboprophylaxis for a minor provoking risk factor in individuals without thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For individuals with a family history of VTE and unknown thrombophilia status in the family who have a minor provoking risk factor for VTE (eg, immobility or minor injury, illness, or infection), the ASH guideline panel suggests not testing for all hereditary thrombophilias (using a panel of tests) to guide thromboprophylaxis (conditional recommendation based on very low certainty in the evidence about effects)."
- "For individuals with a family history of FVL or PGM (low-risk thrombophilia) but no family history of VTE who have a minor provoking risk factor for VTE (eg, immobility or minor injury, illness, or infection), the ASH guideline panel suggests not testing for the known thrombophilia to guide thromboprophylaxis (conditional recommendation based on very low certainty in the evidence about effects). For individuals with a first-degree family history of antithrombin, protein C, or protein S deficiency (high-risk thrombophilia) but no family history of VTE who have a minor provoking risk factor for VTE, the ASH guideline panel suggests testing for the known thrombophilia. The panel suggests thromboprophylaxis in individuals with thrombophilia and no thromboprophylaxis in individuals without

thrombophilia (conditional recommendation based on very low certainty in the evidence about effects). For individuals with a second-degree family history of antithrombin, protein C, or protein S deficiency (high-risk thrombophilia) but no family history of VTE who have a minor provoking risk factor for VTE, the ASH guideline panel suggests either testing for the known thrombophilia or not testing for thrombophilia to guide the use of thromboprophylaxis (conditional recommendation based on very low certainty in the evidence about effects)."

- "For women from the general population who are considering using COCs, the ASH guideline panel recommends not performing thrombophilia testing to guide the use of COC (strong recommendation based on low certainty in the evidence about effects)."
- "For women from the general population who are considering using HRT, the ASH guideline panel suggests not performing thrombophilia testing to guide the use of HRT (conditional recommendation based on low certainty in the evidence about effects)."
- "For women with a family history of VTE and unknown thrombophilia status in the family who are considering using COCs, the ASH guideline panel suggests not testing for hereditary thrombophilia (using a panel of tests) to guide the use of COC (conditional recommendation based on very low certainty in the evidence about effects)."
- "For women with a family history of VTE and unknown thrombophilia in the family who are considering using HRT, the ASH guideline panel suggests not performing thrombophilia testing for any hereditary thrombophilia to guide the use of HRT (conditional recommendation based on very low certainty in the evidence about effects)."
- "For women with a family history of VTE and known FVL or PGM in the family (low-risk thrombophilia), the ASH guideline panel suggests not testing for the known familial thrombophilia to guide the use of COC (conditional recommendation based on very low certainty in the evidence about effects). For women with a family history of VTE and known antithrombin, protein C, or protein S deficiency in the family (high-risk thrombophilia), the ASH guideline panel suggests testing for the known familial thrombophilia. The panel suggests avoidance of COCs for women with high-risk thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."
- "For women with a family history of VTE and known FVL or PGM in the family (low-risk thrombophilia), the ASH guideline panel suggests not testing for the known familial thrombophilia to guide the use of HRT (conditional recommendation based on very low certainty in the evidence about effects). For women with a family history of VTE and known antithrombin, protein C, or protein S deficiency in the family (high-risk thrombophilia), the ASH guideline

panel suggests testing for the known familial thrombophilia. The panel suggests avoidance of HRT for women with high-risk thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."

- "For women with a family history of VTE and known homozygous FVL, a combination of FVL and PGM, or an antithrombin deficiency in the family, the ASH guideline panel suggests testing for the known familial thrombophilia. The panel suggests antepartum thromboprophylaxis for women with the same familial thrombophilia (ie, homozygous FVL, combination of FVL and PGM, or antithrombin deficiency) and no antepartum prophylaxis for women without the same familial thrombophilia (conditional recommendation based on very low certainty in the evidence about effects). For women with a family history of VTE and a known protein C or protein S deficiency in the family, the ASH guideline panel suggests either testing for the known familial thrombophilia or not testing for thrombophilia to guide antepartum prophylaxis (conditional recommendation based on very low certainty in the evidence about effects)."
- "For women with a first-degree family history of VTE and known homozygous FVL, a combination of FVL and PGM, antithrombin deficiency, protein C deficiency, or protein S deficiency in the family, the ASH guideline panel suggests testing for the known familial thrombophilia. The panel suggests postpartum thromboprophylaxis for women with the same familial thrombophilia (ie, homozygous FVL, combination of FVL and PGM, or antithrombin deficiency) and no postpartum prophylaxis for women without the same familial thrombophilia (conditional recommendation based on very low certainty in the evidence about effects). For women with a second-degree family history of VTE and a known combination of FVL and PGM, or antithrombin deficiency in the family, the ASH guideline panel suggests testing for the known familial thrombophilia. The panel suggests postpartum thromboprophylaxis for women with thrombophilia and no postpartum prophylaxis for women without thrombophilia (conditional recommendation based on very low certainty in the evidence about effects). For women with a second-degree family history of VTE and a known protein C or protein S deficiency in the family, the ASH guideline panel suggests either testing for the known familial thrombophilia or not testing for thrombophilia to guide postpartum thromboprophylaxis (conditional recommendation based on very low certainty in the evidence about effects)."
- "For ambulatory patients with cancer receiving systemic therapy who have a family history of VTE and are otherwise determined to be at low or intermediate risk for VTE, the ASH guideline panel suggests testing for hereditary thrombophilia. The panel suggests ambulatory thromboprophylaxis for patients with thrombophilia and no thromboprophylaxis for patients without

thrombophilia (conditional recommendation based on very low certainty in the evidence about effects)."

American College of Obstetricians and Gynecologists

The 2013 ACOG clinical management guidelines recommend that screening for inherited thrombophilia "may be considered in the following clinical settings:

1. "A personal history of venous thromboembolism that was associated with a non-recurrent risk factor
2. A first degree relative (parent or sibling) with a history of high-risk thrombophilia" (ACOG, 2013).

The 2018 ACOG Practice Bulletin Summary Number 197 supersedes the above 2013 guidelines (Practice Bulletin Number 138). In this update, the ACOG makes the following recommendations regarding screening based on "limited or inconsistent scientific evidence":

"Screening for inherited thrombophilias is not recommended for women with a history of fetal loss or adverse pregnancy outcomes including abruption, preeclampsia, or fetal growth restriction because there is insufficient clinical evidence that antepartum prophylaxis with unfractionated heparin or low molecular-weight heparin prevents recurrence in these patients."

"Because of the lack of association between either heterozygosity or homozygosity for the *MTHFR* C677T polymorphism and any negative pregnancy outcomes, including any increased risk of VTE, screening with either *MTHFR* mutation analyses or fasting homocysteine levels is not recommended."

The 2018 ACOG recommends the following screening guideline based on "consensus and expert opinion":

"Among women with personal histories of VTE, recommended screening tests for inherited thrombophilias should include factor V Leiden mutation; prothrombin G20210A mutation; and antithrombin, protein S, and protein C deficiencies" (ACOG, 2018).

Evaluation of Genomic Applications in Practice and Prevention

"The Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group found adequate evidence to recommend against *routine* testing for Factor V Leiden (FVL) and/or prothrombin 20210G>A (Gupta et al.) in the following circumstances: (1) adults with idiopathic venous thromboembolism (VTE). In such

cases, longer term secondary prophylaxis to avoid recurrence offers similar benefits to patients with and without one or more of these mutations. (2) Asymptomatic adult family members of patients with VTE and an FVL or PT mutation, for the purpose of considering primary prophylactic anticoagulation. Potential benefits are unlikely to exceed potential harms. The evidence was insufficient to determine whether FVL/PT testing might have clinical utility in some circumstances, such as for identifying FVL homozygosity among asymptomatic family members of adults with idiopathic VTE or counseling patients about the risks and benefits of antithrombotic therapy. The recommendations do not extend to patients with other risk factors for thrombosis, such as contraceptive use, as the evidence review that serves as the basis for the recommendations focused primarily on idiopathic VTE" (EGAPP, 2011).

The Anticoagulation Forum

The Anticoagulation Forum published guidance in the Journal of Thrombosis and Thrombolysis on (Stevens et al., 2016):

- "Do not perform thrombophilia testing following an episode of provoked VTE. A positive thrombophilia evaluation is not a sufficient basis to offer extended anticoagulation following an episode of provoked VTE.
- Do not perform thrombophilia testing in patients following an episode of unprovoked VTE. If a patient with unprovoked VTE and low bleeding risk is planning to stop anticoagulation, test for thrombophilia if test results would change this decision. A negative thrombophilia evaluation is not a sufficient basis to stop anticoagulants following an episode of unprovoked VTE in a patient with low bleeding risk and willingness to continue therapy.
  Heterozygosity for FVL or PGM does not increase the predicted risk of recurrence after unprovoked VTE to a clinically significant degree.
- Do not test for thrombophilia in asymptomatic family members of patients with VTE or hereditary thrombophilia. As a family history of VTE confers an excess risk of thrombosis, relatives should be counseled regarding use of prophylaxis in high-risk situations.
- Do not test for thrombophilia in asymptomatic family members of patients with VTE or hereditary thrombophilia who are contemplating use of estrogen. If an [individual] is contemplating estrogen use has a first-degree relative with VTE and a known hereditary thrombophilia, test for that thrombophilia if the result would change the decision to use estrogen.
- Do not perform thrombophilia testing at the time of VTE diagnosis or during the initial 3-month course of anticoagulant therapy. When testing for thrombophilias following VTE, use either a 2-stage testing approach or perform testing after a minimum of 3 months of anticoagulant therapy has been completed, and

anticoagulants have been held.

- Do not test for thrombophilia in asymptomatic family members of patients with VTE or hereditary thrombophilia who are contemplating pregnancy. If [an individual] contemplating pregnancy has a first-degree relative with VTE and a known hereditary thrombophilia… test for that thrombophilia if the result would change VTE prophylaxis decisions" (Stevens et al., 2016).

American College of Cardiology (ACC)

In 2017, guidance published in the New England Journal of Medicine by Gupta was summarized by Barnes for the American College of Cardiology:

1. "Venous thromboembolism (VTE) affects an estimated 300,000-600,000 patients annually in the United States.
2. The risk of VTE recurrence is best predicted by whether the initial VTE episode was provoked or unprovoked, not the results of inherited thrombophilia testing.
3. Most patients with a provoked VTE have recently undergone surgery, immobility, trauma, or have a concurrent cancer diagnosis. Concurrent use of hormones (e.g., estrogen-containing contraceptive pills) is also frequently considered a provoking factor for VTE development.
4. For patients with a first provoked VTE event, guidelines recommend anticoagulation for only 3 months (not longer). Prolonged anticoagulation is associated with an increased risk of bleeding that outweighs the risk of VTE recurrence for these patients.
5. Patients with an unprovoked VTE (none of the provoking risk factors listed above) require longer anticoagulation due to a higher risk of recurrence that outweighs the risk of bleeding associated with long-term anticoagulation therapy.
6. Thrombophilia testing performed in the setting of an acute clot or ongoing anticoagulation therapy will often result in spurious results (usually false positive). For example, natural anticoagulants (e.g., protein C and S, antithrombin) are consumed during an acute thrombotic event and the levels can be reduced by ongoing anticoagulant therapy.
7. A recent study identified that up to 55% of Medicare patients with provoked VTE had undergone inappropriate thrombophilia testing, associated with significant cost to the healthcare system.
8. While thrombophilia testing rarely impacts management decisions about anticoagulation therapy, it may be beneficial for genetic testing purposes in patients presenting with a first unprovoked VTE at a young age (e.g., <45 years) or at an unusual site.
9. For patients with unprovoked VTE at a young age, VTE at an unusual site, arterial thrombosis, or pregnancy morbidity, testing for antiphospholipid antibodies,

JAK2 mutation, and paroxysmal nocturnal hemoglobinuria may be beneficial.
10. There is no role for extensive cancer screening (e.g., computed tomography scanning) in patients with VTE. Only routine, age-appropriate cancer screening is recommended" (G. Barnes, 2017; Gupta et al., 2017).

Again in 2017, key points—inclusive of guiding points—published in the New England Journal of Medicine by Connors were captured by Barnes for the American College of Cardiology:

1. "The majority of patients with venous thromboembolism (VTE) should not be tested for thrombophilia. Data supporting clinical usefulness and benefits are limited or nonexistent.
2. Most patients with inherited thrombophilia can be identified by coagulation experts based on the patient's personal and family history of VTE. Thrombophilia testing is usually not required.
3. Factors associated with an inherited thrombophilia include VTE at a young age (<40-50 years), a strong family history of VTE, VTE in conjunction with weak provoking factors at a young age, recurrent VTE, and VTE in an unusual site (e.g., cerebral or splanchnic veins).
4. Do not perform thrombophilia testing at the time of a VTE event, as it can be inaccurate (often false positive). Perform testing (when indicated) after completion of initial therapy and if it might change management strategies.
5. Do not perform thrombophilia testing while a patient is receiving anticoagulation. Instead, wait until 2 weeks after discontinuing warfarin, or 2 days for direct oral anticoagulants and heparin.
6. The goal of thrombophilia testing should be to aid decision making regarding future VTE prophylaxis, to guide testing of family members, and to determine the cause in severe or fatal VTE. Test results alone should not be used to decide on the duration of anticoagulation therapy.
7. Most VTE recurrence risk tools do not incorporate thrombophilia test results into their risk stratification schemes.
8. For patients with provoked VTE, even if they have homozygous factor V Leiden, prothrombin gene mutations, or deficiencies of protein S, C, or antithrombin, they do not require lifelong anticoagulation.
9. Currently available thrombophilia tests are insufficient to identify inherited risks of VTE. Therefore, a negative test should not be interpreted as a patient being free of thrombophilia.
10. Testing for the antiphospholipid antibody syndrome may be useful in patients with unprovoked VTE if there is clinical equipoise about extended anticoagulation courses. It can also be useful to determine warfarin versus direct oral anticoagulant therapy" (G. D. Barnes, 2017; Connors, 2017).

European Society of Cardiology

The ESC has published guidelines for the diagnosis and management of acute PE. These guidelines state:

- "D-dimer measurement and clinical prediction rules should be considered to rule out PE during pregnancy or the post-partum period
- Plasma D-dimer measurement, preferably using a highly sensitive assay, is recommended in outpatients/emergency department patients with low or intermediate clinical probability, or those that are PE-unlikely, to reduce the need for unnecessary imaging and irradiation
- A D-dimer test, using an age-adjusted cut-off or adapted to clinical probability, should be considered as an alternative to the fixed cut-off level
- D-dimer measurement is not recommended in patients with high clinical probability, as a normal result does not safely exclude PE, even when using a highly sensitive assay
- Assessment of the RV [right ventricle] by imaging methods or laboratory biomarkers should be considered, even in the presence of a low PESI [Pulmonary Embolism Severity Index] or a negative sPESI [simplified Pulmonary Embolism Severity Index]" (Konstantinides et al., 2019).

In 2021, the ESC Working Group released guidelines on diagnosis and management of acute deep vein thrombosis. These guidelines suggest that "ELISA D-dimer or highly sensitive immunoturbidimetric tests should be measured in 'unlikely' clinical probability patients to exclude DVT diagnosis" (Mazzolai et al., 2022).

World Health Organization (WHO)

In the WHO medical eligibility criteria for contraceptive use, known thrombogenic mutations (e.g. factor V Leiden; prothrombin mutation; protein S, protein C, and antithrombin deficiencies) are "a condition which represents an unacceptable health risk if the contraceptive method is used" when considering combined hormonal contraceptives, and the method is "not to be used." The WHO notes that "among women with thrombogenic mutations, COC users had a 2- to 20-fold higher risk of thrombosis than non-users." When considering progestogen-only contraceptives, intrauterine devices, barrier methods, or female surgical sterilization, known thrombogenic mutations are "a condition for which there is no restriction for the use of the contraceptive method" or "the advantages of using the method generally outweigh the theoretical or proven risks." In all cases, the WHO clarifies that "routine screening is not appropriate because of the rarity of the conditions and the high cost of screening" (WHO, 2015).

National Institute for Health and Care Excellence (NICE)

In the NICE venous thromboembolic disease guidelines, for thrombophilia testing, it is recommended:

- "Do not offer testing for hereditary thrombophilia to people who are continuing anticoagulation treatment.
- "Do not offer thrombophilia testing to people who have had provoked DVT or PE."
- "Consider testing for antiphospholipid antibodies in people who have had unprovoked DVT or PE if it is planned to stop anticoagulation treatment, but be aware that these tests can be affected by anticoagulants and specialist advice may be needed."
- "Consider testing for hereditary thrombophilia in people who have had unprovoked DVT or PE and who have a first-degree relative who has had DVT or PE if it is planned to stop anticoagulation treatment, but be aware that these tests can be affected by anticoagulants and specialist advice may be needed."

"Do not routinely offer thrombophilia testing to first-degree relatives of people with a history of DVT or PE and thrombophilia" (NICE, 2023).

American College of Radiology (ACR)

The ACR has guidelines for suspected pulmonary embolisms (PE). The ARC prefaced that their publication "focuses on the initial evaluation for clinically suspected PE, recognizing that as many as 80% of PE cases are associated with DVT" and that "PE also may occur without detectable DVT." The guidelines do not mention any laboratory or genetic testing, although some of the imaging recommendations are based on positive or negative D-dimer results (Kirsch et al., 2022).

Thrombosis Canada

Thrombosis Canada released guidelines on the diagnosis of PE (Thrombosis Canada, 2023). They state: "The constellation of symptoms and signs may be suggestive of PE but do not alone have the sensitivity or specificity to rule in or rule out the diagnosis. When the diagnosis of PE is considered, the clinical stability of the patient and associated pre-test probability will dictate the diagnostic approach." The guidelines further recommend:

- "In patients without hypotension (SBP >90 mmHg), pre-test probability can be assessed by a validated clinical prediction rule such as the Well's score. In patients who are <50 years of age, with a low pretest probability of PE, further testing (such as d-dimer measurement or diagnostic imaging) is not necessary

provided all clinical features/criteria in the Pulmonary Embolism Rule-out Criteria (PERC) are present."

- "In cases with PE unlikely pre-test probability, a negative high sensitivity D-dimer result rules out the diagnosis of PE. However, a positive D-dimer test MUST be followed up with a definitive test to confirm/refute the diagnosis of PE.
- When a high-sensitive d-dimer assay is used, age-adjusted D-dimer levels can increase the specificity of D-dimer testing without sacrificing sensitivity. In patients over the age of 50, a D-dimer result is considered negative if it is less than the patient age multiplied by 10 (for example, in a 76-year-old, a negative result is less than 760 µg/L). For patients under the age of 50, a D-dimer value less than 500 µg/L remains the cutoff for a negative result.
- With a high PE pre-test probability (Well's score > 4.5), there is no role for ordering a D-dimer, as the clinical likelihood of PE remains unacceptably high among those with a negative D-dimer result. Therefore, when the Wells score is 4.5 or greater, one should go directly to imaging to establish the diagnosis" (Thrombosis Canada, 2023).

The Wells Score is a total score of: clinical symptoms and signs of DVT (3 points), previous DVT or PE (1.5 points), immobilization of over three days or surgery within four weeks (1.5 points), heart rate over 100 beats per minute (1.5 points), hemoptysis (1 point), malignancy (1 point), and no alternative diagnosis more likely than PE (3 points). A total score under 4.5 equates to PE unlikely, and a toal score of 4.5 or over equates to PE likely (Thrombosis Canada, 2023).

The PE Rule-out Criteria (PERC) for patients with low pretest probability for PE are: age less than 50, initial heart rate of less than 100 beats per minute, initial SaO2 of over 94% on room air, no unilateral leg swelling, no hemoptysis, no surgery or trauma in the past four weeks, no history of VTE and no estrogen use (Thrombosis Canada, 2023).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, please visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81240	F2 (prothrombin, coagulation factor III) (eg, hereditary hypercoagulability) gene analysis, 20210G>A variant
81241	F5 (coagulation factor V) (eg, hereditary hypercoagulability) gene analysis, Leiden variant
81291	MTHFR (5,10-methylenetetrahydrofolate reductase) (eg, hereditary hypercoagulability) gene analysis, common variants (eg, 677T, 1298C)
81400	Molecular pathology procedure, Level 1 (eg, identification of single germline variant [eg, SNP]) by techniques such as restriction enzyme digestion or melt curve analysis.
81479	Unlisted molecular pathology procedure
85300	Clotting inhibitors or anticoagulants; antithrombin III, activity
85301	Clotting inhibitors or anticoagulants; antithrombin III, antigen assay
85302	Clotting inhibitors or anticoagulants; protein C, antigen
85303	Clotting inhibitors or anticoagulants; protein C, activity
85305	Clotting inhibitors or anticoagulants; protein S, total
85306	Clotting inhibitors or anticoagulants; protein S, free
85307	Activated Protein C (APC) resistance assay
0278U	Hematology (genetic thrombosis), genomic sequence analysis of 14 genes, blood, buccal swab, or amniotic fluid Proprietary test: Versiti™ Thrombosis Panel Lab/Manufacturer: Versiti™

Whole Genome and Whole Exome Sequencing

Policy Number: AHS – M2032 – Whole Genome and Whole Exome Sequencing	Prior Policy Name and Number, as applicable: • AHS – M2032 Whole Genome Whole Exome Sequencing
Initial Policy Effective Date: 01/01/2026	

POLICY DESCRIPTION | RELATED POLICIES | INDICATIONS AND/OR LIMITATIONS OF COVERAGE | TABLE OF TERMINOLOGY | SCIENTIFIC BACKGROUND | GUIDELINES AND RECOMMENDATIONS | APPLICABLE STATE AND FEDERAL REGULATIONS | APPLICABLE CPT/HCPCS PROCEDURE CODES | EVIDENCE-BASED SCIENTIFIC REFERENCES

I. Policy Description

Whole genome sequencing (WGS) is the strategy of using next-generation technology to sequence the entire genome. Whole Exome Sequencing (WES) refers to sequencing of the exome, the component of the genome that predominantly encode proteins. Next generation sequencing (NGS) involves sequencing of multiple small fragments of DNA in parallel, producing fast, accurate sequencing results (Hulick, 2024).

This policy is applicable for undiagnosed rare germline disorders.

II. Related Policies

Policy Number	Policy Title
AHS-M2145	General Genetic Testing, Germline Disorders
AHS-M2146	General Genetic Testing, Somatic Disorders

III. Indications and/or Limitations of Coverage

Application of coverage criteria is dependent upon an individual's benefit coverage at the time of the request. Specifications pertaining to Medicare and Medicaid can be found in the "Applicable State and Federal Regulations" section of this policy document.

1) For the evaluation of unexplained congenital or neurodevelopmental disorder in individuals less than 18 years of age, whole exome sequencing (WES) and comparator analysis (e.g., parents/siblings) WES **MEET COVERAGE CRITERIA** when **all** of the following criteria are met:

a) When the individual has been evaluated by an ABMGG board-certified medical geneticist or an ABGC board-certified genetic counselor (CGC) and has been counseled about the potential risks of genetic testing;

b) When the WES results will impact patient management and clinical outcome for the individual being tested;

c) When a genomic etiology is the most likely explanation for the phenotype;

d) When no other causative circumstances (e.g., environmental exposures, injury, infection) can explain the symptoms;

e) When the clinical presentation does not fit a well-described syndrome for which single-gene or targeted panel testing (e.g., comparative genomic hybridization/chromosomal microarray analysis) is available;

f) When the differential diagnosis list and/or phenotype warrant testing of multiple genes and one of the following:

   i) WES is more practical than the separate single gene tests or panels that would be recommended based on the differential diagnosis.

   ii) WES results may preclude the need for multiple and/or invasive procedures, follow-up, or screening that would be recommended in the absence of testing.

2) For a fetus with ultrasound anomalies, WES and comparator analysis (e.g., parents/siblings) WES **MEETS COVERAGE CRITERIA** when **all** of the following criteria are met:

   a) When pre-test counseling has been provided by an ABMGG board-certified medical geneticist or an ABGC board-certified genetic counselor (CGC);

   b) When standard chromosomal microarray testing (CMA) and karyotype analysis have failed to yield a definitive diagnosis;

   c) When a genomic etiology is the most likely explanation for the phenotype;

   d) When no other causative circumstances (e.g., environmental exposures, injury, infection) can explain the symptoms;

   e) When clinical presentation does not fit a well-described syndrome for which single-gene or targeted panel testing is available. If a specific diagnosis is suspected, molecular testing for the suggested disorder (with single-gene test or gene panel) should be the initial test.

3) Reanalysis of exome sequencing (ES) data with WES and comparator analysis (e.g., parents/siblings) WES **MEETS COVERAGE CRITERIA** for **any** of the following situations:

   a) For individuals less than 18 years of age with initial negative ES results as an aid in clinical diagnosis when additional phenotypic findings are noted during a child's growth and development.

   b) For diagnostic results and results deemed to be possibly (but not definitively) associated with the fetal phenotype (new gene-disease associations might have been unknown at the time of initial diagnosis).

   c) For fetal ES with nondiagnostic or negative results, if a new phenotype develops in the proband after birth, a future pregnancy is planned, or a significant amount of time has passed (at least 12 months) since the initial testing was performed.

   d) If the original prenatal ES report does not account for the complete phenotype or if new/additional phenotypes develop over time.

4) When WES is unable to identify a causative variant and the clinical suspicion of a genomic etiology remains in situations where any of the above criteria are met in their entirety, whole genome sequencing (WGS) **MEETS COVERAGE CRITERIA.**

The following does not meet coverage criteria due to a lack of available published scientific literature confirming that the test(s) is/are required and beneficial for the diagnosis and treatment of an individual's illness.

5) If WES has been previously performed, further genetic tests involving only exome analyses **DO NOT MEET COVERAGE CRITERIA**.

6) Focused exome sequencing and targeted WGS **DO NOT MEET COVERAGE CRITERIA.**

7) For all other situations not described above, WES **DOES NOT MEET COVERAGE CRITERIA**.

8) For all other situations not described above, WGS **DOES NOT MEET COVERAGE CRITERIA**.

IV. Table of Terminology

Term	Definition
AAN	American Academy of Neurology
AANEM	American Association of Neuromuscular and Electrodiagnostic Medicine

AAP	American Academy of Pediatrics
ABGC	American Board of Genetic Counseling
ABMGG	American Board of Medical Genetics and Genomics
ACMG	American College of Medical Genetics and Genomics
ACOG	American College of Obstetricians and Gynecologists
ACTA2	*Actin alpha 2 smooth muscle*
ACTC1	*Actin alpha cardiac muscle 1*
AFF2	*AF4/FMR2 family member 2*
AMP	Association for Molecular Pathology
APC	*APC regulator of WNT signalling pathway*
APOB	*Apolipoprotein B*
AR	*Androgen receptor*
ASD	Autism spectrum disorder
ATN1	*Atrophin 1*
ATP7B	*ATPase copper transporting beta*
ATXN1	*Ataxin 1*
ATXN10	*Ataxin 10*
ATXN2	*Ataxin 2*
ATXN3	*Ataxin 3*
ATXN7	*Ataxin 7*
ATXN8OS	*Ataxin 8 opposite strand lncRNA*
AXL	*AXL receptor tyrosine kinase*
BMPR1A	*Bone morphogenetic protein receptor type 1A*
BRCA1	*BRCA1 DNA repair associated*
BRCA2	*BRCA2 DNA repair associated*
BTD	*Biotinidase*
C9orf72	C9orf72-SMCR8 complex subunit
CA	Congenital anomalies
CACNA1A	*Calcium voltage-gated channel subunit alpha1 A*
CACNA1S	*Calcium voltage-gated channel subunit alpha1 S*
CCDC141	*Coiled-coil domain containing 141*
CCDC88C	*Coiled-coil domain containing 88C*
CDON	*Cell adhesion associated; oncogene regulated*
CES	Clinical exome sequencing
CFES	Clinically focused exome sequencing
CGC	ABGC board-certified genetic counselor
CHD7	*Chromodomain helicase DNA binding protein 7*
CLIA '88	Clinical Laboratory Improvement Amendments of 1988
CMA	Chromosomal microarray analysis

CMS	Centers for Medicare and Medicaid Services
CNBP	*CCHC-type zinc finger nucleic acid binding protein*
COL3A1	*Collagen type III alpha 1 chain*
CSTB	*Cystatin B*
DCAF17	*DDB1 and CUL4 associated factor 17*
DCC	*DCC netrin 1 receptor*
DD	Developmental delay
DIP2B	*Disco interacting protein 2 homolog B*
DMPK	*DM1 protein kinase*
DMXL2	*Dmx like 2*
DNA	*Deoxyribonucleic acid*
DSC2	*Desmocollin 2*
DSG2	*Desmoglein 2*
DSP	*Desmoplakin*
EGF	Epidermal growth factor
EP	Expected pathogenic
ES	Exome sequencing
FBN1	*Fibrillin 1*
FGFR1	*Fibroblast growth factor receptor 1*
FMR1	*Fragile X messenger ribonucleoprotein 1*
FXN	*Frataxin*
GADL1	*Glutamate decarboxylase like 1*
GDD	Global developmental delay
Gdna	Genomic DNA
GLA	Galactosidase alpha
GnRH	Gonadotropin-releasing hormone
GS	Genome sequencing
HTT	*Huntingtin*
ID	Intellectual disability
IGSF10	*Immunoglobulin superfamily member 10*
IHH	Idiopathic hypogonadotropic hypogonadism
ISPD	International Society for Prenatal Diagnosis
JAMA	Journal of the American Medical Association
JPH3	*Junctophilin 3*
KCNH2	*Potassium voltage-gated channel subfamily H member 2*
KCNQ1	*Potassium voltage-gated channel subfamily Q member 1*
KP	Known pathogenic
LDLR	*Low density lipoprotein receptor*
LDT	Laboratory developed test

LMNA	*Lamin A/C*
MCC	*MCC regulator of WNT signalling pathway*
MEN1	*Menin 1*
MLH1	*MutL homolog 1*
MSH2	*MutS homolog 2*
MSH6	*MutS homolog 6*
MUTYH	*MutY DNA glycosylase*
MYBPC3	*Myosin binding protein C3*
MYH11	*Myosin heavy chain 11*
MYH7	*Myosin heavy chain 7*
MYL2	*Myosin light chain 2*
MYL3	*Myosin light chain 3*
NOA	Nonobstructive azoospermia
NDD	Neurodevelopmental disorders
NF2	*NF2, moesin-ezrin-radixin like (MERLIN) tumor suppressor*
NGS	Next-generation sequencing
NOP56	*NOP56 ribonucleoprotein*
NOTCH1	*Notch receptor 1*
NOTCH2NLC	*Notch 2 N-terminal like C*
OB-GYN	Obstetrician-gynecologist
OTC	Over the counter
PABPN1	*Poly(a) binding protein nuclear 1*
PCSK9	*Proprotein convertase subtilisin/kexin type 9*
PDE3A	*Phosphodiesterase 3A*
pES	Prenatal exome sequencing
PFS	Progression-free survival
PHOX2B	*Paired like homeobox 2B*
PICU	Pediatric intensive care unit
PKP2	*Plakophilin 2*
PMS2	*PMS1 homolog 2, mismatch repair system component*
PNPLA6	*Patatin like phospholipase domain containing 6*
POLR3A	*RNA polymerase III subunit A*
PPP2R2B	*Protein phosphatase 2 regulatory subunit Beta*
PQF	Perinatal Quality Foundation
PRKAG2	*Protein kinase AMP-activated non-catalytic subunit gamma 2*
PROKR2	*Prokineticin receptor 2*
PTEN	*Phosphatase and tensin homolog*
RB1	*RB transcriptional corepressor 1*
RELN	*Reelin*

RET	*Ret proto-oncogene*
rWGS	Rapid whole genome sequencing
RYR1	*Ryanodine receptor 1*
RYR2	*Ryanodine receptor 2*
SCN5A	*Sodium voltage-gated channel alpha subunit 5*
SDHAF2	*Succinate dehydrogenase complex assembly factor 2*
SDHB	*Succinate dehydrogenase complex iron sulfur subunit B*
SDHC	*Succinate dehydrogenase complex subunit C*
SDHD	*Succinate dehydrogenase complex subunit D*
SFM/SMFM	Society for Maternal and Fetal Medicine
SLIT2	*Slit guidance ligand 2*
SMAD3	*SMAD family member 3*
SMAD4	*SMAD family member 4*
SPRED3	*Sprouty related EVH1 domain containing 3*
STK11	*Serine/threonine kinase 11*
TCF4	*Transcription factor 4*
TGFBR1	*Transforming growth factor beta receptor 1*
TGFBR2	*Transforming growth factor beta receptor 2*
TMEM43	*Transmembrane protein 43*
TNNI3	*Troponin I3, cardiac type*
TNNT2	*Troponin T2, cardiac type*
TP53	*Tumor protein p53 gene*
TPM1	Tropomyosin 1
TRAPPC9	*Trafficking protein particle complex subunit 9*
TSC1	*TSC complex subunit 1*
TSC2	*TSC complex subunit 2*
VHL	*von Hippel-Lindau tumor suppressor gene*
VUS	Variants of unknown significance
WES	Whole exome sequencing
WGS	Whole genome sequencing
WT1	*WT1 transcription factor*

V. Scientific Background

DNA sequencing is a critical tool for the evaluation of many medical conditions. The two primary methods of DNA sequencing in the clinical setting are Sanger sequencing and next-generation sequencing or NGS. NGS is a technique that allows for the rapid sequencing of multiple strands of DNA. It is not limited to one specific type of test; rather it encompasses numerous technologies that produce swift and high-volume sequencing. NGS can be used to sequence larger sequences, such as the exome or the

entire genome. This is opposed to the traditional Sanger sequencing, which is more useful for sequencing a specific gene (Hulick, 2024).

The NGS procedure typically includes the following steps: first the patient's DNA is prepared to serve as a template, then DNA fragments are isolated (on solid surfaces such as small beads) where sequence data is generated. Then these results are compared against a reference genome. Any DNA sample may be used if the quality and quantity of that sample is sufficient, but the methods of library generation and data analysis often vary from panel to panel. Evaluating the results of a gene panel typically requires expertise in bioinformatics. Since NGS reports data on any variants found, great care must be taken to evaluate these gene variants, especially variants of unknown significance (VUS) and secondary findings (Hulick, 2024; Rehm et al., 2013).

Exome and genome sequencing are usually performed with NGS. The exome represents all the protein-encoding genes, and at least 85% of pathogenic mutations are found in the exome. Further, the exome only comprises approximately 1.5%-2% of the genome, thereby making it more cost effective to sequence than whole genome sequencing. The entire exome includes approximately 30 megabases compared to the genome's 3.3 gigabases. However, sequencing an entire genome may be useful as a pathogenic mutation may be in a noncoding region of the genome, such as gene regulation dysfunction. Most clinical NGS testing uses targeted panels or whole exome sequencing (WES), and whole genome sequencing (WGS) is only used in select cases. For instance, conditions such as nonsyndromic hearing loss (possible pathogenic variants in over 60 genes) may benefit from WES evaluation (Hulick, 2024).

Several companies have pivoted towards focused exome sequencing. These are panels tailored to individual phenotypes and target a maximum number of genes depending on the company. There is a >30% diagnostic yield, with freedom for clinicians to choose specific genes they are interested in, with reduced cost and options to reflex to WES for negative cases (GGC, 2022). In their study, Jia et al. (2023) retrospectively analyzed 372 pediatric patients who were referred to clinically focused exome sequencing (CFES), and concluded that CFES may be first-line for "diagnosing young children with suspected genetic conditions, as it validates the identification of molecular genetics alterations and facilitates comprehensive medical management. The patients that were more likely to receive diagnoses via CFES were those with "metabolism/homeostasis abnormalities, craniofacial /otolaryngology/ ophthalmologic abnormalities, and/or [abnormalities of] the integument" (Jia et al., 2023). Despite the novelty and expected benefits of focused exome sequencing, more clinical studies with larger sample sizes are necessary.

Proprietary Testing

Many proprietary technologies for WES and WGS are available. Companies such as Variantyx provide highly specialized genetic testing to patients and clinicians. The Genomic Unity® Exome Plus Analysis test sequences the exome, including intronic and regulatory variants, identifies disease causing deletions or duplications in the genome, and analyzes the mitochondrial genome with heteroplasmy (≥5%). This test may identify many genes for a variety of disorders including *AR, ATN1, ATXN1, ATXN2, ATXN3, ATXN7, ATXN8OS, ATXN10, C9ORF72, CACNA1A, CNBP, CSTB, DMPK, FMR1, FXN, HTT, JPH3, NOP56, NOTCH2NLC, PABPN1, PPP2R2B, TBP* (for adult-onset movement disorders), *AFF2, DIP2B, FMR1* (for early-onset intellectual disability disorders), and *PHOX2B, TCF4* (for other disorders) (variantyx, 2020). This test requires either a blood, saliva or gDNA (genomic DNA) sample and has an eight-week turnaround time.

Clinical Utility and Validity

Alfares et al. (2018) compared the cost-effectiveness and clinical utility of both WES and WGS. Data was analyzed from 108 participants; all 108 individuals had negative array comparative genomic hybridization (also known as chromosomal microarray) results and negative or inconclusive WES results before WGS was performed. Chromosomal microarray (CMA) is another common genetic testing method that can analyze many pieces of DNA simultaneously. The authors only pinpointed three positive cases where WGS identified a genetic or inherited disorder that WES did not recognize; further, it was noted that "30% of the positive cases identified by WGS could be identified by reanalyzing the WES raw data, and WGS achieved an only 7% higher detection rate. Therefore, until the cost of WGS approximates that of WES, reanalyzing WES raw data is recommended before performing WGS" (Alfares et al., 2018).

Yang et al. (2014) conducted a single-center observational study of 2000 patients with clinical whole exome sequencing performed for a suspected genetic disorder. A molecular diagnosis was reported for 504 patients (25.2%) with 58% of the diagnostic mutations not previously reported. The investigators concluded that "the yield of whole-exome sequencing may offer advantages over traditional molecular diagnostic approaches in certain patients" (Yang et al., 2014). Best et al. (2018) reviewed 31 different WES studies and noted that the diagnostic rates varied between 6.2% and 80%; however, the researchers state that the "differences in inclusion criteria and trio versus singleton approaches to sequencing largely account for the wide range of diagnostic rates."

Tammimies et al. (2015) evaluated the molecular diagnostic yield of CMA and WES in children with autism spectrum disorder (ASD). The patient cohort included 258 consecutively enrolled unrelated children with ASD, stratified into three groups based

on the presence of major congenital abnormalities and minor physical anomalies. All probands underwent CMA, with WES performed for 95 proband-parent trios. The molecular diagnostic yields of CMA and WES were comparable. Among the 95 patients undergoing WES, eight children (8.4%) received an ASD-related molecular diagnosis. Among the children who underwent both CMA and WES testing, the estimated proportion with an identifiable genetic etiology was 15.8%. The investigators concluded that "if replicated in additional populations, these findings may inform appropriate selection of molecular diagnostic testing for children affected by ASD" (Tammimies et al., 2015). A similar study was performed by Arteche-López et al. (2021) to validate WES as a "first-tier test for the genetic diagnosis of [ASD], when there is no suspicion of fragile X syndrome." Upon comparing the clinical utility of CMA, *FMR1* testing, and WES testing, the researchers "achieved a global diagnostic rate of 12.8% (44/343), the majority of them being characterised by WES (33/44; 75%) compared to CMA (9/44; 20.4%) or *FMR1* testing (2/44; 4.5%)," evidently demonstrating the "higher diagnostic power" of WES compared to CMA (Arteche-López et al., 2021).

Taylor et al. (2015) performed whole genome sequencing in 217 individuals across a broad spectrum of genetic disorders in whom previous screening had identified no pathogenic variants. Disease-causing variants were identified in 21% of cases, with the proportion increasing to 34% (23/68) for mendelian disorders and 57% (8/14) in family trios. The investigators concluded that the results "demonstrate the value of genome sequencing for routine clinical diagnosis but also highlight many outstanding challenges" (Taylor et al., 2015).

Miller et al. (2017) performed exome/whole genome sequencing to identify the genetic cause in patients with craniosynostosis, in whom prior clinically driven genetic testing had been negative. Out of the 40 patients' tests, associated mutations were identified in 15 patients (37.5%) involving 14 different genes. In five of the 15 positive cases, the molecular diagnosis had immediate, actionable consequences in patient management. The investigators concluded that "the benefits of exome/whole genome sequencing to identify causal mutations in craniosynostosis cases for which routine clinical testing has yielded negative results" (Miller et al., 2017).

Crowley et al. (2020) used WES in a single-center cohort study of 1005 pediatric IBD patients and found a 3% prevalence of damaging variants in genes linked to monogenic IBD, and that 1% of monogenic pediatric IBD patients have variants in genes associated with primary immunodeficiency that are potentially curable through allogeneic hematopoietic stem cell transplantation. As rare genetic variants could manifest in different phenotypes, the researchers believe that the "data supports the diagnosis of monogenic disease beyond the very early onset IBD population especially in children with a family history of autoimmune diseases and those with evidence of

extra-intestinal manifestations of IBD" and that WES will lend itself to provide definitive and personalized treatments in the future (Crowley et al., 2020).

Srivastava et al. (2014) conducted a retrospective cohort study on 78 children with neurodevelopmental disabilities and a prior unrevealing workup before WES. The overall presumptive diagnostic testing rate was 41% (32/78 patients). Results of WES affected patient management in all cases, most often related to reproductive planning (27/78). The investigators concluded that the high diagnostic yield of WES could lead to earlier diagnosis, impacting medical management, prognostication, and family planning (Srivastava et al., 2014).

https://ng.neurology.org/content/4/1/e212Haskell et al. (2018) studied the diagnostic utility of exome sequencing in the evaluation of neuromuscular disorders. A total of 93 undiagnosed patients with potential neuromuscular disorders participated in this study; the diagnostic yield of these 93 patients with exome sequencing was 12.9% "with one or more pathogenic or likely pathogenic variants identified in a causative gene associated with the patient's disorder" (Haskell et al., 2018). In this study, exome sequencing was able to provide or clarify a neuromuscular disorder diagnosis, but only in a small percentage of the population studied.

Involving WGS or WES as a supplemental level of evaluation has been able to effect change in medical care and treatment pathways. In the NIH-funded Undiagnosed Diseases Network, among 382 patients with complete evaluations, "28 (21%) of the patients who received a diagnosis, the diagnosis led to a recommendation regarding a change in therapy. In 49 (37%), the diagnosis led to a change in care other than therapy, such as the narrowing of diagnostic testing. In 48 (36%), the diagnosis led to variant-specific genetic counseling but did not lead to a change in the diagnostic or therapeutic strategy." The changes in therapy ranged from known drugs, vitamins, coenzyme supplementations, and transplant in one patient. This demonstrated evidence supporting usage of DNA sequencing for genetically determined conditions and a representative lens of how it can affect medical care (Splinter et al., 2018).

Muthaffar (2021) conducted a retrospective chart review for WES results between January 2018 to November 2019 for patients at a pediatric neurology clinic in Saudi Arabia to identify the utility of WES. It was found that "twenty-six children with undiagnosed neurological conditions were identified and underwent WES diagnosis. Nineteen patients (73.0%) of the cohort were diagnosed with pathogenic variants, likely pathogenic variants or variants of unknown significance (VUS)." The researcher also furthered the conclusions of the WES high diagnostic rate by proving direct implications on clinical management based on testing results. One patient who had a positive pathogenic *BTD* mutation, diagnosed at seven-years old with a biotinidase

deficiency, was started on biotin supplements after WES testing, and was able to breathe independently off a ventilator, regain motor capabilities with physical therapy, improve hearing, and eliminate convulsions (Muthaffar, 2021).

Using WES on eleven probands from ten Jordanian families who have been formerly diagnosed with limb-girdle dystrophy (LGMD) and Charcot-Marie-Tooth disease (CMT), Ababneh et al. (2021) identified a series of missense, nonsense, and deletion variants associated with neuromuscular disorders. Consequently, the researchers argue that "Utilization of WES is helpful to facilitate rapid and accurate NMDs diagnosis, complementing a thorough clinical evaluation", especially in a country where the risk of autosomal-recessive disorders is increased by consanguinity and the implementation of genetic diagnosis is limited and the results misunderstood (Ababneh et al., 2021).

Sanford et al. (2019) investigated the clinical utility of rWGS in children within the pediatric intensive care unit (PICU). They were able to make a molecular diagnosis by rWGS in 17 of 38 children, and in four of the 17 children diagnosed by rWGS (24%), "the genetic diagnoses led to a change in management while in the PICU, including genome-informed changes in pharmacotherapy and transition to palliative care… Eighty-two percent of diagnoses affected the clinical management of the patient and/or family after PICU discharge, including avoidance of biopsy, administration of factor replacement, and surveillance for disorder-related sequelae" (Sanford et al., 2019). In this retrospective analysis, benefits of rWGS were further elucidated in the setting of unknown or unclear clinical etiologies.

Reda et al. (2020) studied WES for metastatic solid cancer diagnoses in 506 patients. In this study, the somatic and germline exome analysis was restricted to 317 specific genes. Exome sequencing was successful in 386 tumor samples, and 342 patients received a therapeutic proposal based on their genetic results. However, only 79 patients were treated with an NGS matched therapy. While this study shows that WES is a possible tool to assist with metastatic solid cancer diagnoses and treatments, "no differences were observed between PFS [progression-free survival] ratios of patients treated with matched therapy versus standard therapy" (Reda et al., 2020).

Other studies have also yielded bifurcating results on the periodic revisiting of unsolved exome cases and for variants of unknown significance. Salfati et al. (2019) found that re-analysis of 101 WES cases one to seven years after initial analysis resulted in "the identification of additional diagnostic variants in 3 rare disease cases (5.9%) and 1 sudden unexplained death case (2%), which increased our molecular diagnostic yield to 31.4% and 12%, respectively." However, though they recognize the importance of any diagnostic yield to those families potentially affected, the authors

also acknowledge that "most of our cases remain unexplained after our re-analysis", which they attribute to an enduring lack of coverage of functional exonic variants, along with "the possibility of complicated oligogenic disease that is not easily dissected in small families, and the possibility of disease due to epigenetic, somatic, or other uninterrogated genomic aberrations." As such, "We [the authors] suggest that a 6-month cycle of automated re-analysis could improve the pace at which new findings are disseminated to patients. Periodic re-analysis by third party or other software not originally used to analyze cases is also potentially useful to uncover pathogenic variants that may be missed by the differences across genome interpretation platforms" (Salfati et al., 2019).

Parent-child Trio Testing

Parent-child trio testing is a strategy which helps to identify single pathogenic mutations among the many genomic variants in an individual. Specifically, the sequencing of both the parents and the patient allows for the variant to be identified easier and "filtered based on consistency or inconsistency according to the laws of Mendelian inheritance" (Sakai et al., 2013).

Lee et al. (2014) reported on the initial clinical indications for clinical exome sequencing (CES) referrals and molecular diagnostic rates for different indications and different test types. CES was performed on 814 patients with undiagnosed, suspected genetic conditions who underwent WES. CES was conducted using a trio-CES technique which involves both parents and their affected child sequenced simultaneously. Overall, a molecular diagnosis with a causative variant in a well-established clinical gene was provided for 213/814 (26%) cases. The trio-CES was associated with a higher molecular diagnostic yield (31%; 127/410 cases) than proband-CES or traditional molecular diagnostic methods. The investigators concluded that "additional studies designed to validate these findings and to explore the effect of this approach on clinical and economic outcomes are warranted" (Lee et al., 2014).

Soden et al. (2014) performed diagnostic WGS and/or WES in parent-child trios for 100 families with 119 children with neurodevelopmental disorders (NDD). A total of 45% of the families received molecular diagnoses of an established genetic disorder (53/119 affected children). An accelerated sequencing modality, rapid WGS, yielded diagnoses in 73% of families with acutely ill children (11/15). In this study, WES proved to be less costly than continued conventional diagnostic testing of children with NDD in whom initial testing failed to yield a diagnosis. The investigators concluded that "initial diagnostic evaluation of children with NDD should include trio WGS or WES, with extension of accelerated sequencing modalities to high-acuity patients" (Soden et al., 2014).

Another study compared fetal WES versus trio analysis WES on fetuses with sonographic abnormalities. The researchers found that trio analysis yielded a positive/definitive diagnosis in 30% (3/10) of the cases as compared to only 14.3% (2/14) of the singleton cases. They conclude, "In order to expedite interpretation of results, trio sequencing should be employed, but interpretation can still be compromised by incomplete coverage of relevant genes" (Drury et al., 2015). Similarly, these data are supported by another study of trio analysis of thirty different cases. A total of 10% of the cases were positive for a pathogenic finding, and 17% were de novo, inherited recessive, or X-linked variants. The authors conclude, "This study outlines the way for a substantial improvement in the diagnostic yield of prenatal genetic abnormalities through the application of next-generation sequencing" (Carss et al., 2014).

Yates et al. (2017) performed WES, including trio analysis, using samples obtained from deceased fetuses with ultrasound anomalies. They note that 20% of cases were positive overall with a definitive diagnosis with another 45% positive for possible pathogenic candidate variants. Comparing trio analysis to singleton analysis, 24% (n=11) of trio analysis resulted in a definitive diagnostic finding versus 14% (n=3) for singleton testing (Yates et al., 2017).

https://www.nature.com/articles/s41525-018-0053-8Clark et al. (2018) compared the diagnostic and clinical utility of WGS, WES and CMA in children with suspected genetic disorders. Trio analyses were also analyzed. Many studies were reviewed in this meta-analysis; the authors state that "In 37 studies, comprising 20,068 children, diagnostic utility of WGS (0.41, 95% CI 0.34-0.48, I2 = 44%) and WES (0.36, 95% CI 0.33-0.40, I2 = 83%) were qualitatively greater than CMA (0.10, 95% CI 0.08-0.12, I2 = 81%) (Clark et al., 2018). Further, a statistical difference was not found regarding the diagnostic utility of WES and WGS. Finally, "Subgroups with higher WGS/WES diagnostic utility were trios and those receiving hospital-based interpretation. WGS/WES should be considered a first-line genomic test for children with suspected genetic diseases" (Clark et al., 2018).

Zhang et al. (2021) performed WES and trio analysis on 18 unrelated men who have idiopathic hypogonadotropic hypogonadism (IHH), which is a rare genetic disorder that causes delayed or absent puberty as well as infertility due to gonadotropin-releasing hormone (GnRH) insufficiency/deficiency, and their parents. With this testing, "one reported and 10 novel variants in eight known IHH causative genes (*AXL, CCDC141, CHD7, DMXL2, FGFR1, PNPLA6, POLR3A,* and *PROKR2*), nine variants in nine recently reported candidate genes (*DCAF17, DCC, EGF, IGSF10, NOTCH1, PDE3A, RELN, SLIT2,* and *TRAPPC9*), and four variants in four novel candidate genes for IHH (*CCDC88C, CDON, GADL1,* and *SPRED3*) were identified in 77.8% (14/18) of IHH cases."

This analysis also supported oligogenic etiology for disease presentation, with 44.4% cases carrying at least two variants in IHH-related genes. They also found that the variants "tended to be maternally inherited (maternal with n = 17 vs paternal with n = 7; P = 0.028)," which was confirmed by their previous literature review, and due to the presence of female carriers, extends the notion that females may be more tolerant of "deleterious" IHH-related gene mutations. This study exemplifies the clinical utility of WES and trio analysis for reproductive genetic disorders and could be used to continue pedigree analyses for IHH (Zhang et al., 2021).

Malcher et al. (2022) investigated the use of whole-genome sequencing in identifying new candidate genes for nonobstructive azoospermia (NOA). The authors applied WGS for 39 patients with NOA to identify novel NOA-associated SNVs, yielding "8 potentially disease causing *[sic]* variants in 4 genes, followed by 30 variants in 20 genes that were previously linked to infertility, and 20 variants in 13 genes that have never been investigated with respect to male infertility but could be important in patients with NOA" in 29 of the 39 azoospermic individuals. Of these 58 variants, 16 were newly discovered and, as such, "highly recommended to examine their possible function and mechanism of participation in gametogenesis" (Malcher et al., 2022).

In their examination of whole exome and genome sequencing in a Mendelian disorder cohort, Ewans et al. (2022) determined that "WGS resulted in a diagnosis in one third (34%; 13/38 families) of undiagnosed families who had previously had WES." However, when adjusting for "factors such as improvements to gene-disease knowledge and genomic pipelines through contemporary WES reanalysis, the WGS diagnostic yield reduced to 19% (6/31 remaining families)", primarily due to "due to reduced WES coverage of critical regions that may be solved through an improved WES platform." Such results contribute to the debate about the "trade-off between the lower cost of WES and the higher diagnostic yield of WGS" and will ultimately be a function of "the clinical scenario and local resourcing and availability" (Ewans et al., 2022).

VI. Guidelines and Recommendations

American College of Medical Genetics (ACMG)

In 2012, the ACMG released a policy statement outlining points to consider in the clinical application of genomic sequencing to the detection of germ-line mutations. The ACMG recommended that WGS/WES should be considered in the clinical diagnostic assessment of a phenotypically affected individual when:

- "The phenotype or family history data strongly implicate a genetic etiology, but the phenotype does not correspond with a specific disorder for which a genetic test targeting a specific gene is available on a clinical basis."

- "A patient presents with a defined genetic disorder that demonstrates a high degree of genetic heterogeneity, making WES or WGS analysis of multiple genes simultaneously a more practical approach."
- "A patient presents with a likely genetic disorder, but specific genetic tests available for that phenotype have failed to arrive at a diagnosis."
- "A fetus with a likely genetic disorder in which specific genetic tests, including targeted sequencing tests, available for that phenotype have failed to arrive at a diagnosis."

ACMG stated that "WGS/WES may be considered in preconception carrier screening, using a strategy to focus on genetic variants known to be associated with significant phenotypes in homozygous or hemizygous progeny." ACMG further stated that WGS and WES should not be used at this time as an approach to prenatal screening or as a first-tier approach for newborn screening (ACMG, 2012).

ACMG released a guideline on informed consent for genome/exome sequencing. In that guideline, they noted that WGS/WES was not recommended "before the legal age of majority" unless for "phenotype-driven clinical diagnostic uses or circumstances in which early monitoring or interventions are available and effective" (ACMG, 2013).

In 2014 the ACMG published guidelines (Alford et al., 2014) for the clinical evaluation and etiologic diagnosis of hearing loss which state: "Pretest genetic counseling should be provided, and, with patient's informed consent, genetic testing, if available, should be ordered to confirm the diagnosis—this testing may include single-gene tests, hearing loss sequencing panels, whole-exome sequencing(WES), whole-genome sequencing (WGS), chromosome analysis, or microarray-based copy-number analysis, depending on clinical findings."

In 2020 the ACMG published guidelines on the use of fetal exome sequencing (ES) in prenatal diagnoses. These guidelines are below (Monaghan et al., 2020):

Pretest Considerations

- "Exome sequencing may be considered for a fetus with ultrasound anomalies when standard CMA and karyotype analysis have failed to yield a definitive diagnosis. If a specific diagnosis is suspected, molecular testing for the suggested disorder (with single-gene test or gene panel) should be the initial test. At the present time, there are no data supporting the clinical use for ES for other reproductive indications, such as the identification of sonographic markers suggestive of aneuploidy or a history of recurrent unexplained pregnancy loss.
- Trio analysis consisting of the proband and both biological parents is preferred to singleton (fetus only) or duo (fetus and one parent) analyses. Trio analysis

consistently shows higher diagnostic yields compared with nontrio analysis. It allows for the immediate identification of de novo variants, determination of phase for biallelic variants, and confirmation of carrier status in both parents when a homozygous variant is detected. For laboratories not requiring trio analysis for prenatal ES, all efforts should be made to determine inheritance of identified fetal variants with targeted testing of the biological parents. There may be circumstances where both biological parents are unable to submit specimens. In this scenario, variant segregation testing using the available parent or testing of other closely related family members should be considered.

- Pretest counseling is ideally provided by a genetics professional during which the types of variants that may be returned in a laboratory report for all tested family members would be reviewed.

Posttest Considerations

- Post-test counseling is recommended, regardless of the test result. It should be provided by individuals with relevant expertise, preferably a genetics professional.

Reanalysis Considerations

- For patients with initial negative ES results, reanalysis of exome sequencing data aids clinical diagnosis after 12 months. This outcome has been validated in the pediatric population as additional phenotypic findings might be noted during a child's growth and development. Continuous updates in database resources and new publications may provide further information for variant and gene classification.
- Due to the discovery of new gene–disease associations (that were unknown at the time of initial analysis), reanalysis can also be considered for diagnostic results and results deemed to be possibly (but not definitively) associated with the fetal phenotype.
- For fetal ES with nondiagnostic or negative results, reanalysis may be considered if a new phenotype develops in the proband after birth, a future pregnancy is planned, or a significant amount of time has passed (either at the discretion of the testing laboratory or at least 12 months) since the initial testing was performed.
- If the original prenatal ES report does not account for the complete phenotype or if new/additional phenotypes develop over time, a reanalysis could be considered" (Monaghan et al., 2020).

In 2020 the ACMG conducted a systematic evidence review to support guideline development for the use of exome and genome sequencing among patients with congenital anomalies, developmental delay, or intellectual disability (CA/DD/ID). From

their review, the ACMG concluded, "There is evidence that ES/GS for patients with CA/DD/ID informs clinical and reproductive decision-making, which could lead to improved outcomes for patients and their family members. Further research is needed to generate evidence regarding health outcomes to inform robust guidelines regarding ES/GS in the care of patients with CA/DD/ID" (Malinowski et al., 2020).

In 2021 the ACMG asserted that as the body of literature surrounding this continues to burgeon, it urges them to "strongly recommend ES and GS as a first-tier or second-tier test (guided by clinical judgment and often clinician–patient/family shared decision making after CMA or focused testing) for patients with one or more CAs prior to one year of age or for patients with DD/ID with onset prior to 18 years of age" (Manickam et al., 2021).

American College of Obstetricians and Gynecologists (ACOG) and Society for Maternal and Fetal Medicine (SFM)

In 2016 the ACOG and SFM published a joint committee opinion on "Microarrays and Next-Generation Sequencing Technology: The Use of Advanced Genetic Diagnostic Tools in Obstetrics and Gynecology", which states that "the routine use of whole-genome or whole-exome sequencing for prenatal diagnosis is not recommended outside of the context of clinical trials until sufficient peer reviewed data and validation studies are published" (ACOG & SFM, 2016).

However, ACOG and SFM note that WES may be considered when "specific genetic tests available for a phenotype, including targeted sequencing tests, have failed to determine a diagnosis in a fetus with multiple congenital anomalies suggestive of a genetic disorder." The guideline further clarifies that "in select circumstances (recurrent or lethal fetal anomalies in which other approaches have been noninformative), [WES] may be considered as a diagnostic tool, but only after other appropriate testing has been noninformative and after extensive counseling by an [OB-GYN[or other health care provider with genetics expertise who is familiar with these new technologies and their limitations" (ACOG & SFM, 2016). This committee opinion was reaffirmed in 2023.

Joint Position Statement from the International Society for Prenatal Diagnosis (ISPD), the Society for Maternal Fetal Medicine (SMFM), and the Perinatal Quality Foundation (PQF)

Per the guideline, the word "sequencing" is used to refer to "whole exome sequencing, targeted analysis using clinical panels, and whole genome sequencing."

"The use of diagnostic sequencing is currently being introduced for evaluation of fetuses for whom standard diagnostic genetic testing, such as chromosomal

microarray analysis (CMA), has already been performed and is uninformative or is offered concurrently according to accepted practice guidelines, or for whom expert genetic opinion determines that standard genetic testing is less optimal than sequencing for the presenting fetal phenotype" (ISPD et al., 2018).

Routine use of prenatal sequencing as a diagnostic test cannot be supported due to "insufficient" validation and data about benefits and pitfalls (ISPD et al., 2018).

Within the section on recommendations for all diagnostic applications of genome-wide sequencing, concerning trio analysis, they state, "Diagnostic sequencing for fetal indications is best done as a trio analysis, where fetal and both parental samples are sequenced and analyzed together. The trio approach currently benefits timeliness of result interpretation and aids assignment of pathogenicity for detected sequence variants. If proband-only sequencing is performed, validation of diagnostic or potentially diagnostic findings best includes a determination of inheritance through targeted testing of samples from biological parents" (ISPD et al., 2018). However, the guideline could not recommend one sequencing method over another, nor was the guideline certain on the best way to interpret variants found in genome-wide sequencing.

The guideline provides three scenarios in which fetal sequencing may be "beneficial":

"A current pregnancy with a fetus with a single major anomaly or with multiple organ system anomalies that are suggestive of a possible genetic etiology, but no genetic diagnosis was found after CMA; or in select situations with no CMA result, following a multidisciplinary review and consensus, in which there is a fetus with a multiple anomaly 'pattern' that strongly suggests a single gene disorder."

"A personal (maternal or paternal) history of a prior undiagnosed fetus (or child) affected with a major single anomaly or multiple anomalies suggestive of a genetic etiology, and a recurrence of similar anomalies in the current pregnancy without a genetic diagnosis after karyotype or CMA. In addition, when such parents present for preconception counseling and no sample is available from the affected proband, or if a fetal sample cannot be obtained in an ongoing pregnancy, it is considered appropriate to offer sequencing for both biological parents to look for shared carrier status for autosomal recessive mutations that might explain the fetal phenotype. However, where possible, obtaining tissue from a previous abnormal fetus or child for exome sequencing is preferable."

"In families with a history of recurrent stillbirths of unknown etiology after karyotype and/or CMA, where the fetus in the current pregnancy has a recurrent pattern of anomalies (ISPD et al., 2018).

International Society for Prenatal Diagnosis (ISPD)

In 2022, the ISPD released an updated position statement on the use of genome-wide sequencing for prenatal diagnosis. Below are the pertinent recommendations:

- "Diagnostic sequencing for fetal indications is best done as a trio analysis, where fetal and both parental samples are sequenced and analyzed together."
- "Approaches to sequence analysis may vary from examination of genes known to be associated with fetal or neonatal phenotypes to a broader genome-wide strategy. It is also uncertain whether interpretation of variants found by genome-wide sequencing should follow the general guidelines for interpretation and reporting of results for children and adults, or whether a more restrictive approach, limited to those variants that explain the phenotype is preferable in the prenatal setting, or if a new approach restricting reporting to severe childhood conditions should be considered."
- "The current existing data support that prenatal sequencing is beneficial for the following indications:
    - A current pregnancy with a fetus having a major single anomaly or multiple organ anomalies:
        - For which no genetic diagnosis was found after CMA and a clinical genetic expert review considers the phenotype suggestive of a possible genetic etiology.
        - For which the multiple anomaly "pattern" strongly suggests a single gene disorder with no prior genetic testing. As pES is not currently validated to detect all CNVs, CMA should be run before or in parallel with pES in this scenario.
    - A personal (maternal or paternal) history of a prior undiagnosed fetus (or child) affected with a major single or multiple anomalies:
        - With a recurrence of similar anomalies in the current pregnancy without a genetic diagnosis after karyotype or CMA for the current or prior undiagnosed pregnancy.
        - When such parents present for preconception counseling and no sample is available from the affected proband, or if a fetal sample cannot be obtained in an ongoing pregnancy, it is considered appropriate to offer sequencing for both biological parents to look for shared carrier status for autosomal recessive mutations that might explain the fetal phenotype. However, where possible, obtaining tissue from a previous abnormal fetus or child for pES is preferable.
- There is currently no evidence that supports routine testing (including upon parental request) on fetal tissue obtained from an invasive prenatal procedure

(amniocentesis, CVS, cordocentesis, other) for indications other than fetal anomalies
    - There may be special settings when prenatal sequencing in the absence of a fetal phenotype visible on prenatal imaging can be considered, such as with a strong family history of a recurrent childhood-onset severe genetic condition with no prenatal phenotype in previous children for whom no genetic evaluation was done and is not possible. Such scenarios should be reviewed by an expert multidisciplinary team preferentially in the context of a research protocol. If sequencing is done for this indication, it must be done as trio sequencing, using an appropriate analytical approach" (Van den Veyver et al., 2022).

American Academy of Neurology (AAN) and American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM)

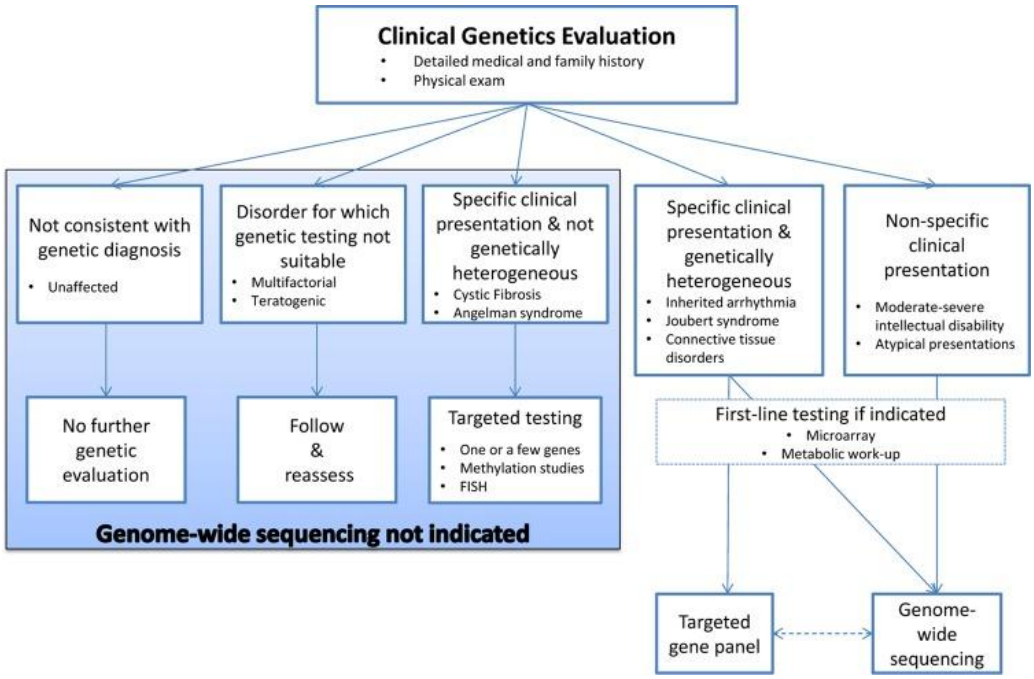
The AAN/AANEM published guidelines (Kang et al., 2015) on the evaluation, diagnosis, and management of congenital muscular dystrophy (CMD) which state: "In individuals with CMD who either do not have a mutation identified in one of the commonly associated genes or have a phenotype whose genetic origins have not been well characterized, physicians might order whole-exome or whole-genome sequencing when those technologies become more accessible and affordable for routine clinical use (Level C)."

The AAN/AANEM published guidelines (Narayanaswami et al., 2014) on the diagnosis and treatment of limb-girdle and distal dystrophies which state: "In patients with suspected muscular dystrophy in whom initial clinically directed genetic testing does not provide a diagnosis, clinicians may obtain genetic consultation or perform parallel sequencing of targeted exomes, whole-exome sequencing, whole-genome screening, or next-generation sequencing to identify the genetic abnormality (Level C)."

Association for Molecular Pathology (AMP)

The AMP published a report on the spectrum of clinical utilities in molecular pathology testing procedures for inherited conditions and cancer. The background of this report states, "Whole genome sequencing is currently more expensive than WES, requires greater analysis, and generates more variants of uncertain significance. WES is a plausible approach when the clinical picture cannot be affirmed using a specific gene panel. As technologies and understanding of variants advance, whole genome sequencing might become the test of choice" (Joseph et al., 2016).

American Academy of Pediatrics (AAP)



AAP published guidelines on the evaluation of children with autism spectrum disorder. According to the guidelines, CMA is recommended if the etiology for developmental disability is not known. Since Fragile X Syndrome increases the risk for autism spectrum disorder, DNA testing for Fragile X should be recommended in all children with ASD, especially for boys and children with a family history of intellectual disability. "The cytosine-guanine-guanine trinucleotide repeat expansion that is responsible for fragile X syndrome is not detected on CMA and must be ordered as a separate test. When the history and physical examination, CMA, and fragile X analysis do not identify an etiology, the next step at this time in the etiologic evaluation for [autism spectrum disorder] is whole-exome sequencing (WES)." AAP does not recommend the use of commercially marketed tests as they do not provide a molecular etiologic diagnosis (Hyman et al., 2020).

Canadian College of Medical Geneticists

In 2015, the Canadian College of Medical Geneticists published a position statement on genome-wide sequencing for monogenic diseases. Their relevant recommendations include the following:

- "Recommendations for diagnostic assessment:
  - Clinical exome sequencing, at this time, should only be used to interrogate the genome for nucleotide sequence variants in genes known to cause disease. Clinical WGS may be used to detect CNV and structural variation in addition to sequence variants, though it is not currently a first-tier test for such analyses.
  - Clinical genome-wide sequencing should be considered in the investigation of an affected individual when his/her phenotype or family history suggests a monogenic aetiology in whom the causal mutation(s) are unknown, and one or more of the following additional conditions apply:
    - the phenotype is associated with a high degree of genetic heterogeneity;
    - specific genetic tests have failed to arrive at a diagnosis and testing of other clinically relevant genes is appropriate;
    - genome-wide sequencing is a more cost-effective approach than available individual gene or gene panel testing."
- "Until the benefits of reporting incidental findings are established, we do not endorse the intentional clinical analysis of disease-associated genes other than those linked to the primary indication."

Below is a figure of a "decision aid to facilitate the diagnostic evaluation of patients with rare disease of suspected monogenic aetiology" (Boycott et al., 2015).

The Royal Australasian College of Physicians

In 2021, the Royal Austalasian College of Physicians provided guidelines on pediatric genetic testing in the context of intellectual disability (ID) and global developmental delay (GDD). For childhood syndromes or ID/GDD, the group recommends WES or WGS as tests of choice, since they offer "a broad, agnostic screen," but acknowledge that WES is more widely available and cost-effective at the time of publication. In terms of ordering singleton or trio testing, the group states that "the latter (trio) approach is highly recommended given it simplifies analysis… it is also a more streamlined clinical test as trio testing identifies fewer variants of uncertain significance than singleton testing" (Sachdev et al., 2021).

VII. Applicable State and Federal Regulations

DISCLAIMER: If there is a conflict between this Policy and any relevant, applicable government policy for a particular member [e.g., Local Coverage Determinations (LCDs) or National Coverage Determinations (NCDs) for Medicare and/or state coverage for Medicaid], then the government policy will be used to make the determination. For the most up-to-date Medicare policies and coverage, please visit the Medicare search website: https://www.cms.gov/medicare-coverage-database/search.aspx. For the most up-to-date Medicaid policies and coverage, visit the applicable state Medicaid website.

Food and Drug Administration (FDA)

Genotyping is considered a laboratory developed test (LDT); developed, validated, and performed by individual laboratories. Additionally, many labs have developed specific tests that they must validate and perform in house. These laboratory-developed tests (LDTs) are regulated by the Centers for Medicare and Medicaid (CMS) as high-complexity tests under the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88). LDTs are not approved or cleared by the U. S. Food and Drug Administration; however, FDA clearance or approval is not currently required for clinical use.

VIII. Applicable CPT/HCPCS Procedure Codes

CPT	Code Description
81415	Exome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis
81416	Exome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis, each comparator exome (eg, parents, siblings) (List separately in addition to code for primary procedure)
81417	Exome (eg, unexplained constitutional or heritable disorder or syndrome); re-evaluation of previously obtained exome sequence (eg, updated knowledge or unrelated condition/syndrome)
81425	Genome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis
81426	Genome (eg, unexplained constitutional or heritable disorder or syndrome); sequence analysis, each comparator genome (eg, parents, siblings) (List separately in addition to code for primary procedure)
81427	Genome (eg, unexplained constitutional or heritable disorder or syndrome); re-evaluation of previously obtained genome sequence (eg, updated knowledge or unrelated condition/syndrome)
81479	Unlisted molecular pathology procedure
0209U	Cytogenomic constitutional (genome-wide) analysis, interrogation of genomic regions for copy number, structural changes and areas of homozygosity for chromosomal abnormalities
0214U	Rare diseases (constitutional/heritable disorders), whole exome and mitochondrial DNA sequence analysis, including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variants, proband Proprietary test: Genomic Unity® Exome Plus Analysis -Proband, Lab/Manufacturer: Variantyx Inc,

CPT	Code Description
0215U	Rare diseases (constitutional/heritable disorders), whole exome and mitochondrial DNA sequence analysis, including small sequence changes, deletions, duplications, short tandem repeat gene expansions, and variants in non-uniquely mappable regions, blood or saliva, identification and categorization of genetic variants, each comparator exome (eg, parent, sibling) Proprietary test: Genomic Unity® Exome Plus Analysis - Comparator, Lab/Manufacturer: Variantyx Inc, Variantyx Inc
0265U	Rare constitutional and other heritable disorders, whole genome and mitochondrial DNA sequence analysis, blood, frozen and formalin-fixed paraffin-embedded (FFPE) tissue, saliva, buccal swabs or cell lines, identification of single nucleotide and copy number variants
0335U	Rare diseases (constitutional/heritable disorders), whole genome sequence analysis, including small sequence changes, copy number variants, deletions, duplications, mobile element insertions, uniparental disomy (UPD), inversions, aneuploidy, mitochondrial genome sequence analysis with heteroplasmy and large deletions, short tandem repeat (STR) gene expansions, fetal sample, identification and categorization of genetic variants
0336U	Rare diseases (constitutional/heritable disorders), whole genome sequence analysis, including small sequence changes, copy number variants, deletions, duplications, mobile element insertions, uniparental disomy (UPD), inversions, aneuploidy, mitochondrial genome sequence analysis with heteroplasmy and large deletions, short tandem repeat (STR) gene expansions, blood or saliva, identification and categorization of genetic variants, each comparator genome (eg, parent)
0425U	Genome (eg, unexplained constitutional or heritable disorder or syndrome), rapid sequence analysis, each comparator genome (eg, parents, siblings)
0426U	Genome (eg, unexplained constitutional or heritable disorder or syndrome), ultra-rapid sequence analysis
